Medicine is an ever-changing science. Research and clinical experience are continually expanding our knowledge, in particular our understanding of proper treatment and drug therapy. The authors, editors, and publisher have made every effort to ensure that all information in this book is in accordance with the state of knowledge at the time of production of the book. Nevertheless, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the contents of the publication. Every reader should examine carefully the package inserts accompanying each drug and should carefully check whether the dosage schedules mentioned therein or the contraindications stated by the manufacturer differ from the statements made in this book. Such examination is particularly important with drugs that are either rarely used or have been newly released on the market.

Preface to the Second Edition

Advances in our understanding of stroke recovery and rehabilitation have continued to accelerate since the first edition of this text was published, and this trend shows no signs of abating. These advances include new tools to understand the neurophysiological and anatomical underpinnings of stroke recovery, as well as a growing evidence base on an array of clinical therapies. Two broad principles continue to guide this field, however. First, optimizing functional recovery from stroke is contingent on intense and challenging activities that target functional motor and cognitive skills. The new learning and relearning that results produces measurable cortical neuroplastic changes. Second, despite the first principle and the demonstrated effectiveness of many rehabilitation techniques, many stroke survivors continue to exhibit substantial activity limitations and participation restrictions. Accordingly, we continue to rely on compensatory approaches for restoring mobility and activities of daily living. The tension between these restorative and compensatory approaches arguably drives the field forward, prompting advocates of each strategy to design studies to find the most effective treatment for each stroke-related impairment.

Our goal for the second edition of this book is to provide updated information on all aspects of stroke recovery and rehabilitation, and to expand areas that were not fully addressed in the first edition. Examples include the inclusion of a chapter written by a stroke survivor to provide the most important perspective of this field—that of the person affected by stroke. New chapters have been added on transcranial magnetic stimulation and biomarkers of stroke recovery, on the genetics of stroke recovery, and the use of medications to facilitate recovery after stroke. Topics that have grown too large for a single chapter, such as robotics and virtual reality, have been divided into more manageable and focused chapters.

Some aspects of this text have not changed. As in the prior edition, the chapters are written by basic scientists and clinicians from a variety of fields including biomedical engineering, neurology, physical medicine and rehabilitation, psychology, neuroscience, physical therapy, occupational therapy, speech and language pathology, neuroradiology, optometry, orthotics, and rehabilitation nursing. The intent is to provide an up-to-date practical clinical guide to evidence-based stroke recovery and rehabilitation built on a foundation of basic neurophysiology, neuroscience, and psychological science.

We would like to thank the authors for taking the time away from busy clinical activities, mentoring students, proposing, performing, and publishing research, and other academic responsibilities to write these chapters. We also thank the editorial staff at Demos Medical Publishing for their patience, encouragement, and support. We hope that this updated second edition of *Stroke Recovery and Rehabilitation* continues to serve as a valuable reference for academicians and clinicians alike, and for all disciplines that have the responsibility and pleasure of helping stroke survivors achieve their maximum potential.

Preface to the First Edition

The 1990s were declared the decade of the brain by the National Institutes of Health. It was during this decade that neuroscience and clinical rehabilitation research began to converge into a new science of neurorehabilitation. The knowledge gleaned from the past 20 years has led to the clear understanding that optimizing functional recovery from stroke is contingent on relatively intense and challenging targeted motor and cognitive relearning of functional skills. This relearning results in measurable cortical neuroplastic changes. This consensus represents a paradigm shift for rehabilitation clinicians who had for the most part previously focused on the neurodevelopmental process of carefully normalizing trunk and limb movement, teaching one-handed techniques, and educating patients on the use of adaptive equipment.

If there had been a standard comprehensive text on stroke rehabilitation, these changes in our conception of rehabilitation and recovery would most certainly require that it be updated. In fact, no such text has been previously assembled that included the basic neuroscience and anatomy of stroke, the physiology of neural recovery after focal injury, or clinical rehabilitation interventions for stroke based on randomized clinical trials. This text was written to fulfill that need: providing the reader with a multidisciplinary and international perspective. The chapters are written by basic scientists and clinicians from a variety of fields including biomedical engineering, neurology, physical medicine and rehabilitation, psychology, neuroscience, physical therapy, occupational therapy, speech and language pathology, neuroradiology, optometry, orthotics, and rehabilitation nursing. The intent was to provide a practical clinical guide to evidence-based stroke rehabilitation built on a foundation of basic neurophysiology and neuroscience.

We would like to thank the authors of this text for taking the time away from their busy clinical schedules, grant writing, and other academic responsibilities to write these chapters. We also would like to thank the editorial staff at Demos Medical Publishing for their patience, encouragement, and support. We hope that this text on stroke recovery and rehabilitation becomes a valuable reference for academicians and clinicians alike, and for all disciplines that have the pleasure of helping survivors of stroke achieve their maximum potential.

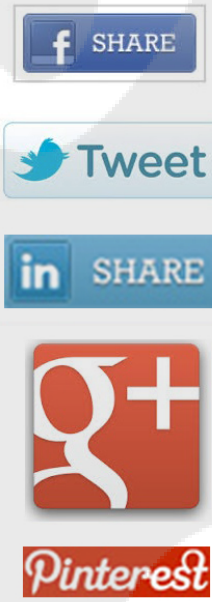
Stroke Recovery and Rehabilitation: Second Edition



I

INTRODUCTION

1

The Historical Origins of Stroke Rehabilitation

Douglas J. Lanska

Physical medicine and rehabilitation (PM&R) is a relatively young specialty that developed during the 20th century, with significant growth and development stimulated by two World Wars and by increasingly severe epidemics of paralytic poliomyelitis during the first half of the 20th century (1–4). During and after each of the World Wars, many soldiers returned with serious injuries and severe disabilities, and physicians and therapists were needed to treat and manage their chronic disabling conditions. This was particularly true after World War II, when the availability of antibiotics and improved surgical techniques allowed more injured soldiers to survive, albeit with significant disabilities. Similarly, over the same time period, increasingly severe epidemics of polio, frequent industrial accidents, and escalating motor vehicle accidents as a result of the increased availability of automobiles and higher-speed roadways added greatly to the burden of impairment and disability among the civilian population. Thus, events in the first half of the 20th century necessitated the development of new restorative treatment programs incorporating new physical and rehabilitative techniques, and the establishment of training programs for physicians and therapists to administer the treatments.

Nevertheless, with the exception of a relatively few scattered physical medicine physicians, it was not until the second half of the 20th century that specialists in rehabilitation medicine could profitably direct their energies exclusively, or even preferentially, to rehabilitation outside of the unprecedented and unsustainable circumstances of wartime military programs. Also largely missing until the second half of the 20th century were separate departments in academic and nonacademic medical centers devoted to the specialty, established training programs in PM&R, a sufficient number of PM&R practitioners, separate dedicated facilities for provision of rehabilitation services (e.g., dedicated wards in hospitals or separate rehabilitation centers), forums for the interchange of ideas (e.g., texts, journals, and professional societies), recognition by professional colleagues and the public that rehabilitation medicine specialists provided a needed service, and supportive legislation that would provide financial mechanisms to develop and provide such resources (5).

WORLD WAR I AND ITS AFTERMATH: BEGINNINGS OF PHYSICAL MEDICINE AND VOCATIONAL REHABILITATION

During much of the 19th century, physicians who employed physical modalities or advocated treatment with fresh air, water, exercise, and dietary modification were at risk of being labeled quacks by other members of the medical profession. However, near the turn of the century, orthopedic surgeons, in particular, began using selected physical treatments—massage, exercise, hydrotherapy—as part of special programs to augment medical care and convalescence within hospitals under physician supervision.

During World War I (1914–1918), physical and occupational therapy became increasingly important adjuncts to surgical practice, particularly in the treatment of orthopedic casualties, because surgeons realized that surgery alone was insufficient to achieve maximum return of function, and because empirical experience indicated that physical methods were useful adjuncts in the medical care and convalescence of wounded and disabled soldiers (1,4). In particular, with active U.S. involvement in the war beginning in 1917, Colonel Joel Ernst Goldthwait, MD (1866–1961), chief surgeon in the Orthopedic Medical Corp of the American Expeditionary Forces, and Colonel Elliott G. Brackett, MD, in the Home Service, also an orthopedic surgeon, enthusiastically supported a role for physical therapists in the rehabilitation of orthopedic casualties (6,7). Late in 1917, a program of Women's Auxiliary Medical Aides was established in the Surgeon General's Office, but by April 1918, this was transferred to the Division of Physical Reconstruction and renamed "Reconstruction Aides" (Figure 1.1) (6). Major (later Lieutenant Colonel) Frank B. Granger, MD (1875–1928), was named director of the Physiotherapy Service of the Reconstruction Division for the Army, and under his command the reconstruction aid program was directed by Chief Aide Marquerite Sanderson (formerly from Dr. Goldthwait's office in Boston) (6,8). Training programs for the reconstruction aides were established at Walter Reed General Hospital, headed by therapist Mary McMillan; later at Reed College in Portland, Oregon (where McMillan also initially taught during a leave of absence from Walter Reed); and eventually at 13 other programs across the country (6,9,10).

Colonel Frank C. Billings, MD (1854–1932), chief of the Division of Physical Reconstruction in the Medical Department of the U.S. Army, established separate sections for education, therapy, and clinical work (Figure 1.2). Military physicians in "reconstruction hospitals" then began treating wounded and disabled soldiers with occupational therapy (then called bedside occupations and curative workshops) and "physiotherapy" (a term indicating use of various physical methods in treatment, including heat, exercise, hydrotherapy, electrotherapy, and massage) (7). By the end of the war, therapy was provided by nearly 800 women volunteers (physical educators or nurses) trained as "reconstruction aides" under the Reconstruction Aide Program (4,6,7,10,11).

Some individuals criticized the prolonged bedside therapeutic activities provided by female reconstruction aides because they were felt to promote dependence and invalidism (12,13). However, in 1918, Billings described the work of the reconstruction aides and clearly distinguished it as superior to the types of "diversional" tasks previously employed:

> [Ward work] has consisted frequently of work not so purposeful in its character, but rather as diversional in character, in the form of knitting, in the form of basket weaving, etc. But the work which the Surgeon-General utilizes as curative in character in the general hospital for these soldiers is more purposeful than knitting, basket weaving and the like. In other words, it is of the kind and character of curative work that will look toward the training of the soldier for employment after his discharge from the Army. (14)

By the end of the war, physical reconstruction services were available in 35 general hospitals and 18 base hospitals across the country (4,15), and nearly 50,000 veterans (or about 40% of the 125,000 disabled during the war) had been treated at these facilities (16).

In 1923, Dr. F.B. Granger, who had been instrumental in developing the program for reconstruction aides in the United States and who was the first physician specializing in physical medicine to become a member of the American Medical Association (AMA) Council on Physical Therapy (9), summarized how physical therapy originated:

> With the onset of the World War the urgent need of hastening the return of the wounded to the front lines, or rehabilitating them sufficiently so that they could be

FIGURE 1.2 Colonel Frank C. Billings (1854–1932), chief of the Division of Physical Reconstruction in the Medical Department of the U.S. Army during World War I. Knopf Collection.

Courtesy of the U.S. National Library of Medicine.

> given noncombatant duty, thus presumably relieving an able-bodied man, forced the unification of [the separate treatment modalities]. The Surgeon General of the U.S. Army, at one stroke, completed their amalgamation when he defined physiotherapy as "Physical measures such as are employed under physiotherapy, including hydro, electro, mechano therapy, active exercises, indoor and outdoor games, and passive exercises in the form of massage." Thus was born modern physiotherapy. (17)

Following the war, Dr. Elliott Brackett, a Harvard-trained orthopedic surgeon, promoted the establishment of hospitals "devoted to the medical care of all men who should be returned, also planned and equipped to reinstate the disabled soldier in the industrial world and allow him to become an independent wage earner" (16). Unfortunately, interest in rehabilitative services in the military waned after the war (1).

THE 1920s: BEGINNINGS OF PROFESSIONAL ORGANIZATIONS AND FORMAL TRAINING PROGRAMS

Physical Medicine

The 1920s and 1930s saw the beginnings of professional organizational development in the nascent field of PM&R. The so-called "physical therapy physicians" (i.e., physicians practicing early forms of physical medicine) began efforts to organize themselves and vied for a voice in the AMA. Specifically, in 1923, the American College of Radiology and Physiotherapy was founded as a professional organization of physicians who used physical methods to diagnose and treat illness and disability. Samuel B. Childs, MD, a radiologist from Denver, was elected as the first president. Very soon, however, radiologists separated and developed their own organizations so that, by 1925, the organization became the American Congress of Physical Therapy. Subsequent developments included the assimilation in 1933 of the American Physical Therapy Association (whose membership comprised only physicians) and various changes in the name of the organization initially intended to clarify the distinction between physicians and nonphysician therapists using physical methods in treatment (until the present name of the American Congress of Rehabilitation Medicine was selected in 1966).

Specialty physical medicine journals also developed during this period, corresponding to the increasing professional orientation of a small group of physicians to this new area of specialization. The journal *Radiology* began publication in 1920 under the editorship of Albert Franklin Tyler, MD (1881–?), and in 1926, it was renamed the *Archives of Physical Therapy, X-ray, Radium* to reflect its expanded focus. Subsequent name changes in the journal reflected an early shift away from radiology; a later distinction between physician and nonphysician therapists utilizing physical methods in treatment; and, ultimately, a broadening emphasis on rehabilitation (until the present name of the *Archives of Physical Medicine and Rehabilitation* was selected in 1952).

Most physicians who practiced physical medicine in this era used it as an adjunct to their regular general medical practices, but starting in the mid-1920s, some physicians began devoting their careers to this area and were recognized with academic faculty appointments. The first of these was John Stanley Coulter, MD, who joined the faculty of Northwestern University Medical School in Chicago in 1926 as the first full-time academic physician specializing in physical medicine. He initiated the first continuing teaching program in physical medicine in the form of 3- to 6-month, and later, 12-month courses. He became chairman of the AMA Council on Physical Therapy (18). For the next two decades, he was a key leader in the development of educational programs for the practice of physical medicine as well as in the development of professional organizations for physical medicine.

Physical Therapy

Formal training for allied health professionals in civilian practice was not available until 1918, when the Mayo Clinic initiated a training program in physiotherapy (19). In 1920, Lieutenant Colonel Hard D. Corbusier wrote to former reconstruction aide Mary McMillan, proposing the formation of a professional society of physical therapists to "advertise to all the physicians and surgeons of the country the importance of treatment by physical means and to elevate and standardize the work and place it on a more substantial basis" (6). In 1921, McMillan organized a group of nearly 300 former reconstruction aides to form the American Women's Physical Therapeutic Association, which elected McMillan as the first president. The first issue of the association's official publication, *The P.T. Review*, was published in March 1921, and the same year McMillan published *Massage and Therapeutic Exercise*, the first textbook written by a physical therapist (10,20). The organization was renamed the American Physiotherapy Association in 1922, and in 1930 the organization was incorporated to establish educational standards for physical therapists to support regulation of physical therapy practice and to cooperate with the medical profession to establish a central registry of physical therapists (10,21).

Occupational Therapy

In 1914, George Edward Barton—a disabled architect who had benefited from care he received at a convalescent hospital—introduced the term *occupational therapy* at a meeting of the Massachusetts State Board of Insanity in Boston (22) and subsequently founded Consolation House in Clifton Springs, New York, where he provided vocational assistance and workshop activities to other disabled people (13,22–24). In 1917, Barton organized the first meeting of the National Society for the Promotion of Occupational Therapy at Clifton Springs for "the advancement of occupation as a therapeutic measure, the study of the effects of occupation upon the human being, and the dissemination of scientific knowledge on this subject" (25). In addition to Barton, the founding members included Dr. William Rush Dunton, Jr., a Maryland psychiatrist, who was responsible for the occupations program at the Sheppard and Pratt Institute and had written monographs and articles on using occupational activities as therapy, including one of the first textbooks on occupational therapy, *Occupational Therapy—A Manual for Nurses* (1915) (26,27); Eleanor Clarke Slagle, who worked with Dunton at Johns Hopkins in Baltimore and who developed a regimented treatment program ("habit training") for chronic schizophrenic patients; Susan Cox Johnson, director of occupations for the New York State Department of Public Charities; Thomas Kidner, an architect who was the vocational secretary of the Canadian Military Hospitals Commission; Isabel Newton, who was Barton's secretary; and Susan Tracy, a nurse who was a training school superintendent and instructor of occupational therapy courses for nursing students, including the first such course (in 1911) at the Massachusetts General Hospital Training School for Nurses (13,22–24,28,29). Barton became the first president (22). The organization was renamed the American Occupational Therapy Association in 1923 (22). The *Maryland Psychiatric Quarterly*, edited by Dunton, became the official organ of the National Society for the Promotion of Occupational Therapy until 1922, when the *Archives of Occupational Therapy* was first published as the official publication of the organization (13,22).

In 1929, Colonel James A. Mattison described the purposes of occupational therapy as employed at the National Home for Disabled Volunteer Soldiers:

> One of the principal aims of occupational therapy is to create morale, and to provide every opportunity for the coordination of all hospital efforts toward returning the patient to community life and economic usefulness. (30)

The first textbook in the United States concerning occupational therapy, written primarily by occupational therapists, was *Principles of Occupational Therapy*, edited by Helen S. Willard and Clare S. Spackman and first published in 1947 (31).

Speech Therapy

Speech therapy had 18th- and 19th-century antecedents—particularly in the practical treatment approaches of the elocutionists (i.e., focused on improving speaking, orating, or singing); the beginnings of aphasiology with French neurologist Paul Broca (1824–1880), German neuropsychiatrist Carl Wernicke (1848–1905), and others; and the various "methods" for treating speech impediments, mispronunciation, and articulatory disturbances among the deaf (32,33). Development of professional organizations for speech therapy in the United States began with the founding of the American Speech and Hearing Association in 1925 as the American Academy of Speech Correction (33–35). In 1927, a nomenclature committee of the American Speech Correction Association outlined and described the conditions treated by "speech correctionists" under seven major categories: dysarthria, dyslalia, dyslogia, dysphasia, dysphemia, dysphonia, and dysrhythmia (33,36).

PROFILE OF FRANK KRUSEN (1898–1973): "THE FATHER OF PHYSICAL MEDICINE"

Frank Hammond Krusen (1898–1973) is widely regarded as "the father of physical medicine," and during the 1930s and 1940s, was influential in the development of this field both in the United States and internationally (Figure 1.3) (37). Krusen graduated from Jefferson Medical College in Philadelphia in 1921, but his planned surgical career was interrupted when he developed pulmonary tuberculosis in 1924. During his convalescence at a sanitarium, he became interested in physical medicine. In particular, his own experiences and observations at this time helped Krusen

FIGURE 1.3 American physician Frank Krusen (1898–1973), "the Father of Physical Medicine."

realize that physical deconditioning increased dependence on institutional living and eroded self-esteem. He believed that self-assurance and independence could be restored in disabled patients with appropriate physical reconditioning, vocational rehabilitation, and reintegration into noninstitutional society (38). From this point forward, Krusen worked to develop physical medicine into a scientifically based and accepted medical specialty.

On his return to Philadelphia in 1926, Krusen was appointed as associate dean at Temple Medical School, where in 1929, he started the first academic department of physical medicine in the United States (38–40). In 1930, Krusen published an undergraduate curriculum in physical medicine (41). In 1935, at the invitation of one of the founders of the Mayo Clinic, surgeon William James Mayo, MD (1861–1939), Krusen moved to the Mayo Clinic in Rochester, Minnesota, where he founded the department of physical medicine (1935), initiated the first 3-year residency program in physical medicine (1936), and developed a school of physical therapy (1938) (18,19,39). In 1941, he was promoted to professor. In 1942, during World War II, he helped train a large cadre of medical officers from the U.S. Armed Forces through 90-day intensive courses in physical medicine at the Mayo Graduate School of Medicine, with the trainees being labeled "90-day wonders" (3,15). Krusen's influence was tremendous as judged by his own contributions as well as by the number and quality of his trainees, and their roles in, and subsequent contributions to, the further development of the specialty (42).

In addition to his role in the development of clinical practice and training programs in physical medicine, Krusen was an organizational leader for the specialty during the late 1930s and through the 1940s. In 1937, with William Bierman and John S. Coulter, Krusen established the American Registry of Physical Therapy Technicians to credential physical therapists (who were conferred the title of "registered physical therapist" on passing the certifying examination) (3,38). In 1938, with a small group of other pioneering physical medicine physicians, Krusen and Coulter founded the Society of Physical Therapy Physicians (later named the American Academy of Physical Medicine and Rehabilitation) "to develop physical therapy as a formally recognized specialty," and Krusen was elected its first president (38). In 1941, Krusen wrote the first widely used textbook of physical medicine, *Physical Medicine: The Employment of Physical Agents for Diagnosis and Therapy* (43). Subsequently, Krusen played critical organizational roles in the founding and initial leadership of the Baruch Committee on Physical Medicine (1943), the American Board of Physical Medicine and Rehabilitation (1947), and the International Federation of Physical Medicine (1952).

In 1938, Krusen proposed the term "physiatrist" to designate the physician specializing in physical medicine, and further proposed that "physiatrist" should be pronounced with the accent on the third syllable (fiz ē at´ rist) to minimize confusion with "psychiatrist." The name "physiatrist" was derived from the Greek words "physics" (physical phenomena) and "iatreia" (healer or physician) (15). Later, in 1946, the AMA Council on Physical Medicine voted to support the terms "physiatrist" and "physiatry" (11). In 1961, Arthur Watkins proposed "physiatrics" as a new name for the specialty of PM&R based on Krusen's 1938 proposal, and Watkins further proposed changing the name of the American Academy of Physical Medicine and Rehabilitation to the American Academy of Physiatrics (44). However, Krusen supported maintaining the existing name of the organization because otherwise "the rest of the world wouldn't recognize us" (44).

Beginning in the late 1930s, Krusen, in conjunction with more than a dozen other "physical therapy physicians," repeatedly petitioned the American Medical Association for specialty status and an examining board for physical medicine, but controversies over certification, financing, and whether PM&R should be an independent specialty or a subspecialty delayed its successful resolution for more than a decade. Ultimately, under Krusen's leadership, the American Board of Physical Medicine and Rehabilitation was founded in 1947 and Krusen served as its first chairman (from 1947 to 1951) (39,40).

From 1943 to 1951, Krusen served as a critical leader of the Baruch Committee on Physical Medicine (later the Baruch Committee on PM&R), an activity that greatly fostered the development of physical medicine in the United States (3,18,39,45). The Baruch Committee was established by financier and philanthropist Bernard Mannes Baruch (1870–1965) in honor of his father, Simon Baruch, MD (1840–1921), to advance physical medicine through education, clinical care, and research (Figure 1.4). Dr. Ray Lyman Wilbur (1875–1949), who had been the third President of Stanford University, was the initial chairman of the Committee and Krusen served with him on the Administrative Board; Krusen was also selected as the chairman of both the Scientific Advisory Committee and the Committee on Physical Rehabilitation (3). The Baruch Committee soon recommended the establishment of teaching and research centers for physical medicine, fellowships and residencies in PM&R, the promotion of teaching and research in PM&R in medical schools, and the development of the American Board of Physical Medicine and Rehabilitation (3,46). Through the remainder of the 1940s until its disbanding in 1951, the Committee provided grant funds for fellowships, and for teaching and research programs in physical medicine at universities and medical schools. The legacy of the Baruch Committee included a marked increase in the number of medical schools teaching PM&R, a distinct increase in the number of residencies in PM&R, and more than 30 Baruch Fellows who went on to become department heads in medical schools, the military, or Veterans Administration hospitals (3).

POLIO EPIDEMICS EXPANDED THE NEED AND ROLE FOR PM&R AMONG CIVILIANS

Although unrecognized at the time, the growing epidemics of paralytic poliomyelitis beginning in the 1890s and occurring throughout the first half of the 20th century were partly an unanticipated consequence of improved sanitation. Hygienic advances delayed exposure to polioviruses from early infancy (when protection against paralytic disease was afforded by maternal antibodies) to later in childhood or adulthood, at which time paralytic manifestations were much more likely, a phenomenon expressed memorably by pediatrician John F. Modlin, MD: "Polio . . . was the unanticipated consequence of the invention of the flush toilet and the adoption of the use of toilet paper" (47).

The first major epidemic of poliomyelitis in the United States, and the one that brought polio into national consciousness, occurred in 1916: Nationwide, there were 27,000 cases, with 6,000 deaths, almost all under 5 years of age; and a large number of the survivors were left with lifelong disabilities and, often, deformities. Although there was considerable variability from year to year, subsequent annual summer epidemics were less severe, until they began progressively increasing during the 1940s and early 1950s, with the worst epidemic in 1952 causing nearly 58,000 cases of paralytic poliomyelitis. As increasing numbers of older children and adults became affected during the 1930s and afterward, the original label of "infantile paralysis" was replaced by either the medical term "poliomyelitis" or the shorter term "polio." Because mortality was high, and because survivors were often left with severe paralysis and resulting disability, these epidemics caused widespread anxiety and fear, particularly during the summer months (48). These polio epidemics also led to major advances in respiratory management and physical therapy (49–51), and further established the role of physiatrists in the management of neuromuscular diseases, especially limb and respiratory muscle weakness, contractures, and gait disorders.

The "Iron Lung"

In 1928, following the early epidemics of poliomyelitis in the United States, industrial hygienist Philip A. Drinker (1894–1972) and physiologist Louis Agassiz Shaw, Jr. (1886–1940) at Harvard University designed an electrically

FIGURE 1.5 A U.S. Army nurse and two corpsmen attending a poliomyelitis patient in an iron lung, 1949.

Courtesy of the U.S. National Library of Medicine.

powered tank respirator to facilitate the breathing of patients paralyzed by poliomyelitis (Figure 1.5) (52). This "iron lung" was the first practical means of respiratory support, and in 1929, Drinker and pediatrician Charles F. McKhann soon demonstrated the potential of artificial respiration, using the iron lung for an 8-year-old girl with poliomyelitis who had developed respiratory failure and coma (53,54). Manufacture of these "iron lungs" began in the early 1930s and expanded in the 1940s and early 1950s, until the respirators were replaced in the late 1950s and early 1960s by more sophisticated ventilation devices. The iron lung required intensive nursing care and respiratory therapy, and a supporting hospital infrastructure. Although the iron lung saved thousands of lives, many patients, who would otherwise have died, survived with severe disabilities requiring considerable physical therapy, orthotics, and adaptive equipment.

"Sister" Kenny: An Outspoken Nurse Challenges the Orthodox Treatment of Polio

From the 1920s through at least the early 1940s, the orthodox treatment for polio consisted largely in absolute immobilization of affected limbs through splinting or the use of plaster casts (often for many months) and, subsequently, orthopedic braces (often permanent), leading to disuse atrophy, joint contractures, and lifelong disability (10,55–57). However, since 1911, an unregistered independent nurse practitioner named Elizabeth Kenny (1880–1952) had been treating patients with poliomyelitis using an alternative approach she had developed empirically in a sparsely populated backcountry area of Australia in ignorance of the prevailing orthodox treatments (58–60). Later, when she came into prominence, Kenny employed the title of "Sister," an honorific designation for a head nurse in the British system that she earned during her military service in the Australian Army Nurse Corps during World War I (60–62). "Sister" Kenny's approach to the treatment of poliomyelitis used physical methods (e.g., the labor-intensive application of moist warm wraps of heavy woollen cloth for muscle spasms, aggressive use of passive range of motion, and massage), avoidance of immobilization and bracing, and strong encouragement of functional independence, as well as early mobilization and prompt return to normal activities, coupled with confident optimism for improvement (58,59,61,63–65). Kenny later criticized the immobilization approach then in vogue, claiming that it prolonged muscle spasms, promoted joint stiffness, and prevented restoration of normal muscle action:

> My reasons for the condemnation of the principles of immobilization as generally accepted are as follows: 1. Immobilization prevents the treatment of the disease, that is, the symptoms of the disease, in the acute stage. 2. It prolongs the condition of muscle spasm and prevents its treatment. 3. It prevents the treatment for the restoration of coordination of muscle action, a serious error. 4. It promotes the condition of stiffness which according to all reports prevents satisfactory treatment for the symptoms that brought about the condition (muscle spasm) or the development of muscle power by reeducation, or re-awakening of impulse. (64)

During the 1930s, 10 Sister Kenny Clinics were established in eastern Australia, initially as "Muscle Re-Education Centres" (58). However, Kenny was not accepted by orthodox medicine in Australia, was denounced by an Australian Royal Commission in the late 1930s, and was widely criticized by orthopedic surgeons and other physicians, who charged that she understood neither the pathophysiology of the disease nor the physiology of muscle (58,59). Nevertheless, her approach was empirically successful and she developed a large popular following. In 1939, the Queensland government—in spite of the unpopular conclusions of its own Royal Commission—ordered that the Kenny treatment be made available in the Queensland public hospital system (58,59).

Kenny came to the United States in 1940, where her ideas were initially ignored or resisted until tested by Dr. Wallace Cole, chief of orthopedic surgery at the University of Minnesota Medical School and Dr. Miland Knapp, a surgeon who chaired the school's department of physical therapy (66). The Kenny methods were eventually found to reduce length of hospital stay, greatly diminish contracture formation, and improve functional recovery (66–69). As a result, with encouragement from the American Medical Association and initial funding from the National Foundation for Infantile Paralysis and other donors, a well-regarded and very successful Sister Kenny Institute (later known as the Sister Kenny Rehabilitation Institute) was established in Minneapolis in early 1942 and developed a strong affiliation with the University of Minnesota Medical School, with rotating residents and various specialist staff including physiatrists, orthopedic surgeons, neurologists,

FIGURE 1.6 "Sister" Elizabeth Kenny (1880–1952), shown here demonstrating therapy techniques at the Sister Kenny Institute in Minneapolis, Minnesota, c. 1942.

Courtesy of the Minnesota Historical Society, St. Paul, Minnesota.

and others (Figure 1.6) (10,50,58,60,62). The Kenny methods were widely adopted in the United States and elsewhere in the 1940s (though not in Australia), and were taught to physical therapists and physicians at training satellites around the country. Although the controversial Kenny had her detractors, she also had numerous supporters, including Krusen of the Mayo Clinic. Kenny's approach represented a significant advance in the care of paralyzed patients and helped foster the growth of physical therapy and physical medicine (6,50,70).

> In retrospect there is no denying that Sister Kenny's ideas and techniques marked a turning point, even an about-face, in the aftercare of paralytic poliomyelitis. By determination and sheer willpower she helped to raise the treatment of paralyzed patients out of the slough into which it had sunk in the 1930s. The system which prevailed before her advent, that is, prolonged immobilization of affected limbs which in some instances led to a certain amount of calculated neglect, militated against involving the patient in early efforts to aid return of muscle function. It also eliminated the element of continued encouragement, which [is] so important as a psychological asset to rehabilitation. There was little use in exhorting a patient to exert himself physically if he was in a plaster cast. (71)

FDR, the National Foundation for Infantile Paralysis, and the March of Dimes

Franklin Delano Roosevelt (1882–1945), the most famous victim of polio, contracted the disease in the summer of 1921 and was permanently paralyzed from the waist down (57). Despite his disability, Roosevelt was later elected to the first of four terms as President of the United States in 1932 (57). From the time he became disabled, Roosevelt played an important role in the development of rehabilitation medicine, helped remove some of the social stigma from physical disability, provided inspiration and hope, promoted the idea that polio victims could become "normal" again (even if this was partly because of careful media management limiting the public's knowledge of the extent of his disability), and provided a mechanism for widespread supportive social action and philanthropy. In 1926, Roosevelt purchased a spa in Warm Springs, Georgia, to help facilitate his personal rehabilitation. By 1927, Roosevelt had founded the Georgia Warm Springs Foundation, which helped develop physical therapy and rehabilitation approaches for polio victims (50). In 1937, the Foundation was reorganized as the National Foundation for Infantile Paralysis (and officially incorporated in 1938), under the direction of Roosevelt's former law partner, D. Basil O'Connor (1892–1972). Under O'Connor's effective organizational leadership, the National Foundation began an unprecedented, innovative, and highly successful fundraising campaign utilizing an annual "President's Birthday Ball" with President Roosevelt and a variety of celebrities promoting the event and print advertisements with images of happy children ("poster children") in wheelchairs or braces and crutches asking for financial support, as well as public appeals requesting people to send dimes directly to the White House to help find a cure for polio; this latter campaign was labeled the "The March of Dimes" by entertainer Eddie Cantor (1892–1964) as a play on the words of "The March of Time" newsreel series (72–76). The first March of Dimes appeal in 1938—during the severe 1937 to 1938 recession following closely on the heels of the Great Depression of 1929 to 1934—generated extraordinary interest and raised an unprecedented $268,000 (the equivalent of over $3.4 million in year 2007 currency) (Figure 1.7) (76–78). A stunned President Roosevelt commented on the eve of his birthday:

> During the past few days bags of mail have been coming, literally by the truck load, to the White House. Yesterday between forty and fifty thousand letters came to the mail room of the White House. Today an even greater number—how many I cannot tell you, for we can only estimate the actual count by counting the mail bags. In all the envelopes are dimes and quarters and even dollar bills—gifts from grownups and children—mostly from children who want to help other children to get well. Literally, by the countless thousands, they are pouring in, and I have figured that if the White House Staff and I were to work on nothing else for two or three months to come we could not possibly thank the donors. Therefore . . . I must take this opportunity . . . to thank all who have aided and cooperated in the splendid work we are doing. (76)

The public's fear of contracting the disease, appeals to altruism with heartbreaking stories of afflicted children, requests

from admired role models (movie stars and politicians), and hope that the disease would soon be conquered were all used so effectively in the campaigns that the nonprofit National Foundation became the largest private charity in history. The National Foundation led the "first large-scale, nationwide biomedical initiative" by a charitable organization (75) and, as a result, was instrumental in subsidizing the hospital and rehabilitation costs of polio patients, funding basic and applied research concerning the causes and prevention of polio in the 1940s and early 1950s, training nurses and physical therapists in rehabilitation, sponsoring pilot programs to improve the teaching of rehabilitation medicine in medical schools in the early 1950s, and, ultimately, underwriting the Salk Vaccine Field Trial in 1954 (6,72,73,75). The National Foundation officially changed its name to the March of Dimes in 1979 (after the threat of polio in the United States had passed) (75).

The Salk Vaccine Field Trial of 1954 and Aftermath

Austrian biologist and physician Karl Landsteiner (1868–1943) and his assistant Erwin Popper demonstrated as early as 1908 that poliomyelitis was transmitted by a virus, work for which Landsteiner won the 1930 Nobel Prize in Physiology or Medicine (70,79,80). By 1948, neuroscientist David Bodian, MD, PhD (1910–1992) and colleagues at Johns Hopkins University, and virologist John Rodman Paul, MD (1893–1971) and epidemiologist James Dowling Trask, MD, PhD (1890–1942) at Yale University independently showed that there were three strains of poliovirus (rather than one) as defined by cross-protection within the same group—a finding confirmed by the more extensive work of the Committee on Typing of the National Foundation for Infantile Paralysis in 1951 (in which Jonas Salk was a participant) (70,80–85). In 1949, microbiologist John Franklin Enders, PhD (1897–1985), along with virologist Thomas Huckle Weller, MD (1915–2008) and microbiologist and pediatrician Frederick Chapman Robbins, MD (1916–2003), working at Harvard Medical School and Children's Medical Center in Boston, first cultivated the poliovirus in (nonnervous) tissue culture, for which they were later awarded the 1954 Nobel Prize in Physiology or Medicine (86–90). Also by 1954, several researchers, including epidemiologist, virologist, and pediatrician Dorothy Millicent Horstman, MD (1911–2001) at Yale, had demonstrated that there was a period of viremia preceding neurologic involvement (91,92). These important advances made possible the development, by virologist Jonas Edward Salk, MD (1914–1995), of an inactivated trivalent poliovirus vaccine, which was tested in 1954 in a huge clinical trial funded by the National Foundation for Infantile Paralysis (Figure 1.8) (74,93–96). The 1954 Field Trial of the Salk vaccine was the largest public health experiment ever, involving 1.8 million children who were labeled "Polio Pioneers" and were inoculated with either vaccine or placebo, or were simply observed (70,72,93,97,98). On April 12, 1955, at a press conference in Ann Arbor, Michigan, epidemiologist and virologist Thomas Francis Jr., MD (1900–1969), who had conducted the field trial, declared that the Salk inactivated polio vaccine was both safe and effective (93,98,99). That same afternoon, an advisory committee to the Laboratory of Biologics Control, the federal agency that was responsible for licensing biologic products, recommended that vaccine licenses be granted to five pharmaceutical companies: Eli Lilly, Parke-Davis, Wyeth, Pitman-Moore, and Cutter Laboratories.

FIGURE 1.9 Russian-American virologist Albert Sabin (1908–1993). Sabin developed a live attenuated-virus polio vaccine. From Theodore Woodward's *The Armed Forces Epidemiological Board: Its First Fifty Years* (1990).

This image is a work of a U.S. Army soldier or employee, taken or made as part of that person's official duties. As a work of the U.S. federal government, the image is in the public domain.

However, shortly thereafter, unforeseen manufacturing difficulties with clumping of material and inadequate formaldehyde inactivation of the virus during large-scale processing resulted in a huge outbreak of iatrogenic paralytic poliomyelitis (the so-called "Cutter Incident") with muscle weakness developing in 70,000 people, of whom 164 developed severe paralysis and 10 died (100–104). The litigation that followed (particularly *Gottsdanker v. Cutter Laboratories*, 1957) led to new legal interpretations (i.e., the doctrine of liability without fault) and, ultimately, the development of the National Vaccine Injury Compensation Program in 1986 (103,104). Although these legal issues dragged on for decades, the manufacturing problems were soon corrected, and with wide-scale immunization using the Salk vaccine, the rates of paralytic poliomyelitis plummeted.

In 1957, Russian-American virologist Albert Sabin, MD (1908–1993), utilizing the time-consuming process of infecting monkeys with poliovirus, developed a trivalent live attenuated polio vaccine that was then tested in Russia, endorsed by the American Medical Association in 1961 even before American field trials were begun, and, ultimately, licensed in the United States in 1963 (Figure 1.9). The Sabin vaccine soon became the polio vaccine of choice, because it (a) was less costly, (b) required minimal training to administer, (c) prevented the disease carrier state, and (d) helped prevent the spread of wild poliovirus. However, by this time, the rates of polio in the United States had dropped to 50 to 100 cases per year—down from tens of thousands per year—so the Sabin vaccine had a relatively limited impact on overall polio incidence in the United States, but it did have an important role around the world. By the early 1970s, the remaining incident cases of paralytic poliomyelitis in the United States were almost exclusively either imported cases or those caused by the vaccine itself. The Sabin oral polio vaccine was discontinued in the United States in 2000, because the continued risk of vaccine-related polio outweighed the potential benefits of a live-virus vaccine.

PROFILE OF HOWARD RUSK (1901–1989): THE FATHER OF COMPREHENSIVE REHABILITATION MEDICINE

Origins of Comprehensive Rehabilitation During World War II

In 1942, internist Howard Rusk, MD (1901–1989) (Figure 1.10) left his well-established medical practice in St. Louis to join the Army Air Corps. As Chief of Medical Services at the 1,000-bed hospital at Jefferson Barracks in St. Louis, Rusk observed both a high degree of boredom among the patients and a high rate of readmission because patients were not physically fit enough to return to active duty in their units after hospital discharge, even though they were no longer in need of acute hospitalization (1,48,105–107). Rusk, therefore, sought to engage the patients in mental and physical restorative and training activities that would utilize their time efficiently, increase their fitness, and decrease the rate of recidivism. Rusk's approach to rehabilitation emphasized treating the entire person, including his or her emotional, psychological, and social needs, and not just the illness or a specific disability. By 1943, seven special "convalescent hospitals" had been established in the Army Air Corps, with multidisciplinary staff comprising

> medical and surgical specialists, but also physical therapists, educators, athletic trainers [later called "corrective therapists" and still later called "kinesiotherapists"], occupational therapists, social service workers, personal counselors, and vocational guidance advisors—all of whom worked as a team to meet on an individual basis, the needs of the "whole man." . . . [A] broad program of rehabilitation was put into operation at each convalescent hospital, with the result that each hospital became part school, gymnasium, machine shop, psychiatric clinic, vocational guidance center, and town hall. (45)

FIGURE 1.10 Dr. Howard A. Rusk (1901–1989), the father of comprehensive rehabilitation medicine.

Rusk's efforts were soon recognized by generals (Dr.) David N.W. Grant (1891–1964) and Henry Harley (Hap) Arnold (1886–1950), whereupon Rusk was sent to Washington, DC, in 1943 to set up similar programs for all 253 Army Air Corps hospitals (1,105,108). Rusk's novel Convalescent Training Program was highly effective in decreasing hospital readmissions, saving man-hours, and giving injured and disabled soldiers hope and purpose (Figure 1.11).

> Despite such success, many of us felt our program was grossly inadequate. The feeling became intensified when wounded boys from the battlefields began being packed into our hospitals by the planeload. Suddenly we were faced by men with broken bodies and, all too often, broken spirits. We concluded that our program was a schoolboy project in the context of what needed to be done for the severely wounded—the amputees (the double, triple, and quadruple amputees), the paraplegics and quadriplegics, the blind, the deaf, the disfigured, the emotionally disturbed. These men would need complete rehabilitation, whatever that might be—I wasn't sure. Just exactly what could be done for them? . . . It was horrible to realize that there was no precedent for rehabilitation programs on a large scale in the military. And as far as I knew, there was no extensive civilian programs either. (105)

Later, similar programs, loosely modeled after Rusk's Convalescent Training Program, were adopted by all branches of the service at the instigation of Bernard Baruch and the subsequent request of President Franklin Delano Roosevelt (1882–1945) to Secretary of War Henry Lewis Stimson (1867–1950) (1). Rusk had sought Baruch's assistance, and the letter drafted by Baruch for the President's signature became *de facto* military policy giving official standing to rehabilitation medicine:

> My dear Mr. Secretary, I'm deeply concerned about our casualties returning from overseas, as I know you are. I would like you to see that no one is discharged from service until he has had the full benefit of hospitalization, which will include not only medical care but resocialization, psychological adjustment and rehabilitation. I would like you to see that this is put in operation as soon as possible. (105)

Because of the limited rehabilitation programs available prior to World War II, and the widely held expectation at the time that disabled people could not be productive, people with strokes or other brain and spinal cord injuries received, at best, custodial care and often died within a short time (1).

> I recall someone asking me how paraplegics had lived up to that time. The answer was, except in extremely rare cases, they usually died—their life expectancy in those days was often less than a year. They got terrible bedsores, developed kidney and bladder problems, and simply lay in bed, waiting for death. It was almost the same with strokes. The old wives' tale was that you had one stroke, and then you sat around waiting for a second one, or a third one, or however many it took to kill you. If you had any kind of brain injury affecting your locomotive functions, everyone assumed your life was finished. (105)

Rusk's experience in the rehabilitation of wounded soldiers during World War II helped usher in the concept of comprehensive rehabilitation, with both utilitarian and humanitarian aims (1).

> The modern concept of "the treatment of the whole man" [developed by Rusk, himself] did not develop . . . until World War II, when rehabilitation got its biggest impetus because so many wounded survived—but survived with severe disabilities. (46)

> One of our most immediate frustrations in early 1943 was that if we discharged these wounded and disabled veterans from the service—which we had to do since they could no longer function as soldiers—we were turning them over to the Veterans Administration, which at that time was like sending them into limbo. The V.A. had no program for them. They would simply lie around getting custodial care, with nothing to do, bored to distraction, helpless, hopeless, waiting for some kind of infection or disease

FIGURE 1.11 Vocational rehabilitation posters of the U.S. Army Air Forces during World War II. Photomechanical print created by Jack Wittrup (1912–1987). Published by the Training Aids Division, 1944.

> to carry them off. Gradually the concept of rehabilitation came to me as I found out how much really could be done for these men. In the beginning, I knew only that everything possible should be done to return them to physical and mental health. This meant finding ways for them to function despite their disabilities. First, I had to remember that this was the Air Force, that we were fighting a desperate war, and that we needed all the manpower we could find. It was immediately important, then, to make these men in some way able again. Our initial aim had to be to send them back to duty in the best possible condition and in the shortest time. If they could no longer do their previous jobs, we should help them choose jobs they could do, and then retrain them. This approach would be beneficial to the Air Force and it seemed the best for the boys themselves, too. (105)

The development of comprehensive rehabilitation in the military during World War II was truly novel and the outcomes were unprecedented (1):

> We discovered we had saved at least forty million man-hours of duty time, and that we had gotten more sick or injured men back on duty than any branch of service had done during any war in history. More important, we had prepared thousands of boys for useful roles in civilian life after the war who might otherwise have wasted away for years in veterans hospitals. And by proving the value of rehabilitation, we had made certain that the Veterans Administration, after this war, would actually rehabilitate its disabled men rather than letting them languish in bed, or die for lack of understanding and a program. It is worth noting that of the four hundred men who became paraplegics in World War I, a third died in France, another third died within six weeks thereafter, and of the remaining third, 90 percent were dead within a year. In World War II there were 2,500 American service-connected combat paraplegics, and three-fourths of them were alive 20 years later. I might add parenthetically that of these survivors, 1,400 were holding down jobs. (105)

Rusk earned a Distinguished Service Medal for his work in the U.S. military, and retired as a Brigadier General in the U.S. Air Force Reserve.

Later, in retrospect, he was struck by the irony of such progress having been made in the field of rehabilitation medicine as a result of a brutal war:

> It is paradoxical that through war, a concerted effort to annihilate man, we have learned more and better ways to preserve him. (45)

Change in Management of Disability After Stroke

As an internist prior to World War II, Rusk had been frustrated with the options available for treating patients disabled by stroke, and had felt that his own knowledge was woefully inadequate. Rethinking his prior management and discussing his career options with several former patients who had suffered from stroke reinforced Rusk's belief in the concept of comprehensive rehabilitation and gave him the determination to abandon his previous internal medicine practice and seek opportunities to develop this concept for civilian patients.

> There was so little you could do to help a stroke victim in those days that, like many other doctors, I had developed a technique in dealing with them that did no more than pacify them. I had scores of them in my practice, people who were partially paralyzed, and who, therefore, sat home all day, no longer considered fit to work, and with nothing to do but think about their condition. They would want to see me periodically for checkups, but I wanted to see them as seldom as possible. I didn't realize it at the time, but in front of such patients I was overcome by a feeling of insecurity. Deep down inside I felt guilty because I didn't know how to help them. Whenever they came into the office they wanted to talk. They would talk for an hour if you let them, while thirty other people sat in the waiting room. So I would go through the routine of taking their blood pressure . . . and prescribe a little meaningless change in their medication that would make them feel that at least something was being done. Then I'd hurry out of the room while the nurse came in to dismiss them. I didn't want to talk to them because I really didn't know what to say, and I'm sure that's always been true of most doctors everyplace . . . . If [a patient] was paralyzed . . . or disabled in some other way, there was virtually no one to whom you could send him. You could get him maybe a "nickel's worth" of physical therapy, and that was about all. Such reminiscences reinforced my determination to throw my energies into rehabilitation. (105)

Moreover, by this time Rusk had an entirely different view of the potential for rehabilitation of patients following a stroke, emphasizing what could be done, focusing on remaining abilities, and utilizing simple techniques and equipment to minimize contractures and other secondary impairments and to maximize function:

> There are a number of simple progressive procedures in the rehabilitation of the hemiplegic who suffers from one of the commonest disabilities seen in general practice. In the early stages of treatment, the following procedures should be instituted to prevent deformities: (1) footboard or posterior leg splint to prevent foot drop; (2) sandbags to prevent outward rotation of the affected leg; (3) a pillow in the axilla to prevent adduction of the shoulder, and (4) quadriceps setting to maintain muscle strength. All of these procedures are relatively simple and require no special equipment. Their use, however, will prevent crippling anatomic deformities and hasten the rehabilitation of the patient.
>
> The next procedure indicated is the institution of pulley therapy. This can be done simply with a small pulley attached to a goose neck pipe over the head of the bed, the ordinary clothes line rope being used with a 1 inch (2.5 cm) webbing for the hand loop. With the stretching and passive exercise provided by pulley therapy, the range of motion can be increased and adhesions prevented. Pulley therapy has the advantage over the usual stretching exercises that are done passively, for the patient, knowing his own pain threshold, will proceed to fully tolerated motion much more quickly. . . .
>
> [Ambulation] should be started by (1) the practice of balance in the standing position, progressing to parallel bars; (2) the teaching of a heel and toe gait to minimize clonus and to reestablish normal walking habits stressing reciprocal motion, and (3) a short leg brace, which will be needed in approximately half of all cases to correct foot drop. All of the equipment for training in ambulation is simple and readily obtained by the general practitioner. If parallel bars are not available, two kitchen chairs may be substituted. In the advanced stages of retraining, ambulation is continued with (1) instruction in crutch walking, starting usually with the alternate four point gait, and (2) teaching elevation, stressing climbing steps, curbs, stairs and ramps. Concurrently with the training in ambulation, attention should be given to retraining in the activities of self care and daily living . . . With such a program, many of the complications usually following apoplexy can be avoided and a great deal of time and ability salvaged. (109)

Not only did Rusk feel that such approaches were extremely helpful, but he also felt strongly that *failure* to provide rehabilitation to patients was a form of medical negligence:

> The physician who fails to see that those patients under his care receive the full benefits of modern methods of medical rehabilitation and retraining is in the same category as the physician who still persists in using dietary restriction alone in the management of diabetes, when insulin is available, for medical care is not complete until the patient has been trained to live and work with what he has left. (109)

Rusk later explained the potential for rehabilitation of stroke patients to colleagues at a meeting of the American College of Physicians in Boston:

> I'm talking about the two million people in this country who have suffered strokes and are now sitting around,

> waiting to die because no one is helping them to live. I'd like to tell you today about a few simple things you can do for many of these people, right in your offices, or in the home or bedside. I told them how to prevent painful hips by sandbagging the patient's leg. I told them how to sandbag a shoulder so it wouldn't become what we call "frozen" and require several weeks of painful therapy and stretching to get it back to normal. I took out some props and showed them how they could make an exercise device for arms and shoulders for stroke victims simply by using a window pulley and six or eight feet of clothesline. I pointed out that a patient could help himself more with this device than a therapist could help him because, by doing it himself, he could sense the pain threshold and therefore stretch farther than a therapist would dare to try. I talked about aphasia, the speech difficulty stroke victims suffer, which seems to me one of the most frustrating problems of all. It's like not being able to say an old friend's name, multiplied to infinity. As I talked, this time I noticed there was absolute silence in the hall, and instead of seeing people leave, I noticed that more people kept arriving until, by the end of my presentation, they were standing in the aisles. (105)

Although such information generated considerable interest, referral options were extremely limited because of the lack of comprehensive rehabilitation programs across the country.

Program for Civilian Rehabilitation

After World War II, Rusk began efforts to establish a program for civilian rehabilitation, based in large part upon what he had learned in the military (1). He initially intended to open a rehabilitation institute in St. Louis, where he had practiced internal medicine for 16 years prior to his military service, but colleagues there were not supportive.

> I can't say the idea was well received. The orthopedists, in particular, said, "We're doing all that anyway," and it was true that they had adopted some good methods of therapy. But they failed to see my point: the whole person needed rehabilitation, not just the part of him that had been damaged. They had no concept of the emotional problems which follow disability, or the problems of job placement, or the other fundamentals behind our philosophy. (105)

In 1945, Rusk joined the staff at New York University Medical School, and several wards in Bellevue and Goldwater Hospitals were designated for rehabilitation, although initially the beds were also simultaneously utilized by other services. The previously separate programs for physical and occupational therapy were combined into a new Department of Rehabilitation Medicine (3), and Rusk hired George Gilbert Deaver, MD (1890–?), from New York's Institute of Crippled and Disabled as the medical director (Figure 1.12) (3,46). Deaver had been a pioneer in rehabilitating the severely handicapped, including those with spinal cord injury, cerebral palsy, muscular dystrophy, multiple sclerosis, and rheumatoid arthritis. "At a time when these patients were being rejected and discarded as permanently disabled, Deaver was accepting of them and patiently working with them to achieve the best possible outcomes through rehabilitation" (3). Deaver made unprecedented progress in rehabilitating those with spinal cord injury to independence in self-care, crutch or brace-assisted ambulation, or wheelchair living (3,46): According to Rusk, "It was he who first taught paraplegics how to walk" (46). Deaver had also developed tools and techniques for assessing activities of daily

living (as a guide for independent living capability), crutch walking, and prevocational evaluation (3,46). By 1947, Rusk and Deaver had established the "first comprehensive, total medical rehabilitation program in any community hospital" in the United States at Bellevue Hospital in New York (109).

Despite Rusk's enthusiasm and his previous successes, his initial civilian efforts were regarded skeptically by colleagues:

> Many people, even in the medical profession, considered it foolish to spend money or effort on such a "frilly boondoggle." It wasn't that they disapproved of getting disabled people onto their feet and back into the mainstream of life; it was just that they didn't think it was possible. (105)

Nevertheless, Rusk persevered and gained the support of prominent philanthropists, including Bernard Baruch, Polish-American builder and developer Louis J. Horowitz (1875–1956) and his wife Mary Decker Horowitz (c. 1877–c. 1966), and retail innovator Bernard Feustman Gimbel (1885–1966) and his wife Alva Bernheimer Gimbel (1893–1983). In 1950, Rusk founded the Institute of Physical Medicine and Rehabilitation at New York University Medical Center. The institute opened its doors in 1951, but was initially derided as "Rusk's Folly" by former colleagues in St. Louis (108). Renamed the Howard A. Rusk Institute of Rehabilitation Medicine in 1984, 2 years after Rusk's retirement in 1982, the institute is now the largest university-affiliated center for treatment of civilians with disabilities and for research and training in rehabilitation medicine (110).

Promoting Rehabilitation Medicine

Rusk worked tirelessly, promoting the nascent field of rehabilitation and increasing public awareness of the need for rehabilitation in the spectrum of medical practice in numerous speeches and consultations across the country and around the world, in a weekly column on health issues for *The New York Times* (which Rusk continued until 1971), through influential private sector and government contacts, and through the establishment of rehabilitation training programs, which helped expand the message through various disciples (1). In 1955, Rusk founded the World Rehabilitation Fund to provide technical assistance for the development of rehabilitation programs in underdeveloped countries, as well as funding for education and training programs on prosthetics around the world, and grants for foreign physicians to study rehabilitation in the United States: "Its basic aim was to sponsor international projects which would help the handicapped and create a better understanding of them and their problems" (105). Rusk also authored several books, including *New Hope for the Handicapped* (1949) and *Living with a Disability* (1953), both with his colleague Eugene (Jack) Taylor (1913–1978); served as the senior author of *Rehabilitation Medicine* (1958); and wrote his acclaimed autobiography, *A World to Care For* (1972), which summarized the development of his concepts of comprehensive rehabilitation.

In his autobiography, Rusk explained why he got such satisfaction from working with disabled people:

> You don't get fine china by putting clay in the sun. You have to put the clay through the white heat of the kiln if you want to make porcelain. Heat breaks some pieces. Life breaks some people. Disability breaks some people. But once the clay goes through the white-hot fire and comes out whole, it can never be clay again; once a person overcomes a disability through his own courage, determination and hard work, he has a depth of spirit you and I know little about . . . . Rehabilitation is one branch of medicine in which the patient has more power than the doctor in setting the limits and possibilities. The doctor can tell the patient what to do, but only the patient himself can decide how much he's going to do. In making these decisions, patients are constantly teaching us doctors new things about rehabilitation by proving that they can do more than we had presumed possible. (105)

Rusk promoted these ideas among medical students as well:

> When I lecture to medical students, it's the brightest day of the year for me. They're so delighted to leave the basic sciences behind for an hour, so eager to heal. I always tell them: "If you can get the same satisfaction out of taking an old hemiplegic out of a wet bed, teaching him to walk, to speak so he can be understood, to take care of himself, getting him to the point where he can live a non-institutional life, perhaps getting him a job, and get the same satisfaction as from making some fancy diagnosis of an arcane disease that you may see once in a lifetime, then you'll make a good doctor. Like it or not, if you go into general medicine, 80% of your patients will have either a chronic or a psychosomatic sickness. (108)

Rusk emphasized that physical disability could be accommodated and that through vocational rehabilitation, many disabled people could live productive lives and be valuable members of the workforce:

> When you work with a handicapped person, you've got to think of his abilities more than his disabilities. You've got to remember that our society doesn't pay for physical strength. We now have machines to do the heavy labor. Our society really pays for just two things, the skill of your hands and what you have in your head. (105)
>
> The disabled, if properly placed and trained, are good workers with a better production rate, lower accident and absentee rates, and a labor turnover 10 times less than that of normal workers. (110)

In 1955, Rusk received a Christmas card from Adlai Stevenson containing what has been attributed to be the personal prayer of an unknown Confederate soldier in the Civil War (46):

> I asked God for strength, that I might achieve
> I was made weak that I might learn humbly to obey . . .
> I asked for health, that I might do greater things
> I was given infirmity, that I might do better things.
> I asked for riches, that I might be happy
> I was given poverty, that I might be wise . . .
> I asked for power, that I might have the praise of men
> I was given weakness, that I might feel the need of God . . .
> I asked for all things, that I might enjoy life
> I was given life, that I might enjoy all things . . .
> I got nothing that I asked for
> —but everything I had hoped for
> Almost despite myself,
> my unspoken prayers were answered.
> I am among all men, most richly blessed!

Rusk's disabled patients found personal meaning in this prayer, as did their families, so much so that the father of one young patient had the prayer cast in bronze. The prayer that the boy's father cast in bronze now hangs on the wall in the lobby of the institute Rusk founded (46). The prayer continues to be widely reproduced, and is sometimes referred to as the "Prayer of the Disabled."

Rusk closed his autobiography with a quote from French chemist and microbiologist Louis Pasteur (1822–1895), emphasizing the patient's role in rehabilitation, and in Pasteur's particular case, his successful rehabilitation following a serious stroke:

> Ultimately, the success of all rehabilitation depends on the patient himself . . . I can never forget a philosophical quotation that serves as a constant reminder of this truth: "I hold the unconquerable belief that science and peace will triumph over ignorance and war, that nations will come together not to destroy but to construct, and that the future belongs to those who accomplish most for suffering humanity." Those words were spoken by the great 19th-century scientist Louis Pasteur. Few people know that he suffered a serious stroke when he was in his forties . . . He rehabilitated himself—working to the age of seventy three—and many of his greatest scientific achievements came after his stroke. Pasteur's words express what anyone working in this field must feel. To believe in rehabilitation is to believe in humanity. (105)

Rusk never stopped promoting the concept of rehabilitation. As he noted in 1969:

> We who have dedicated our lives to rehabilitation medicine must be not only practitioners but teachers, crusaders, and zealots. The stakes are high, not only for the welfare of the disabled, but also for the future of world understanding . . . . If we have the courage and strength and the spirit, this program of rehabilitation medicine will never die but will continue to grow and flourish for the benefit of all mankind. (45)

Rusk received many awards and honors, including three Lasker Awards, the first an Albert Lasker Public Service Award in 1952 "for his pioneering work in the service of the physically disabled and as distinguished rehabilitation mentor to the world," the second an Albert Lasker Award given by the International Society for the Rehabilitation of the Disabled in 1957, and the third an Albert Lasker Medical Journalism Special Award in 1959 "for his editorial leadership in advancing medical research and public health programs in his weekly columns in the *New York Times*" (111,112). In 1966, Rusk was recognized by the American Congress of Physical Medicine and Rehabilitation with a gold medal bearing the inscription: "Physician, teacher, author, inspiration to patients and disciples and a prime mover in the development and spread of medical rehabilitation throughout the world" (111).

In 1981, in the "Year of the Disabled," Rusk—then 80—was nominated for the Nobel Peace Prize. At that time, a reporter for the American Medical Association interviewed Rusk, who was still actively promoting comprehensive rehabilitation.

> Although some people, Ronald Reagan among them, call Howard Rusk "The Father of Rehabilitation Medicine," he declines that honor. "Minnesota's Dr. Frank Krusen deserves that title," he says. "He was far ahead of me. He succeeded in getting the AMA to recognize physical medicine as a specialty when most doctors made no bones about brushing it off as a 'social service boondoggle.'" Rusk will admit, however, to being "father, midwife, and pediatrician" to the modern concept of rehabilitation, the radical who argues that physicians should treat the "whole person. Not just the ring finger or toe." . . . Before World War II, physiatrists were concerned almost exclusively with physical and electrical modalities of treating neuromusculoskeletal disease. Under Howard Rusk, rehabilitation medicine has blossomed into a multidisciplinary, in-hospital training program. (108)

Despite Rusk's statement to the contrary, many of his colleagues continued to apply that label to him (3), and to this day the Association of Academic Physiatrists continues to label Rusk the "Father of Rehabilitation Medicine" (and Krusen the "Father of Physical Medicine") (11).

The fully formulated definition of rehabilitation by Rusk, the acknowledged father of comprehensive rehabilitation medicine, is worthwhile recounting:

> Rehabilitation is the restoration of the handicapped to the fullest physical, mental, social, and economic usefulness of which they are capable. Frequently, it has

> been called "the third phase of medicine"—following preventive medicine, and curative medicine (and surgery). In contrast to "convalescence, wherein the patient is left alone to rest while time and nature do their cures," medical rehabilitation is a dynamic concept—an active program. The first objective of medical rehabilitation is to eliminate the disability, if that is possible; the second is to reduce or alleviate the disability to the greatest possible degree; and the third, to retrain the person with a residual physical disability "to live and to work within the limits of his disability, but to the hilt of his capabilities." (46)

At the time of renaming of the Institute of Rehabilitation Medicine as the Rusk Institute in 1984, Rusk noted that he used "the phenomenon of hope" to train people "not just within the limits of their ability, but up to the heights of their latent ability—to help them live the very best lives possible with what is left" (110). Rusk's framework and focus on treating the "whole person" has been the basis of subsequent programs and developments in the field, and has been incorporated into definitions of the field used by major rehabilitation organizations (11).

EVOLVING CONCEPTS OF DISABILITY AND REHABILITATION SINCE THE 1960s

There have been three fundamentally different approaches to modeling disability: the medical model, the social model, and, more recently, various bio-psycho-social models that incorporate features of both the medical and social frameworks (113–116). The medical model of disability

> views disability as a feature of the person, directly caused by disease, trauma or other health condition, which requires medical care provided in the form of individual treatment by professionals. Disability, on this model, calls for medical or other treatment or intervention, to "correct" the problem with the individual. (116)

This medical framework was the foundation of many of the disability-related programs in the United States until the Americans with Disabilities Act (ADA) was passed in 1990:

> The [medical] model defines disabling conditions as principally the product of physical and mental impairments that constrain performance. Influenced by this view, health and social agencies provide a mix of services that, for the most part, categorize affected individuals as permanently ill and incapable of meeting their own needs. Therefore, the problems that disability-related programs seek to address are often viewed as inherent to the individual and as independent of society. (115)

People with disabilities, however, have championed the "demedicalization" of disability, and have argued for recognition that disability is, in large measure, the result of a social environment that does not address the needs of those with physical or mental limitations.

> The independent-living and disability-rights movements blame adherence to the medical model for the creation of disability-related programs that foster dependence rather than personal autonomy. Members of these movements correctly argue that disability is the result of a dynamic process involving complex interactions among biological, behavioral, psychological, social, and environmental factors. (115)

The social model of disability, in contrast, "sees disability as a socially-created problem and not at all an attribute of an individual" (113,116). Within this framework, "disability demands a political response, since the problem is created by an unaccommodating physical environment brought about by attitudes and other features of the social environment" (116). Particularly since the 1970s, there has been greater awareness of the social and environmental contributors to disability, facilitated in part by the advocacy of disability rights groups and by court cases and protest actions initiated by disabled individuals seeking basic civil and human rights (117). These actions helped bring about greater societal acceptance of disability, a shift in the federal government's official objectives to include equal opportunity, independent living, integration, and full participation for all citizens (i.e., a shift "from charity to rights") as well as the most comprehensive disability rights legislation in history, the ADA of 1990 (117). The ADA included provisions prohibiting employers from discriminating against a disabled person in hiring or promotion if the individual is otherwise qualified for the job, and mandating that businesses make "reasonable accommodations" for disabled workers including job restructuring and modification if required; that federal, state, and local governments and programs be accessible; that public transportation be accessible to handicapped people; and that privately operated public accommodations (e.g., restaurants, hotels, and retail stores) make "reasonable modifications" to ensure accessibility.

Both the medical and social models have value, and both can encourage communication among professionals across different disciplines, facilitate understanding of patients' problems, and help guide efforts to improve functioning of people with disability. Since the 1960s and 1970s, models of disability and rehabilitation have been developed and refined integrating aspects of both the medical and social frameworks into more balanced bio-psycho-social models (113–116,118–124). These models specifically acknowledge that "whether a person performs a socially expected activity depends not simply on the characteristics of the person but also on the larger context of social and physical environments" (115). As a result, such models help to "set the rehabilitation agenda clearly in a social context while still recognizing that disease has an important influence on patients' levels of physical activity and social participation and on the process of rehabilitation" (125). Such models also

extend "the boundaries of rehabilitation—from the few conditions where recovery is expected to any condition in which someone experiences disability or handicap secondary to (or as part of) illness" (125).

Unfortunately, the terminology employed in these models has changed over the years, making comparisons difficult and hampering understanding. The term "disability" has variably referred to dysfunction at the level of the person, dysfunction owing to an inadequate social and physical environment, or an entire spectrum of dysfunction affecting organs and organ systems, the person, and the person's interaction with his or her social and physical environment. In the United States and other countries, there has been a movement away from the use of the word "handicap" (115,126).

The World Health Organization's Impairments-Disabilities-Handicaps Framework (1980)

In 1980, the World Health Organization (WHO) introduced the *International Classification of Impairments, Disabilities, and Handicaps (ICIDH)*—a tool for the classification of the *consequences* of disease as a complementary framework for the *International Classification of Diseases (ICD)* (122,127). ICIDH defined the terms "impairment," "disability," and "handicap," and provided a preliminary classification and grading scale for each based on a conceptual framework developed initially in the 1970s by epidemiologist Dr. Philip H.N. Wood (1928–2008) of the University of Manchester Medical School in Manchester, England (122,127). Impairment was considered to represent "exteriorization" of a pathological state (disease), that is, an organ-level disturbance evident through symptoms or signs. Disability was considered "objectification" of impairment, a person-level restriction or lack of ability to perform a normal activity such as personal care or walking. Handicap was considered to represent "socialization" of a disability or impairment: a social disadvantage for an individual that limits or prevents fulfillment of a normal social role such as self-sufficiency. Under this framework, **disease → impairment → disability → handicap**.

ICIDH listed the goals for intervention as they pertain to disability:

1. *Prevention*
2. *Enhancement* (e.g., when activities can be performed unaided but only with difficulty)
3. *Supplementation* (e.g., when activities can be performed only with aid, including the assistance of others)
4. *Substitution* (i.e., when certain activities cannot be performed even with aid) (122).

Under this framework, rehabilitation focuses on the latter three categories (i.e., enhancement, supplementation, and substitution) to minimize handicap.

In many ways, the initial WHO formulation relied heavily on a medical model of disability (115,116), even though it recognized that social factors were inherent in what it called "handicap" (122). This approach resulted in charges that ICIDH promoted the "medicalization" of disability and failed to adequately address the major impact of social and environmental factors (115,121).

The Institute of Medicine's "Disabling Process" Framework (1991)

In a 1991 report of the Institute of Medicine (IOM) titled *Disability in America*, the components of the "disabling process" were refined from those initially described by sociologist Saad Z. Nagi of Ohio State University in the 1960s (115,119–121). Under this framework, the disabling process has four major components: pathology, impairment, functional limitation, and disability, with the usual (although not universal) progression being **pathology → impairment → functional limitation → disability**.

There are exceptions to this typical progression:

> Although [the model] seems to indicate a unidirectional progression from pathology to impairment to functional limitation to disability, and although a stepwise progression often occurs, progression from one stage to another is not always the case. An individual with a disabling condition might skip over components of the model, for example, when the public's attitude toward a disfiguring impairment causes no functional limitation but imposes a disability by affecting social interaction. Also, the effects of specific stages in the model can be moderated by such interventions as assistive devices. Similarly, environmental modification (e.g., elimination of physical obstacles and barriers) is an important form of disability prevention . . . . (115)

There are clearly overlaps and differences between the IOM model and the earlier WHO model (122). In the IOM model, *pathology* concerns the abnormal interruption or interference of normal bodily structures or processes because of factors (e.g., disease, infection, trauma, and genetic defect) operating at the molecular, cellular, or tissue level. *Impairment* concerns the loss or abnormality of a mental, physiological, or biochemical function at the organ or organ systems level. A *functional limitation* is the impaired ability or inability to perform a specific task at the level of the whole organism, such as walking or climbing a flight of stairs. A *disability* is a limitation in performing roles and tasks expected of an individual within a social and physical environment—an abnormal gap between the individual's capabilities and the environmental and societal demands.

In the IOM model, the amount of disability a person experiences is directly linked to the "quality of the surrounding environment—for example, whether appropriate and adequate care is accessible and whether a social support network is in place" (118). Thus, a major focus of rehabilitation is minimizing disability by physical and social environmental modifications so that an individual can participate fully in society.

Although to some degree a mixed bio-psycho-social model, the IOM framework is based heavily on a social model of disability:

> Disability is the expression of a physical or mental limitation in a social context—the gap between a person's capabilities and the demands of the environment. People with such functional limitations are not inherently disabled, that is, incapable of carrying out their personal, familial, and social responsibilities. It is the interaction of their physical and mental limitations with social and environmental factors that determines whether they have a disability. Most disability is thus preventable. (115)

Further, the IOM report correctly emphasized that disability prevention can be directed at any of the stages of the disabling process. Even at the disability stage, "efforts can focus on reversal of disability, restoration of function, or prevention of complications (secondary conditions) that can greatly exacerbate existing limitations or lead to new ones" (115). However, the focus of disability prevention was placed heavily on social and environmental modification:

> [A]lthough disability can be prevented by improving the functional capacity of the individual—the traditional aim of rehabilitation—this is not the only or perhaps even the most effective method. Disability can be prevented by changing societal attitudes that now restrict employment opportunities for persons with functional limitations, by modifying the buildings in which the people work, or by providing accessible modes of transportation (all of which are components of the ADA). (115)

The IOM's "Enabling–Disabling Process" Framework (1997)

In 1997, the IOM published a report titled *Enabling America* as a follow-up to and revision of its previous *Disability in America* report from 1991 (115,118). The 1997 report revised the earlier "Disabling Process" model to formally recognize that the focus of rehabilitative efforts is to assist the individual in reversing the disabling process through an "enabling process":

> *[R]ehabilitation* is the process by which physical, sensory, and mental capacities are restored or developed in (and for) people with disabling conditions—reversing what has been called the disabling process, and may therefore be called the *enabling process*. This is achieved not only through functional changes in the person (e.g., development of compensatory muscular strength, use of prosthetic limbs, and treatment of posttraumatic behavioral disturbances) but also through changes in the physical and social environments that surround them (e.g., reductions in architectural and attitudinal barriers). (118)

A person without disability is considered to be "fully integrated into society" and has access to social opportunities (e.g., education, employment, and parenthood) and physical space, whereas a person with a potentially disabling condition has increased needs that can manifest as a true disability if the social and physical environment are inadequate for these needs. The enabling (or rehabilitative) process attempts to counteract the disabling process by functional restoration and environmental modification.

The WHO's Functioning-Disability-Health Framework (2001)

The initial version of ICIDH promulgated by the WHO in 1980 was widely adopted around the world and was very influential in stimulating research as well as discussion of the best framework for considering disability. Beginning in 1995, ICIDH underwent an exhaustive revision process, with comments from more than 80 countries, field tests in 42 countries, and input from scientists, disability groups, and other nongovernmental organizations. The culmination of this revision process was the publication of the *International Classification of Functioning, Disability and Health* (ICF) in 2001 (123,124).

In a shift from the previous WHO formulation, ICF emphasized health and functioning, rather than disability:

> Previously, disability began where health ended; once you were disabled, you were in a separate category. We want to get away from this kind of thinking . . . . This is a radical shift. From emphasizing people's disabilities, we now focus on their level of health. ICF puts the notions of "health" and "disability" in a new light. It acknowledges that every human being can experience a decrement in health and thereby experience some disability. ICF thus "mainstreams" the experience of disability and recognizes it as a universal human experience. By shifting the focus from cause to impact it places all health conditions on an equal footing allowing them to be compared using a common metric—the ruler of health and disability. (116)

"Functioning" in the ICF framework is specifically structured around two broad components: (a) body functions and structure; and (b) activities and participation (i.e., involvement in a life situation). Further, participation can be viewed from either a performance perspective (i.e., what an individual does in the current environment) or a capacity perspective (i.e., what an individual can do in an optimized environment). The discrepancy between capacity and performance, the capacity–performance gap, suggests what could be changed in the current environment to improve performance (128).

ICF is based on a bio-psycho-social model that integrates medical and social frameworks of disability from earlier models:

> Disability is always an interaction between features of the person and features of the overall context in which

> the person lives, but some aspects of disability are almost entirely internal to the person, while another aspect is almost entirely external. In other words, both medical and social responses are appropriate to the problems associated with disability; we cannot wholly reject either kind of intervention . . . . [In] ICF disability and functioning are viewed as outcomes of interactions between health conditions (diseases, disorders and injuries) and contextual factors. Among the contextual factors are external environmental factors (e.g., social attitudes, architectural characteristics, legal and social structures, as well as climate, terrain, and so forth); and internal personal factors . . . . (116)

Health conditions (i.e., diseases, disorders, and injuries) lead to impairments (i.e., problems in body functions and structure) that may be associated with activity limitations (i.e., difficulties in executing activities), and/or participation restrictions (i.e., problems with involvement in life situations). Thus, a stroke (a health condition) can cause hemiparesis (an impairment), which is associated with impaired mobility (an activity limitation), and which may cause inability to use mass transit, find a job, and so on (participation restrictions). Under this framework, the impairments, activity limitations, and participation restrictions are different categories subsumed under the broad umbrella of "disability." This spectrum of disability is dependent on further interactions with the underlying health condition, and also with contextual factors, including environmental and personal factors. The ICF framework can also be linked to different treatment, rehabilitation, and social/environmental interventions and prevention approaches (116).

EVOLUTION OF STROKE REHABILITATION

In the late 19th and early 20th centuries, most medical investigations concerning stroke dealt with clinical phenomenology, pathology, clinical–pathologic correlation, and pathophysiology. At this time, very little was attempted as far as retraining or rehabilitation of stroke victims was concerned. Although a few scattered prophets of rehabilitation concepts can retrospectively be identified during this period, they made relatively little impact and their proposed treatments were, at best, haphazardly employed (129,130).

Some of the antecedents of rehabilitation available in the early 20th century included, for example, the tedious repetition of reading, spelling, and repeating words for aphasia; passive movement of severely paralyzed limbs or programs of exercises for less severe paralysis; various orthotic and assistive devices such as splints to prevent contractures, light braces for support, canes (Figure 1.13) (131–135), crutches (Figure 1.14) (131–135), and wheelchairs; attempts to use electrical stimulation to facilitate recovery or prevent muscle wasting; and various surgical procedures to try to limit contractures or spasticity (129,130). Even in the 1950s, as noted by Barrow and Metts (1986), the prevailing attitude was one of therapeutic nihilism born of hopelessness, compounded by a lack of resources and trained staff:

> As late as the mid '50s, the attitude of both doctors and families of patients with a completed stroke was one of hopelessness. The patients were placed in a nursing home or in a back room, usually at complete bed rest, and they were waited on and pampered as invalids. Under these conditions, the patients usually deteriorated rapidly and complications of decubitus ulcers, muscle spasms, atrophy, and infections were frequent. Other factors of importance at this time were the lack of physical therapy departments in the hospitals . . . and the unavailability of outpatient physical therapy resources. Even the rehabilitation facilities such as Warm Springs, Georgia, had little activity in the field of stroke rehabilitation. (130)

Rehabilitation of stroke victims was not systemically developed until the second half of the 20th century (129,130). In the 1970s and 1980s, the stroke rehabilitation team approach began to develop and spread; stroke units, sometimes employing a seamless transition between acute care and rehabilitation, were developed in larger hospitals in urban areas; and outpatient rehabilitation resources were developed including services provided by health departments, visiting nurse associations, free-standing day care centers, and hospital-associated and independent physical therapy practices (130). The 1970s and 1980s also saw the beginning of an explosion in stroke rehabilitation research, with an exponential escalation in the use of randomized trials of stroke rehabilitation therapies, particularly since the 1990s (136). Both the total number of journal articles and the number of journal articles reporting the results of randomized clinical trials have grown exponentially, although the rate of growth for randomized trials of stroke rehabilitation has been greater since the 1970s (DJ Lanska, unpublished analyses, 2007). Although spontaneous recovery accounts for most of the improvement in functional ability following stroke (137), a growing body of evidence since the 1990s supports a modest and marginal, but clinically important, benefit of stroke rehabilitation, generally for patients with, at most, moderate disability (138–143).

Organized Inpatient Multidisciplinary Stroke Rehabilitation

Since the 1970s, and particularly since the 1990s, it has become clear that organized inpatient multidisciplinary rehabilitation in the postacute period provides clinically important benefits (138–143). Most data supporting the clinical benefits of inpatient stroke rehabilitation are based on studies of comprehensive stroke units (that provide acute stroke care and rehabilitation) or rehabilitation stroke units (dedicated to rehabilitative care of postacute patients with stroke), rather than the more common mixed rehabilitation

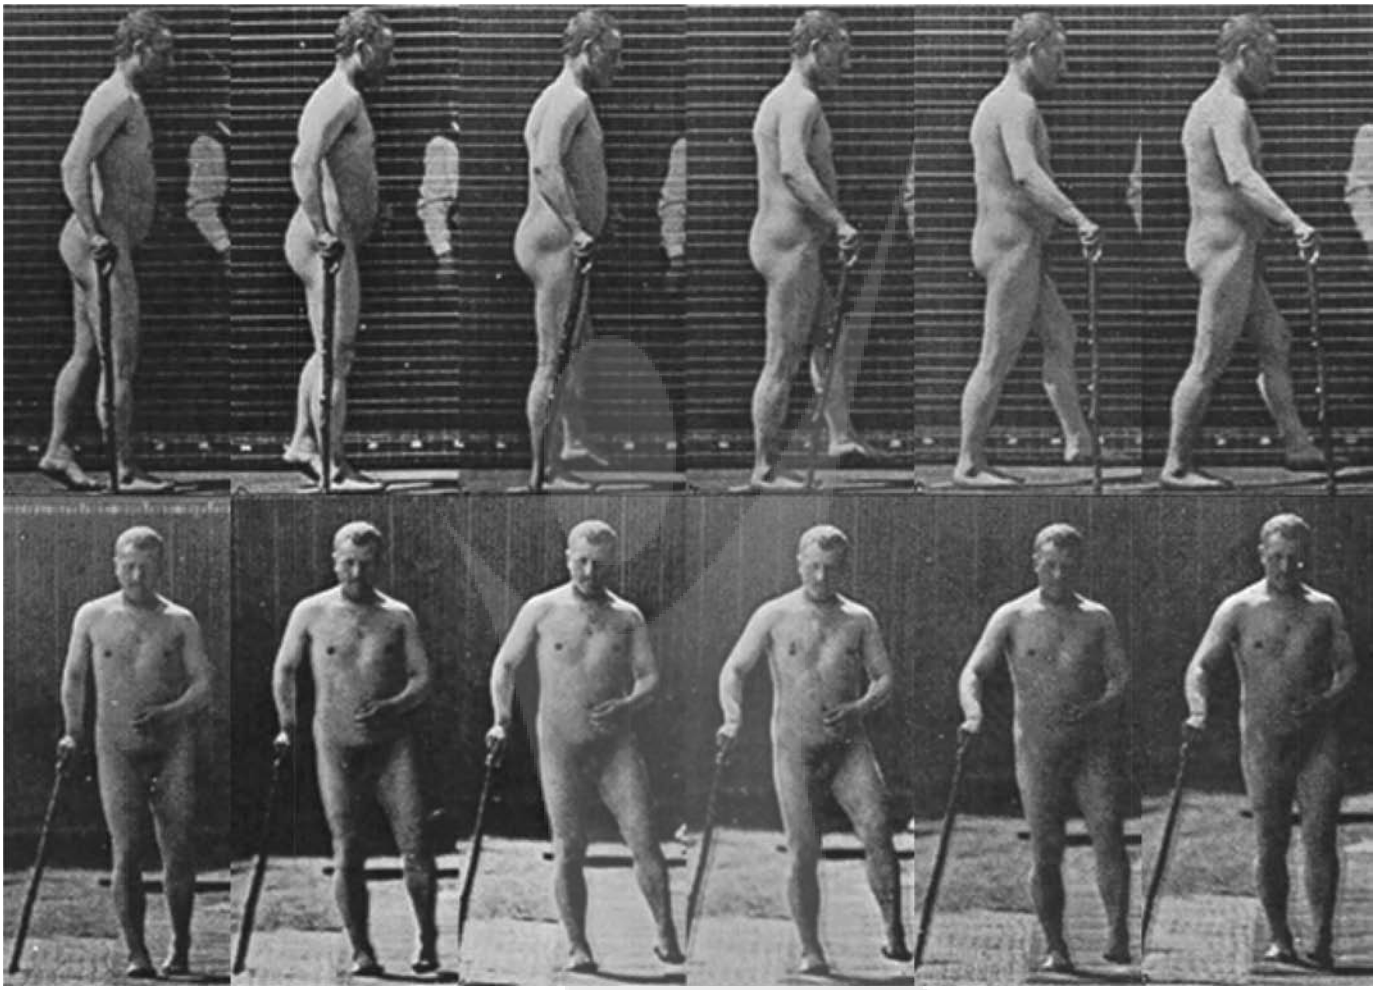

FIGURE 1.13 In the late 1870s and 1880s, prior to the development of movie cameras or projectors, American photographer Eadweard Muybridge (1830–1904) photographed sequential images of people and animals in motion, using arrays of sequentially triggered single-image cameras. In 1885, Philadelphia neurologist Francis Dercum (1856–1931) collaborated with Muybridge at the University of Pennsylvania. This figure shows sequential images of lateral and frontal views from a portion of Muybridge's "Plate 552. Spastic, walking with cane" (*Source*: From Ref. 133). This sequence shows a man with a dense spastic left hemiparesis with the arm held in a flexed posture. As noted by Dercum, "the paralyzed leg is quite stiff, little or no flexion taking place at the knee . . . ." Circumduction of the left leg (seen especially on the frontal views) is quite prominent, with the leg first swinging outward during forward motion and then returning toward the midline in an arc. Notice as well, the equinovarus deformity, or as Dercum commented, "the exaggeration of the normal tendency of bringing the outer edge of the foot to the ground in advance of the sole" (*Source*: From Refs. 131, 132, and 133).

units (that provide stroke rehabilitation in a mixed rehabilitation setting) (142). Stroke patients who receive inpatient rehabilitation provided by a coordinated multidisciplinary team are more likely to recover the ability to perform activities of daily living, more likely to return to the community, and less likely to die—results that are fairly robust in different meta-analyses and across recent controlled trials (140,144–151). A Danish population-based study comparing two communities—one where care was provided in a dedicated comprehensive stroke unit with both acute care and rehabilitation care, and the other in which care was provided on general medical and neurologic wards—found that stroke unit care reduced the length of hospital stay by 30%, reduced the risk of discharge to nursing home by 40%, and reduced the relative risk of death by 50% (140). In a systematic review of 9 trials recruiting 1,437 patients, Langhorne and Duncan found that for every 100 patients who received organized inpatient multidisciplinary rehabilitation, 5 more returned home in an independent state compared to those who do not receive such care (141). Functional, independence, and survival benefits to those who underwent early multidisciplinary stroke rehabilitation after stroke are sustained even 5 to 10 years after stroke (152–156). Patients with moderate or severe strokes appear to benefit the most (150).

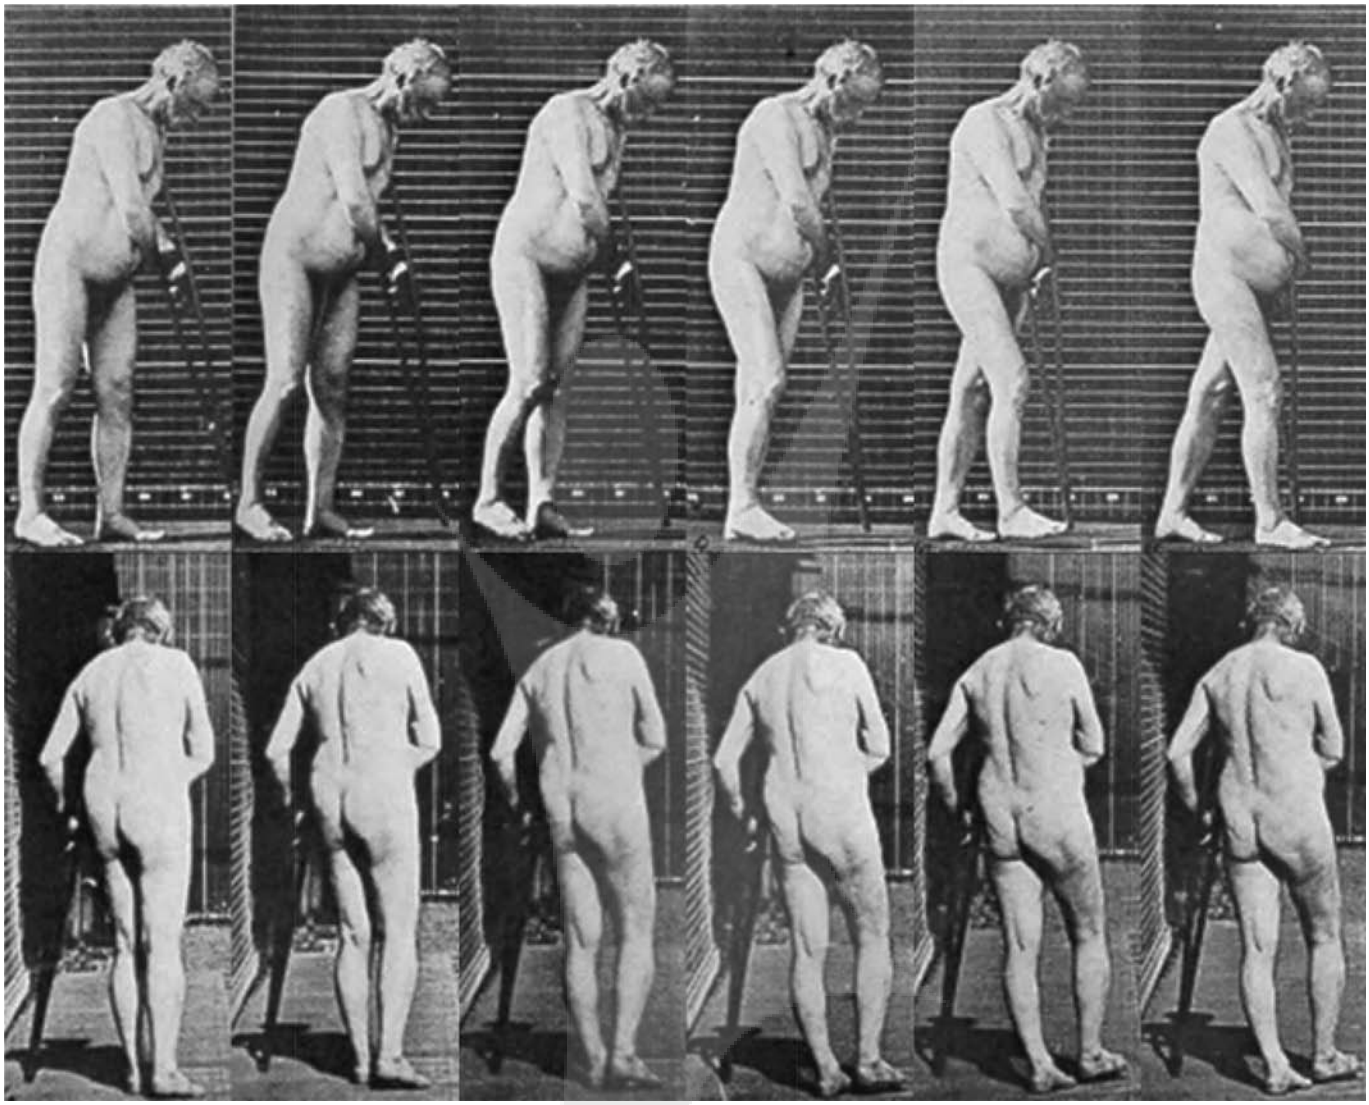

FIGURE 1.14 Sequential images of lateral and posterior views from a portion of Muybridge's "Plate 547. Spastic, walking with crutch" taken in 1885 (*Source*: From Ref. 134). This shows an elderly man with a dense spastic right hemiparesis with the arm held in a flexed posture while using a crutch to walk. As noted by Dercum, "the paralyzed leg is quite stiff, little or no flexion taking place at the knee . . . [The foot is] raised from the ground by the enormous swaying of the trunk toward the sound side, to which additional support is given to receive the sway by means of the crutch." See the legend for Figure 1.4 for further details (*Source*: From Refs. 131, 132, and 133).

Even where evidence supports a clinical benefit of stroke rehabilitation, it has generally been unclear which specific factors, including which therapies or combinations of therapies, among the entire package of individualized treatments for a given patient are most important for providing benefit (142,157–159). Although data supporting the value of individual team members in the multidisciplinary team are limited, most authorities and clinical care guidelines have advocated a broad team composition, including physicians, nurses, physical therapists, occupational therapists, speech therapists, and social workers (140). Although available studies are limited, the intensity of rehabilitation services is a modest predictor of recovery among stroke patients (151,160–164), as is, particularly, an early start to intensive treatment (158,159). It has also been unclear to what extent findings of randomized clinical trials could be generalized to the routine clinical setting: the limited available data suggest that the routine clinical rehabilitation setting can reproduce the benefits of stroke rehabilitation units in controlled trials and meta-analyses, but the magnitude of benefit is smaller outside of the formalized experimental setting (165). Inpatient rehabilitation is also expensive, and the limited available cost–benefit analyses have not strongly supported the cost-effectiveness of inpatient stroke rehabilitation overall (166–168), making it imperative to carefully select patients who will benefit most from such intensive care (169), and also to identify the least expensive care settings that will provide maximum clinical benefit to individual patients (170).

Clinical Pathways

Integrated care pathways have not been shown to improve the outcome of inpatient stroke rehabilitation (171–178). In fact, care pathways for rehabilitation programs have most often resulted simply in decreased patient satisfaction (171–174,178), and some studies have actually reported slower recovery and lower quality of life among patients receiving rehabilitation as part of an integrated care pathway as opposed to conventional multidisciplinary rehabilitative care (171,175). As noted by Teasell, "This apparent paradox may signify the importance of using evidence or guidelines to assist rehabilitation clinicians in individualizing the rehab of stroke patients as opposed to a 'one size fits all' approach" (178). Furthermore, despite potential benefits, many clinical pathway programs for acute or rehabilitation care of stroke fail because of inadequate planning and implementation (173,174). Effective implementation of such programs requires strong administrative and medical staff leadership, active participation of all clinical disciplines involved in the rehabilitative care of patients on the pathway, provision of regular feedback to clinicians, sufficient resources, improved (and often more detailed) documentation, incorporation of the entire rehabilitation period of care into the pathways, integration with ongoing quality and utilization management programs, and periodic evaluation and modification (173,174).

Specific Therapies

Based on expert opinion and limited controlled trial data, physical therapy is modestly beneficial for stroke patients (159,164,179,180). However, there continues to be considerable variation in the beliefs (181) and treatment approaches (182,183) of physical therapists concerning the treatment of stroke patients, in part a function of the treatment approach in vogue when the physical therapists were trained (184). Particularly since the 1950s, several different physical therapy approaches have been developed and applied in the treatment of stroke patients (139,180–194). Some physical therapists advocate and apply Bobath's "neuro-developmental" approach developed by physiotherapist Berta Bobath (c. 1908–c. 1991) and her husband, psychiatrist and neurophysiologist Karel Bobath, MD (c. 1906–c. 1991) (187), both Jewish refugees from Nazi Germany to England; the "motor re-learning programme" of Janet H. Carr, MA, EdD, and Roberta B. Sheperd, MA, EdD (188); Swedish physiotherapist Signe Brunnström's approach utilizing abnormal synergies (186); and various others. Controlled trial data are as yet inconsistent, and no clearly better approach has been identified from among the available approaches for the physical therapy of stroke patients (180,183). Progressive resistance exercises several times a week can help improve strength and functional abilities in patients with adequate motor control (138,195). The intensity of therapy initiated early seems to be important in maximizing the degree of functional improvement (161–164).

Based on the results of systematic reviews, comprehensive occupational therapy is modestly beneficial in improving activities of daily living and social participation among stroke patients (196,197), although there is limited or insufficient evidence supporting many specific occupational therapy interventions, including provision of splints for decreasing muscle tone (196,198). Even when provided in the community, occupational therapy can improve basic activities of daily living, as well as domestic and leisure skills, as indicated by systematic reviews (196,197). Different task-oriented practice strategies can be helpful, especially if intensive training in specific skills is provided (138,161–163,196). Constraint-induced-movement therapy—based on the idea that "learned nonuse" of a weak arm develops because of the greater effort required to use it—seeks to encourage the use of the weak arm and promote helpful cerebral plasticity (138,199); this approach can be helpful in increasing the amount and efficiency of the use of the weak arm in the relatively small subset of patients with fairly good motor control to begin with (138,200–202).

Available data from randomized controlled trials concerning the efficacy of speech therapy in stroke rehabilitation are limited and not entirely consistent (203), with some trials supporting a modest benefit within the first 3 to 6 months after stroke (160,204,205), and others finding lesser or no significant benefit for most patients (206–208). A greater intensity of therapy in the first several months poststroke seems to be an important factor in the degree of improvement (160,203,209).

Early Supported Discharge

In most countries, into the 1990s, stroke patients were treated initially in the hospital, followed by a variable period of inpatient rehabilitation, but rehabilitation often stopped after discharge (210). In some countries, early supported discharge (ESD) approaches have been developed since the 1990s that shorten the period of acute hospital stay and provide rehabilitation services beginning in the hospital and continuing for the first few weeks at home. Proponents have claimed that this approach is not only less costly, but can also improve care by providing "seamless service" spanning inpatient and home care environments; however, until recently there were limited data to evaluate such claims (210). Single-blind randomized controlled trials have been reported from the United Kingdom, Scandinavia, Australia, and Canada (211–224). Although some studies of ESD have not identified any significant benefits of this approach (213), others have reported similar efficacy compared with traditional inpatient rehabilitation along with significant cost savings (212,224); reductions in total hospitalization (of approximately 50%) (217,218,220); reduction in use of inpatient rehabilitation beds (211); improved patient satisfaction (214,217,220); less caregiver stress (221); and, in some cases, improved performance of activities of daily living (215,218,219,222), and longer sustained noninstitutional care (215). In one well-designed study

from Norway, stroke patients who received ESD rehabilitation services spent less time in hospital and were also more likely to be independent and to be living at home after one year (215). As suggested by Langhorne, presumably "the ESD service has improved the patient's ability to regain normal activities despite residual impairment. In particular, the patient's own home is probably the best place for him or her to relearn the skills needed to function in that environment" (210). A home environment for rehabilitation may also facilitate patients with moderate neurologic impairments taking greater responsibility and exercising a greater influence over their own rehabilitation (223). A systematic review of the economic costs of different settings of rehabilitation care found "'moderate' evidence that ESD services provide care at modestly lower total costs than usual care for stroke patients with mild or moderate disability" (166).

Outpatient Rehabilitation

The role of outpatient rehabilitation services (i.e., therapy-based rehabilitation services targeted at stroke patients living at home) has only recently been studied in any detail, and the results remain less certain than in the case of traditional inpatient multidisciplinary stroke rehabilitation (225–229). This is complicated by differences in the types of community-based rehabilitation provided, the setting in which such care is provided (day hospital versus the home), and the clinical circumstances for which this approach is used instead of traditional inpatient rehabilitation (228,229). Several studies have evaluated the use of day hospital rehabilitation care with inconsistent results compared with either inpatient multidisciplinary care or home care (230–232). Costs are generally higher for day hospital rehabilitation than for home care (230,232), but not universally so (231). Functional outcomes for day hospital rehabilitation are generally similar to rehabilitation provided in other settings (230,231), although one study reported better functional outcomes with day hospital rehabilitation than with home care (232). Nevertheless, preliminary results suggest that some therapy-based rehabilitation services provided in the home can result in a greater ability to perform activities of daily living and reduce the risk of deterioration in ability compared with conventional care (i.e., normal practice or no routine intervention) (225–229). Other studies have indicated no benefit for some outpatient services that were not primarily therapy-based, including the use of an outreach nursing support program (233,234). Further studies are needed to define the most appropriate level of service delivery, the most effective services and interventions, and their cost-effectiveness compared with other approaches (225). At present, there is "insufficient" evidence concerning the economic costs of community-based rehabilitation (166).

Caregiver Training

Family involvement in support of the poststroke patient has long been recognized as a strong independent predictor of discharge to home as opposed to an institution (169). Because the degree of family involvement can sometimes be influenced by the rehabilitation team, family and caregiver training has been a major target of therapeutic intervention, and is being increasingly recognized as a predictor of functional outcome as well (169). Caregiver training during the rehabilitation of stroke patients can reduce the cost of care and improve the overall quality of life among caregivers, even as long as a year poststroke (235,236). Problem-solving training, including an in-home visit and subsequent telephone contacts by a trained nurse, may also be useful for family caregivers of stroke survivors even after the latter's discharge from rehabilitation (237). Caregiver training and education may help caregivers be better prepared to deal with issues, facilitate development of caregiver problem-solving skills, lessen caregiver stress and depression, minimize secondary complications among the patients, and facilitate patient motor tasks that promote functional improvements and lessen the risk of further functional declines (e.g., safe swallowing and walking for exercise) (138,237).

Gaps in Theoretical Foundations and Practical Implementation Remain

The development of stroke rehabilitation concepts is still limited, with the recognition in the field that many of the therapeutic approaches currently employed have, at best, limited benefit in a select subgroup of patients; that much of the theoretical justification for different rehabilitation models and approaches remains speculative; and that there is no overall foundation for an accepted "theory of rehabilitation" that could help to prevent fragmentation and division, provide coherence, focus research and development in this area, and facilitate competition for limited research funding (138,142,238,239). Moreover, because rehabilitation interventions are typically multidisciplinary, multifaceted, and customized to the individual patient's needs and goals, they are, in practice, difficult to standardize, and therefore difficult to measure and compare (138,142,238). Available treatment studies are further complicated by the heterogeneity of impairments and disabilities of the patients studied, poor descriptions of the specific treatments administered, inadequate controls, lack of blinding, small sample sizes, and insensitive outcome measures (138).

Current expert consensus has strongly supported the importance of integrating rehabilitation into systems of care to ensure that all patients who could potentially benefit from appropriate stroke care and rehabilitation are provided with the appropriate treatment in a time frame that will maximize recovery and minimize disability (151). According to the American Stroke Association's Task Force on the Development of Stroke Systems:

> Stroke rehabilitation involves a combined and coordinated use of medical, social, educational, and vocational measures for retraining individuals to reach their maximal physical, psychological, social, vocational, and a

> vocational potential. Specifically, stroke rehabilitation programs are provided to optimize neurologic recovery, teach compensatory strategies for residual deficits, teach activities of daily living (ADLs) and skills required for community living, and provide psychosocial and medical interventions to manage depression. The team provides patient and family education about the medical management of post-stroke complications and secondary stroke prevention . . . . Practice guidelines for rehabilitation are well established in this area, although patients often do not receive a level of care that is consistent with these guidelines . . . . The intensity of rehabilitation services often is a critical determinant in the recovery of stroke patients. The use of coordinated, multidisciplinary stroke rehabilitation teams has been shown to diminish mortality rates for stroke patients. In addition, stroke patients who receive care in an inpatient rehabilitation facility are more likely to return to the community and to recover their ability to perform ADLs . . . . Building stroke systems throughout the United States is the critical next step in improving patient outcomes in the prevention, treatment, and rehabilitation of stroke. The current fragmented approach to stroke care in most regions of the United States provides inadequate linkages and coordination among the fundamental components of stroke care. (151)

Practice guidelines are now available for stroke rehabilitation (240–242), but in many cases patients do not receive care consistent with the guidelines (142,151,243,244). Further, there are sociodemographic inequalities in the use of rehabilitation services, suggesting inappropriate underuse among certain populations (245).

Even when patients receive inpatient stroke rehabilitation, they spend only a small amount of their inpatient stay participating in potentially rehabilitative activities, and this low intensity of therapy is less likely to produce beneficial outcomes (138,142,227,246). In an observational behavioral mapping study of five stroke units, patients had therapist contact during only 5% of the day, participated in minimal or moderate therapeutic activity for less than 13% of the therapeutic day (8 a.m. to 5 p.m.), and were resting in bed 53% of the time and alone 60% of the time (247). Poor participation in therapeutic activities is common during inpatient rehabilitation, and is associated with longer lengths of inpatient stay and lower degrees of improvement in functional performance (248). In addition, for financial or policy reasons, formal therapy is typically stopped when there are no evident qualitative gains in function after several weeks of treatment, even though, as Dobkin notes: "A plateau in recovery . . . does not necessarily imply a diminished capacity for further gains in physical speed or precision or in learning a new task" (138).

Furthermore, despite modern treatment and multidisciplinary rehabilitation, perhaps half of the patients with stroke are ultimately discharged home with serious, persistent neurologic impairments, functional limitations, and, often, disability resulting from inadequate environmental supports (249). Stroke survivors (whether residing at home or in institutional care environments) are prone to multiple secondary conditions that further erode health, including social isolation, depression, physical inactivity, painful joint contractures, deep venous thromboses and pulmonary emboli, decubitus ulcers, incontinence, aspiration pneumonia, inadequate nutrition, falls, hip fractures, and seizures. Such patients are often frail and susceptible to aggravation of existing disease or development of new illness, with resulting functional decline, high resource utilization, high rates of rehospitalization, significant added morbidity, and a high risk of death within the first year after stroke onset. Indeed, in the United States, approximately one-fifth of stroke patients die in the first month after stroke, a quarter within 2 months, and a third within 6 months (250). Patients and caregivers can benefit from a close liaison between inpatient and community care programs, and also from continuing professional support and counseling after discharge following a stroke (249).

Further studies are needed to define the most appropriate level of service delivery for stroke rehabilitation, the most effective services and interventions among the "complex packages of care" that comprise current rehabilitation programs, and the most cost-effective stroke rehabilitation service among the different types available (142,225).

Stroke Epidemiology: Global Burden of First-Ever Strokes

Aaron Anderson, Kunio Owada, Ali Saad, Valery L. Feigin, Rita Krishnamurthi, and Preeti Raghavan

Stroke is the second most common cause of death worldwide and a frequent cause of adult disability in developed countries (1,2). Stroke burden on families and society is projected to rise from approximately 38 million disability-adjusted life years (DALYs) lost globally in 1990 to 61 million DALYs in 2020 (3) because of population aging. Stroke also has a large physical, psychological, and financial impact on patients/families, the health care system, and society (4,5). Lifetime costs per stroke patient range from US$59,800 to US$230,000 (5). The majority (about 75%) of cases of stroke occur in people over the age of 65 years (6,7), and about one-third of patients die of stroke within a year of onset (8,9). Over half of the survivors have long-term therapy needs and remain dependent on others for everyday activities, often with significant adverse effects on caregivers (10). Many factors increase the risk of stroke, and these are generally divided into two categories: modifiable and nonmodifiable risk factors. Age, gender, and ethnicity are nonmodifiable risk factors for stroke. Modifiable or potentially modifiable risk factors include a number of physiological and environmental factors, among them hypertension, elevated total cholesterol, smoking, physical inactivity, alcohol consumption, and atrial fibrillation (11).

Stroke mortality data are available from more than 24 countries (12,13) showing, in general, declining rates for several decades. In some countries, stroke mortality has declined since the early 1950s, but the rate of this decline has recently slowed (14,15). Although large national or international stroke mortality data may be used for determining overall burden of fatal strokes and trends in stroke mortality, stroke mortality data are often not accurate (diagnosis classification bias) and have limited value for health care planning and organization. The role of changes in incidence and improved survival to the downward trend in stroke mortality are not adequately quantified, chiefly because of the difficulties in measuring stroke incidence accurately (16,17). However, the results from the World Health Organization (WHO) Monitoring Trends and Determinants in Cardiovascular Disease (MONICA) project suggested that both declining and increasing stroke mortality were principally attributable to changes in case fatality rather than changes in incidence (18).

IMPORTANCE OF POPULATION-BASED STUDIES

Epidemiological studies form the basis of much of the medical research and current knowledge of stroke to inform health professionals about best strategies for stroke care organization, prevention, and management. The gaps in knowledge in stroke prevention and management are continually being filled by randomized controlled trials and case–control and cohort studies. Some of the most informative studies on stroke burden and optimal health care organization have arisen from population-based stroke incidence and outcome studies. It is important that stroke is seen and studied in a population context, as a large proportion of the burden of care for stroke is borne outside the hospital (11–13).

Further, changes in referral patterns can distort longitudinal trends derived from hospitalized cases. Assessing the need for prevention strategies and services is best achieved via population-based stroke registries to determine incidence and outcome (13).

Data on population trends in stroke incidence reflect the success/failure of prevention strategies, whereas trends in case fatality and outcome reflect changes in stroke management and mortality rates. Both are needed to plan stroke services, given high health care costs and limited resources. Accurate and representative population-based data are also crucial to: (a) determining the true incidence, causes, and outcome of stroke; (b) implementing evidence-based health care planning across the care spectrum; (c) evaluating the need for and impact of preventative/management strategies; (d) addressing persistent uncertainty about what key factors (socioeconomic and health service) impact stroke recovery; (e) examining the natural course of recovery, in particular for cognitive and behavioral outcomes; (f) providing information on access to and satisfaction with stroke services; and (g) identifying

service gaps/unmet needs for ensuring evidence-based policy, resource allocation, prevention planning, management services, and evaluation of service performance.

Assessing the need for prevention strategies and services is most sensitively achieved with the use of population-based registers to determine the incidence and outcome of stroke. However, studying stroke in a population-based fashion is particularly challenging (17), because such epidemiological studies are relatively rare compared with studies using mortality data, hospital-based stroke registers, or incidence studies in younger age groups only.

GLOBAL STROKE EPIDEMIOLOGY STUDIES

Investigation of stroke burden by its major pathological types, and study of their practical trends in different regions of the world, are important for targeted region-specific health care planning in stroke (e.g., estimation of resources needed to care for patients with stroke by type), and can provide information on priorities for type-specific prevention strategies. These data are also important for understanding the health consequences and patterns of epidemiological transitions reported worldwide. Findings from systematic reviews suggest that low-income and middle-income countries have a greater proportion of hemorrhagic stroke than do high-income countries (19), that geographical variation is high in the incidence of major pathological types of stroke (19), and that no substantial changes have taken place in the incidence of hemorrhagic stroke in the past three decades (20,21). However, no detailed, systematic, and comprehensive estimates have been made of the global and regional incidence, case-fatality, DALYs lost, and secular trends of incidence of ischemic or hemorrhagic stroke, especially for low-income and middle-income countries (22–24). This chapter provides a summary of the estimates from the Global Burden of Diseases, Injuries, and Risk Factors Study (GBD 2010) for incidence, mortality, mortality-to-incidence ratio, and DALYs lost in ischemic or hemorrhagic stroke in all 21 regions of the world (25) in 1990, 2005, and 2010.

METHODOLOGY OF DATA COMPILATION

Systematic literature review was conducted for data collection. The search included Medline, Embase, LILACS, Scopus, PubMed, Science Direct, Global Health Database, the WHO library, and WHO regional database between 1990 and 2010 to identify studies published between 1990 and 2010. The databases were searched with various key or title words: "stroke," "isch(a)emic stroke," "intracerebral," "intraparenchymal," "subarachnoid," "h(a)emorrhage," and title or key-words "population-based," "community-based," "community," "epidemiology," "epidemiological," "incidence," "attack rates," "survey," "surveillance," "mortality," "morbidity," "fatality," "case-fatality," or "trends." Pathological types of stroke were assessed only for studies that used head CT or MRI within the first two weeks of stroke onset, or for those in which brain autopsy findings for confirmation of type were available for at least 70% of stroke cases. Cases of stroke with no neuroimaging or autopsy verification of pathological types were classified as strokes of undetermined pathological type. Pathological types of stroke were categorized into two groups: ischemic strokes and hemorrhagic strokes (intracerebral hemorrhage and subarachnoid hemorrhage combined). Only first-ever stroke events were assessed.

CALCULATION OF INCIDENCE, MORTALITY, AND DALYS LOST

Statistical analysis strategies are described fully in *The Lancet* (26,27). Briefly, the GBD 2010 analytical technique (DisMod-MR) was applied to calculate regional and country-specific estimates of incidence and mortality per 100,000 person-years for ischemic and hemorrhagic stroke, and of DALYs lost per 100,000 people, by age group (<20 years, 20–64 years, 65–74 years, ≥75 years, total) and level of country income (high, low, and middle) for 1990, 2005, and 2010.

Disease Modeling

For modeling of mortality of ischemic and hemorrhagic stroke, a set of relevant covariates was selected and a plausible direction of effect (increase or decrease in incidence, mortality, and DALYs lost) was assumed based on existing literature. For a full description of methods, see the study by Bennet (26). The mortality-to-incidence ratio for each region and country serves as an indicator of the success or failure of stroke management strategies in a particular region (ratio numbers were based on the total number of incident cases and deaths). Full description of results can be found in *The Lancet* (26,27). The findings included 119 studies (58 from high-income countries and 61 from low-income and middle-income countries) in the analysis.

GLOBAL BURDEN OF ISCHEMIC AND HEMORRHAGIC STROKE

Overall, an estimated 11,569,538 incidents of ischemic stroke (63% in low-income and middle-income countries) and 5,324,997 incidents of hemorrhagic stroke (80% in low-income and middle-income countries) took place worldwide in 2010. A total of 2,835,419 individuals died from ischemic stroke (57% in low-income and middle-income countries) and 3,038,763 died from hemorrhagic stroke (84% in low-income and middle-income countries). A total of 39,389,408 DALYs were lost because of ischemic stroke (64% in low-income and middle-income countries) and 62,842,896 because of hemorrhagic stroke (86% in low-income and middle-income countries). The age-standardized incidence per 100,000 person-years of ischemic stroke ranged from 51.88 in Qatar to 433.97 in Lithuania, and that of hemorrhagic stroke ranged from 14.55 in Qatar to 159.81 in China. Age-standardized mortality rates per 100,000 person-years for ischemic stroke ranged from 9.17 in Qatar to 137.70 in

Russia, and that of hemorrhagic stroke ranged from 9.64 in the United States (USA) to 210.56 in Mongolia. DALYs lost per 100,000 people because of ischemic stroke ranged from 163.89 in Israel to 2032.11 in Afghanistan, and DALYs lost to hemorrhagic stroke ranged from 178.20 in Switzerland to 4118.90 in Mongolia. The mean age of people with incident and fatal stroke has increased worldwide, with the largest increase noted in high-income countries.

In high-income countries, the incidence of ischemic stroke has been significantly reduced by 13% (95% CI 6–18), mortality by 37% (19–39), DALYs by 34% (16–36), and mortality-to-incidence ratios by 21% over the past two decades. Reductions in hemorrhagic stroke were 19% (1%–15%) for incidence, 38% (32%–43%) for mortality, 39% (32%–44%) for DALYs, and 27% (19%–35%) for mortality-to-incidence ratio. Worldwide, in the younger age group, the incidence of ischemic stroke did not change, but there was a significant increase in the incidence of hemorrhagic stroke, from 54.07 (48.56–60.22) to 64.07 (56.45–73.33; $P = 0.028$). In the older age group (≥75 years), no significant change was noted in the incidence of ischemic stroke (from 2614.89/100,000 [2426.49–2809.55] to 2472.93/100,000 [2279.15–2687.39], $P = .176$), whereas a significant reduction was shown in the incidence of hemorrhagic stroke (from 558.61/100,000 [503.36–624.07] to 640.06/100,000 [569.10–724.72], $P = .046$).

In low-income and middle-income countries, the incidence of hemorrhagic stroke increased significantly, by 22% (95% CI 5–30) over the past two decades, with a 19% (5–30) increase in people younger than 75 years. A nonsignificant increase of 6% (18%, –7 to 32) was shown in the incidence of ischemic stroke, but the incidence of both ischemic and hemorrhagic stroke increased significantly in people aged 20 to 64 years. Additionally, nonsignificant reductions in mortality rates (14%, 95% CI –2% to 32%), DALYs lost (16%, 95% CI 1%–35%), and mortality-to-incidence ratio (16%, 95% CI –5% to 37%) were observed. Similarly for hemorrhagic stroke, nonsignificant reductions in mortality rates (23%, 95% CI –3% to 36%), DALYs lost (25%, 95% CI 7%–38%), and mortality-to-incidence ratio (36%, 95% CI 16%–49%) were also observed.

By GBD region, the largest increases in incidence of ischemic stroke were in Eastern Europe, Central and East Asia, North and Sub-Saharan Africa, and the Middle East (Figure 2.1), with the largest increase (22%) noted in the Democratic Republic of Congo. Notably, some of the largest decreases in incidence of ischemic stroke between 1990 and 2010 were also in these regions (South Korea 44%, Chile 41%, Brunei 41%; Figure 2.1). Up to 2010, the highest rates of ischemic stroke were in Eastern Europe (particularly Russia: 238–416/100,000) and Central and East Asia, North Africa, and the Middle East (178–238/100,000).

The largest increases in the incidence of hemorrhagic stroke by GBD region were in Eastern and Central Europe, North and Sub-Saharan Africa, and the Middle East. In contrast, the incidence of hemorrhage stroke decreased significantly in high-income regions of North America, Western Europe, and tropical and Southern Latin America (Figure 2.2). In 2010, the highest incidences of hemorrhagic stroke were in Central and East Asia (101–158/100,000) and East and Southern Sub-Saharan Africa (73–101/100,000), whereas the lowest rates were in high-income regions in North America, Central and Andean Latin America, Western Europe, and Oceania (Australasia; 25–40/100,000). Between 1990 and 2010, mortality-to-incidence ratios for ischemic stroke reduced noticeably in Western Europe, Australasia, and Central and Andean Latin America, but increased in North Africa, the Middle East, and Southeast Asia (Figure 2.3). For hemorrhagic stroke, decreases in mortality-to-incidence ratios occurred in Northern Africa, the Middle East, Central, East, and Southern Sub-Saharan Africa; and East and Southeast Asia, whereas moderate increases were evident in Central Latin America and high-income Asia-Pacific regions (Figure 2.4).

In 2010, the lowest mortality-to-incidence ratios for ischemic stroke were in high-income North America and East Asia (0.17–0.19), and for hemorrhagic stroke in high-income North America (0.25). The highest mortality-to-incidence ratios for ischemic stroke were in Central Europe and the Caribbean (0.34–0.38), and for hemorrhagic stroke in Oceania (0.94–1.27). Age-specific mortality rates, mortality-to-incidence ratios, and DALYs for both stroke types were greater overall in low-income to middle-income countries than in high-income countries, but significant differences between higher-income and lower-income countries were apparent only for hemorrhagic stroke incidence, mortality, DALYs in people older than 40 years, and mortality-to-incidence ratios across all age groups

IMPLICATIONS OF THE GLOBAL BURDEN OF ISCHEMIC AND HEMORRHAGIC STROKE

The burden of both ischemic and hemorrhagic stroke has increased significantly between 1990 and 2010 in terms of an increased absolute number of people with incident stroke, number of deaths, and number of DALYs lost. Although the absolute number of incident ischemic stroke is twice that of hemorrhagic stroke, the overall global burden of hemorrhagic stroke (deaths and DALYs) is higher. Despite the fact that ischemia is the more common etiology of stroke in high-income countries, most of the stroke burden worldwide is because of hemorrhage.

Second, the bulk of stroke burden in terms of incident events, deaths, and DALYs lost is borne by low-income to middle-income countries. These countries are disproportionately affected by the burden of hemorrhagic stroke compared with high-income countries. In contrast to high-income countries, where the overall incidence, mortality, DALYs, and mortality-to-incidence ratio of both ischemic and hemorrhagic stroke has declined in the past two decades in both younger (<75 years) and older (≥75 years) age groups, low-income and middle-income countries have experienced a significant increase in the incidence of both stroke types. The average age at which people had ischemic and hemorrhagic strokes is three to five years younger in low-income and middle-income countries than in high-income countries.

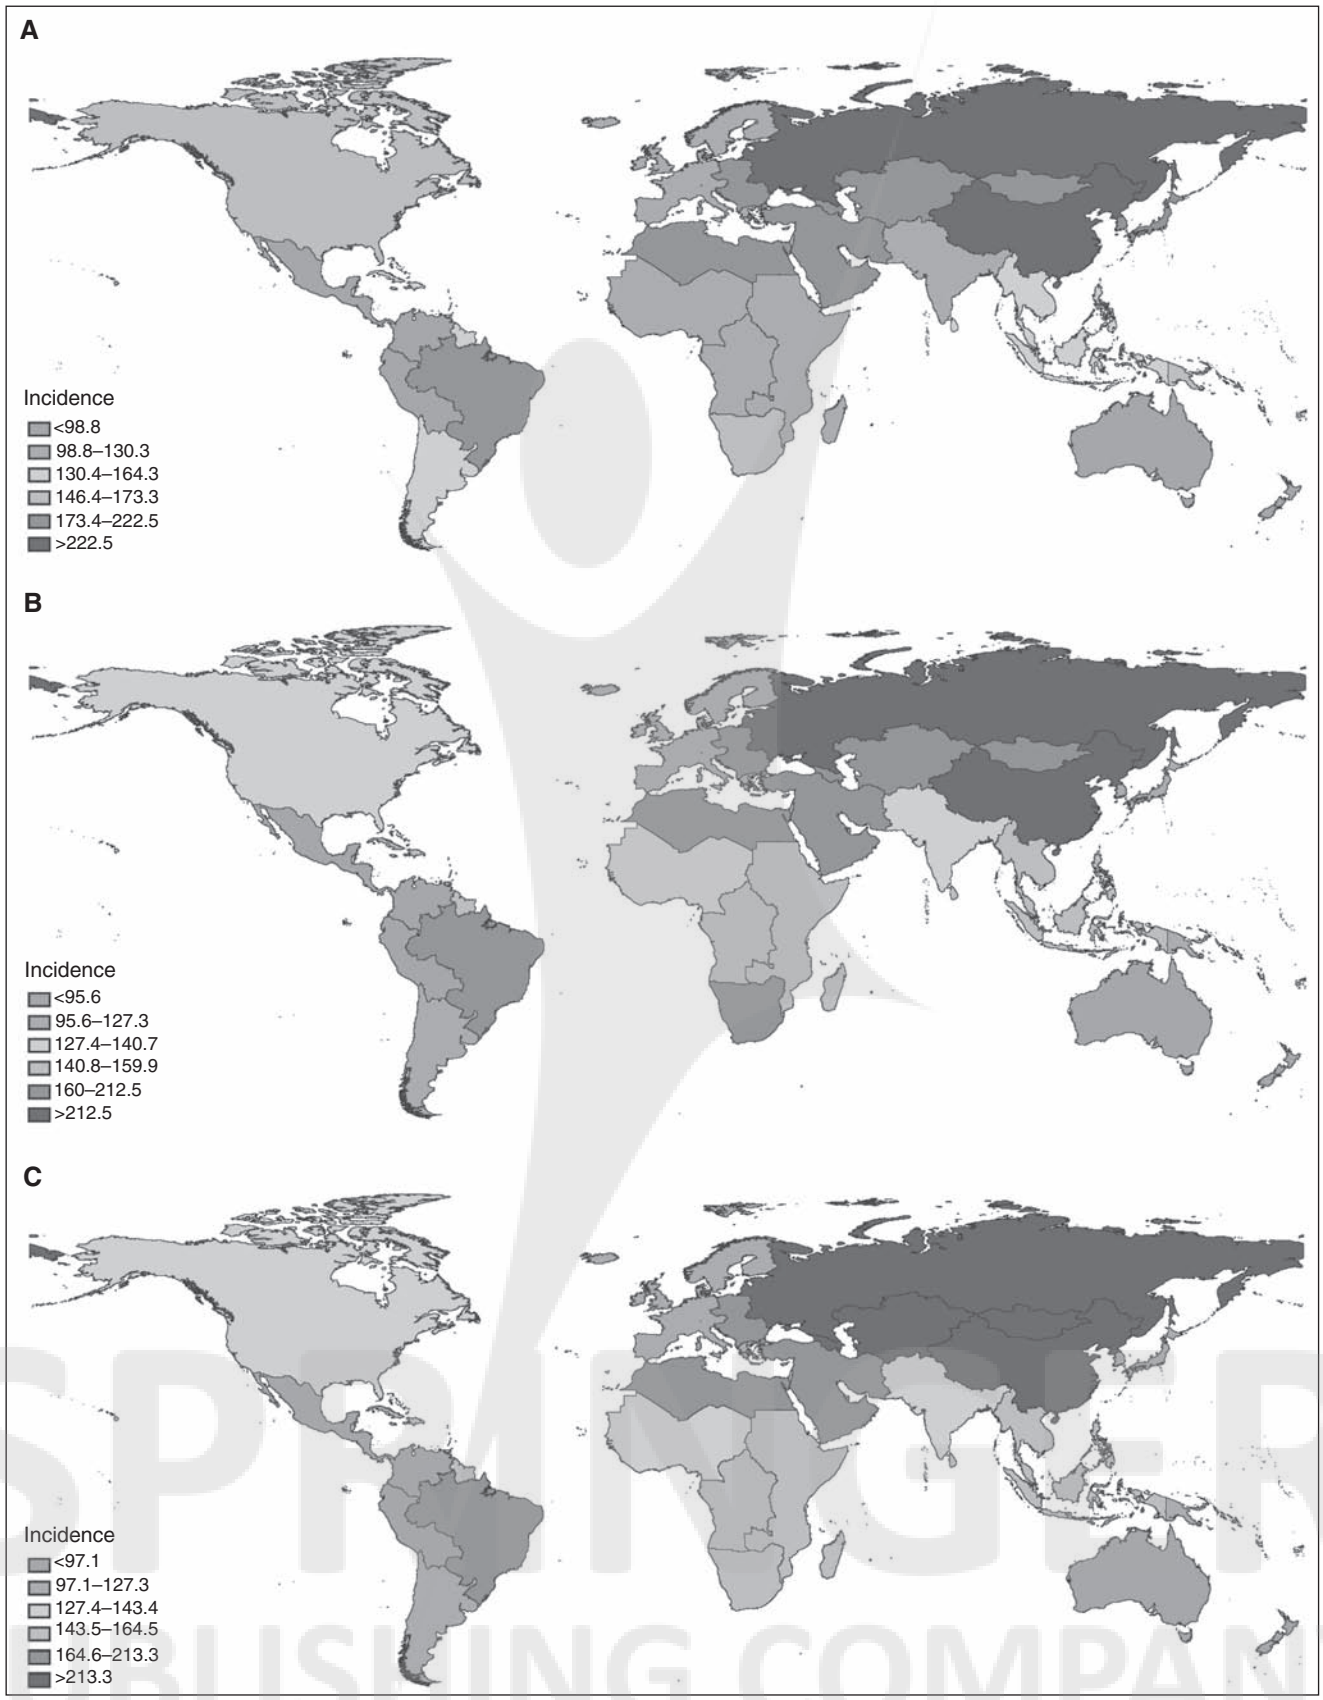

FIGURE 2.1 Age-standardized incidence of ischemic stroke per 100,000 person-years for 1990 (A), 2005 (B), and 2010 (C).

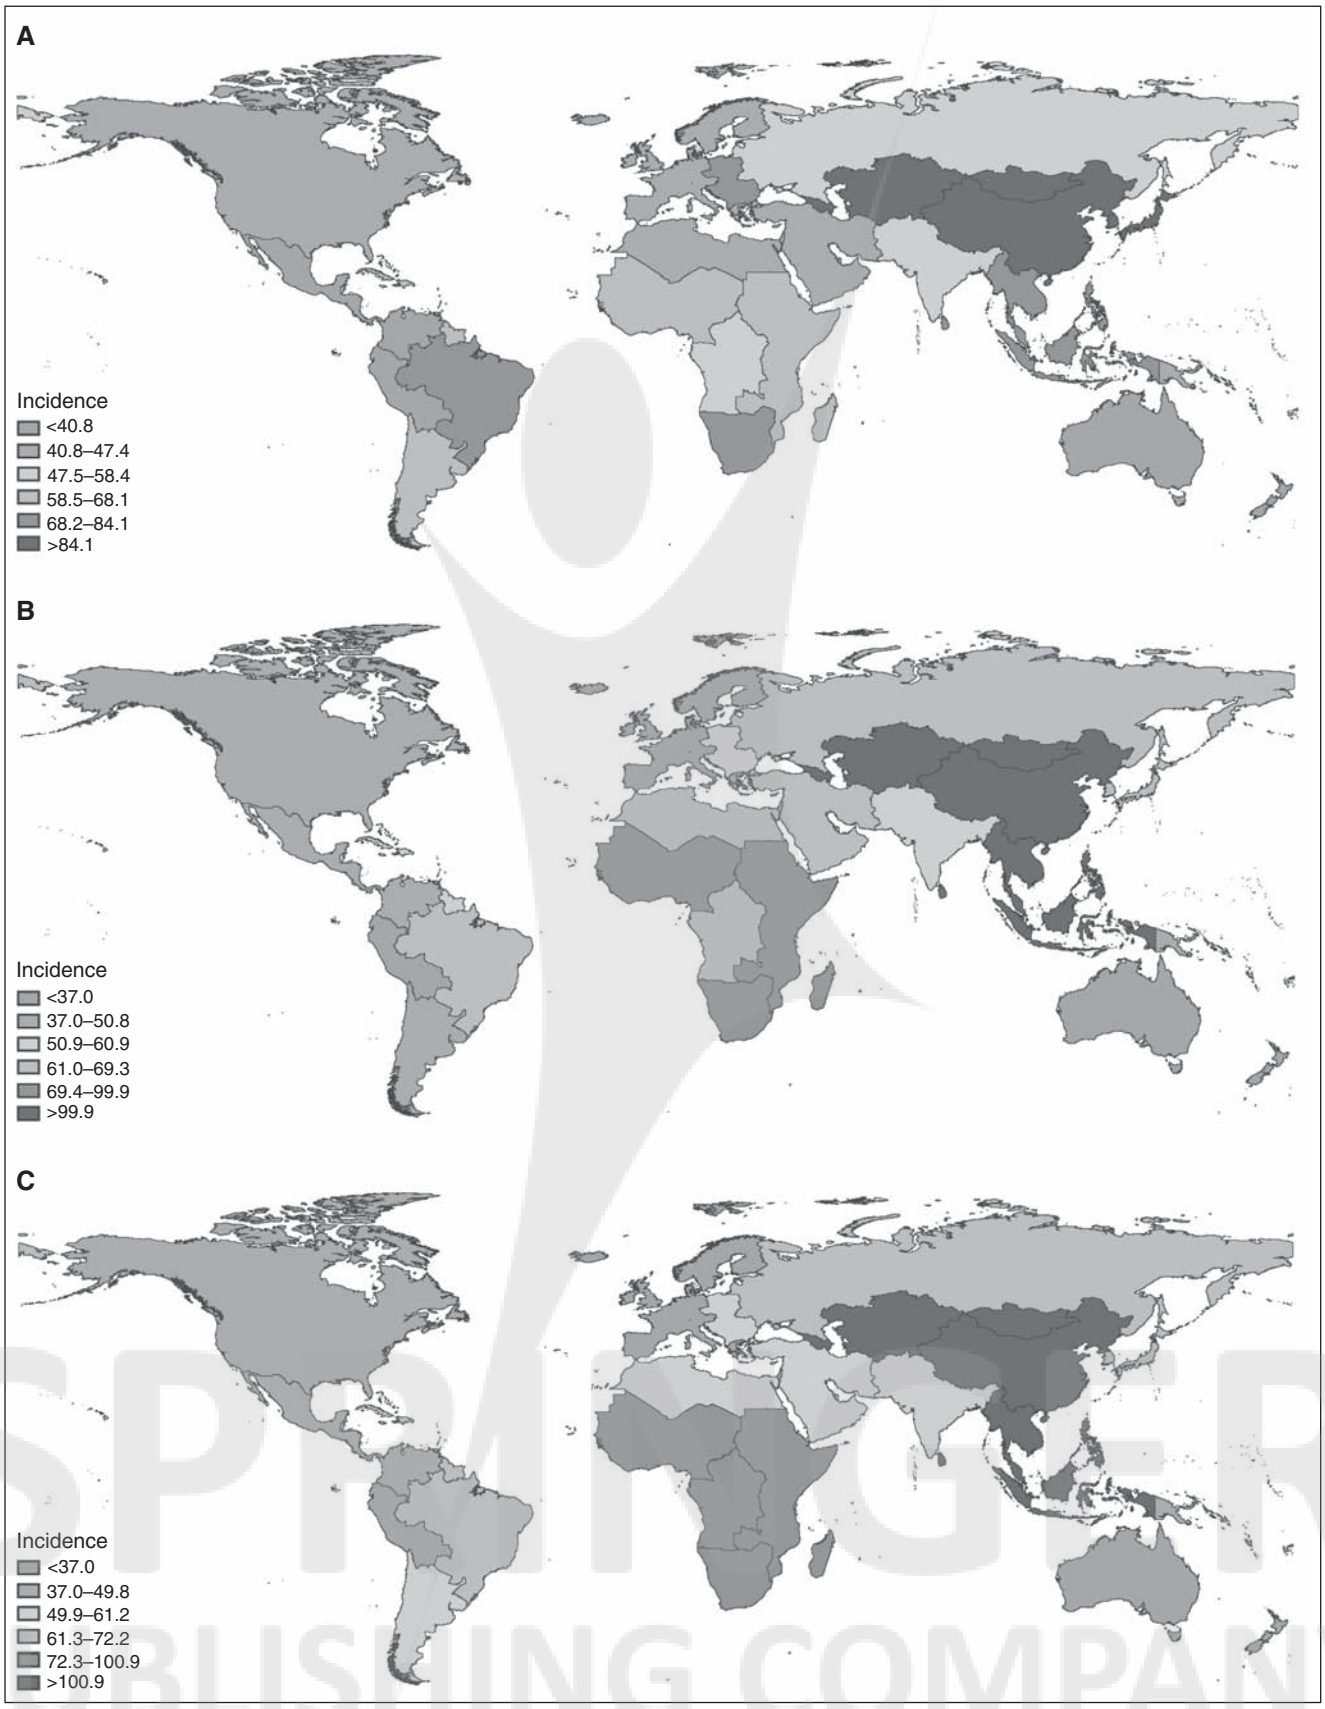

FIGURE 2.2 Age-standardized incidence of hemorrhagic stroke per 100,000 person-years for 1990 (A), 2005 (B), and 2010 (C).

FIGURE 2.3 Mortality-to-incidence ratio (MIR) for ischemic stroke for 1990 (A), 2005 (B), and 2010 (C).

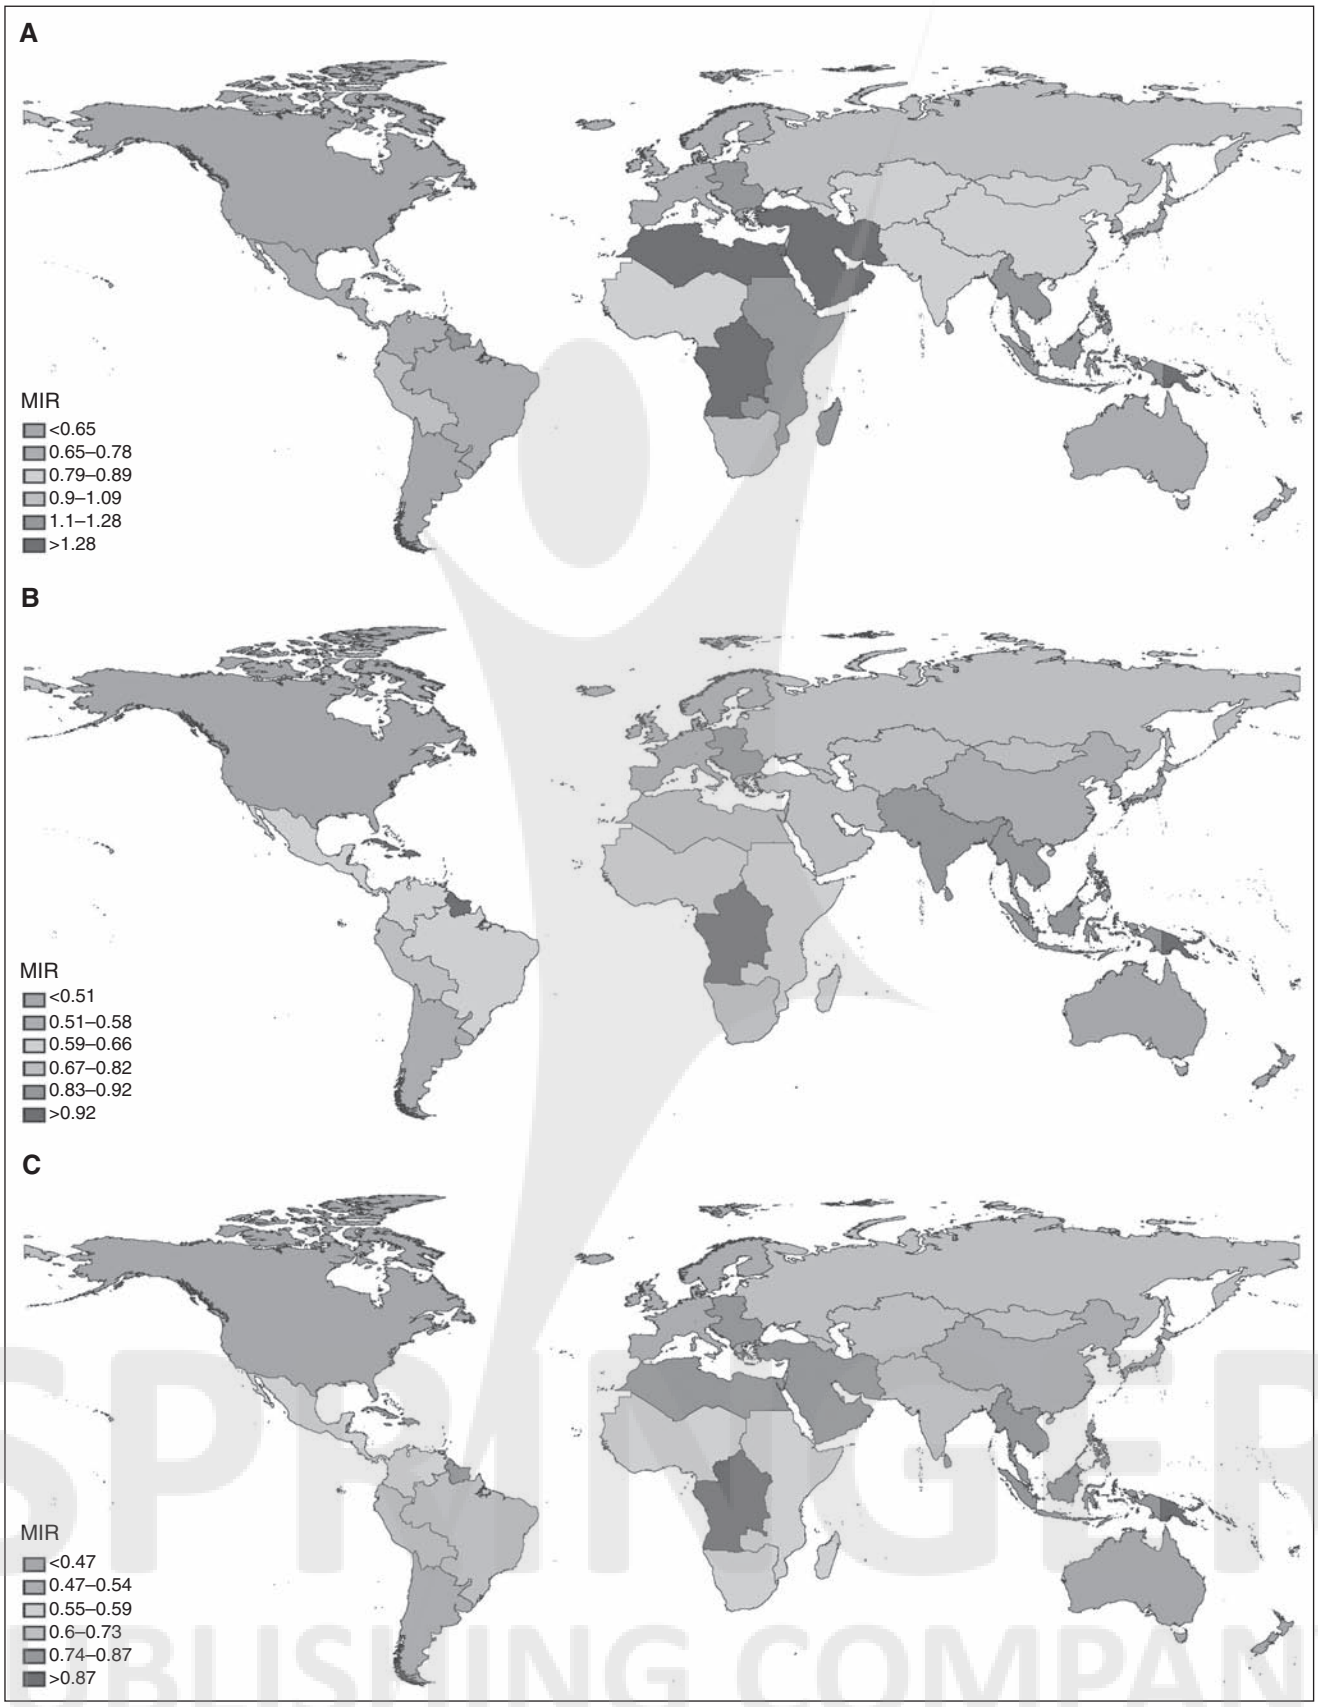

FIGURE 2.4 Mortality-to-incidence ratio (MIR) for hemorrhagic stroke for 1990 (A), 2005 (B), and 2010 (C).

Roughly a quarter of all ischemic strokes and about half of all hemorrhagic strokes occur in people younger than 65 years of age, with 73% and 83% of them, respectively, residing in low-income and middle-income countries. In 1990–2010, the incidence of both stroke types increased significantly in adults aged 20 to 64 years in low-income and middle-income countries. The findings of a greater proportion of hemorrhagic stroke in low-income and middle-income countries compared with high-income countries, noticeable geographical variation in the incidence of major pathological types of stroke, and diverging trends in stroke incidence between low-income countries (increase in rates) and high-income countries (decrease in rates) are in line with the results of a systematic review of population-based studies of stroke incidence (19). However, unlike findings from that review, there have been significant changes in the incidence of hemorrhagic stroke during the past two decades.

Encouragingly, although there is a trend toward an increase in the incidence of ischemic stroke, a trend toward reduction in mortality rates for both ischemic and hemorrhagic stroke, DALYs, and mortality-to-incidence ratios is also evident in low-income and middle-income countries. This finding might reflect advances in the diagnosis of stroke type, and more targeted health care in some developing regions in low-income and middle-income countries.

The discrepancies between countries of different income levels are probably driven by the occurrence of epidemiological transition (28). In the past few decades, life expectancy has increased, childhood mortality has reduced, and health status has improved overall in many regions of the world (29). Globally, aging populations are driving increases in the incidence of both ischemic and hemorrhagic stroke. In low-income and middle-income countries, diseases related to infection and undernutrition have been replaced with more chronic diseases such as stroke and heart disease as leading causes of disease burden. However, unlike many low-income and middle-income countries, most high-income countries have implemented improved prevention strategies and better health care for these chronic disorders (30). Moreover, industrialization and urbanization have led to changes in the nutritional quality of foods, with high-fiber carbohydrates and fresh produce being replaced with more processed carbohydrates and high-fat diets (31). The resultant increase in the prevalence of diabetes, together with increases in smoking rates and sedentary lifestyles, has contributed to increased atherosclerotic disease (30). During different phases of epidemiological transition, an increased incidence of hemorrhagic stroke is expected, particularly in low-income and middle-income countries, because hypertension is the dominant risk factor for this stroke type.

There are substantial differences between countries in incidence, mortality, DALYs, and mortality-to-incidence ratio for both stroke types. The alarmingly high stroke burden in China, particularly for hemorrhagic stroke, might be attributable to the increased prevalence of risk factors for this stroke type—namely high blood pressure and smoking—and an aging population (32,33). A review suggested that hemorrhagic stroke contributed to more stroke burden in China than in high-income countries, but wide regional differences were reported in the incidence and type of stroke (34). Hypertension, diabetes, dyslipidemia, and smoking are modifiable risk factors that have increased in China. In India, many deaths have been attributed to smoking, particularly in men, with vascular causes being among the main contributors to death (35). Eastern European countries have undergone many socioeconomic changes in the past two decades. In particular, in Russia, alcohol was strongly associated with adult mortality (36). More than half of the deaths among Russian men are attributable to cardiovascular disease, with hypertension, hypercholesterolemia, tobacco use, inadequate diet, obesity, insufficient physical activity, and alcohol being among the prevalent risk factors for death (37).

The decline in incidence, mortality, DALYs, and mortality-to-incidence ratios in high-income countries is likely a result of improved prevention, and better acute and chronic treatment of stroke. High-income regions such as Western Europe, North America, Australia, and New Zealand have increased efforts to prevent and diagnose stroke, which is shown by the delay of stroke incidence to older age groups (30). Mortality-to-incidence ratios for ischemic stroke in people younger than 40 years of age were significantly higher in low-income and middle-income countries when compared to that of high-income countries. This finding might reflect an increased prevalence of risk factors such as alcohol use, tobacco smoking (including second-hand exposure), and high blood pressure in this age group (38). By contrast, the increased overall global burden of stroke in low-income and middle-income countries could be attributable to reduced levels of awareness of risk factors, low levels of primary and follow-up health care, and a scarcity of basic drugs and equipment for the prevention and treatment of stroke (39).

Population-wide preventive strategies should be given priority because even modest changes in prevalence of risk factors (e.g., reduction of blood pressure, smoking cessation, and reduction of salt intake) could contribute substantially to the cumulative population risk reduction (24,40). Interventions to reduce the burden of chronic disease in low-income and middle-income countries should be cost effective and financially viable (41). Because of the overlap of risk factors related to ischemic stroke and ischemic heart disease, preventive efforts focused on these factors (e.g., raised blood pressure, cholesterol, diabetes, and smoking) would be a cost-effective way to target prevention in a wide population. Hypertension is the strongest risk factor for both ischemic and hemorrhagic stroke, and on the basis of the high burden of both types, prevention programs should focus on control of blood pressure, including both individual screening and treatment and population-wide lowering of blood pressure.

Tobacco control (via increased taxes, reduced advertising, and banning of smoking in public places), strategies for salt reduction, and evidence-based multidrug strategies to

treat those at high risk of cardiovascular disease, would be relevant for prevention of both hemorrhagic and ischemic stroke. Several successful and cost-effective campaigns have already been identified and need to be adopted on a wider scale worldwide (41). Government initiatives to encourage and support healthy diets and increased physical activity are imperative in countries of all income types. Similarly, engaging food manufacturers to achieve these goals by reduction of salt levels and fat content in processed foods would need to be implemented at government level (42,43). All of these strategies are applicable to secondary stroke prevention as well.

Hemorrhagic stroke was once a major cause of death in high-income nations, but its prevalence has decreased in those regions over the 20th century (44). However, hemorrhagic stroke remains an important cause of death and disability worldwide, particularly because of its disproportionate prevalence in low-income and middle-income countries. With the possible exception of hypertension, risk factors for hemorrhagic stroke have not been researched as well as those for ischemic stroke. Hence, studies to elucidate risk factors for hemorrhagic stroke are a high priority for future epidemiological research. A global perspective on stroke burden can be used as a vital source of information for future planning of prevention, treatment, and rehabilitation strategies for stroke worldwide.

Pathophysiology and Management of Acute Stroke

Marco Gonzalez-Castellon and Tomoko Kitago

Stroke is the fourth leading cause of death in the United States, and the most common medical cause of disability. Each year 800,000 Americans have a new or recurrent stroke—a number that will double in the coming decades as our population advances in age. This condition is, therefore, the most significant neurologic condition managed in the hospital setting. With the advent of recombinant tissue plasminogen activator (rt-PA) for the acute treatment of stroke in 1996, the management of stroke changed dramatically. Acute stroke is a medical emergency in which the outcome is highly dependent on prompt recognition and treatment. Several states have adopted legislative Stroke Acts, which require emergency medical personnel to transport stroke victims to the nearest certified stroke center. The Joint Commission has developed certification criteria for Primary and Comprehensive Stroke Centers based on the evidence published in the medical literature. With the advent of specialized stroke centers, the inclusion of guideline-driven acute stroke care, including early rehabilitation, has become an important component in the total management of the stroke patient. Acute care issues address prevention of common poststroke complications such as deep venous thrombosis; emphasize early mobilization, assessment, and management of dysphagia and nutritional status, cognitive and communication deficits, incontinence, and preventative skin care; and initiate interactive rehabilitation education including the family and caregivers. Multiple rehabilitation modalities must be initiated during the acute care period, and continuity of care plans established to optimize long-term functional and health outcomes for the stroke survivor. The care of stroke patients is divided into phases of emergency management, acute inpatient care, rehabilitation, and long-term care. This chapter focuses primarily on the management of acute ischemic stroke and provides a brief introduction to major rehabilitation issues that are commonly encountered during early stroke care.

STROKE PATHOPHYSIOLOGY

The two main classifications of stroke are ischemic and hemorrhagic stroke. In ischemic stroke, which accounts for the majority, interruption or reduction of blood flow to an area of the central nervous system results in neuronal injury and clinical symptoms. Ischemic stroke can be caused by different mechanisms: thrombosis, embolism, or hypoperfusion. In thrombotic stroke, there is local occlusion of a blood vessel, most commonly because of atherosclerosis or a hypercoaguable state. In embolic stroke, thrombus or other material forms at a distant site and travels to the site of occlusion. Sources of emboli include the heart, proximal arteries (e.g., the aorta, carotid, and vertebral arteries), and systemic veins in the case of paradoxical embolism, in which a venous thrombus can travel to the brain via a patent foramen ovale. In stroke caused by hypoperfusion, reduction in systemic perfusion causes a reduction in cerebral blood flow (CBF), which can be exacerbated when there is preexisting vessel stenosis.

The Ischemic Penumbra

CBF is normally 50 to 60 mL/100 g/min. With reduction in CBF to 20 mL/100 g/min, electrical activity is affected, and when CBF falls to less than 10 mL/100 g/min, there is irreversible injury. In ischemic stroke, there is a core area of the ischemic brain region in which blood flow drops below a critical level, and, therefore, is destined for cell death and infarction. A surrounding *penumbric* area of ischemic tissue may also exist that is physiologically impaired, but not necessarily destined for death. It is believed that restoration of CBF to this penumbra can prevent further cerebral infarction. While the precise duration of brain tissue viability for the penumbra has been debated and may vary among patients, depending on numerous pathophysiologic processes, most clinical and animal studies indicate a declining temporal profile of tissue survival that is on the order of hours. Hence, "time is brain," and the more rapidly cerebral perfusion can be restored, the better the neurologic outcome.

STROKE SYNDROMES

Knowledge of the vascular anatomy of the brain and the effects of specific arterial occlusions is important in determining the location and size of the infarct. Chapters 5 provides detailed clinical and vascular-neuroanatomic descriptions of anterior and posterior circulation stroke syndromes. Most

This chapter is an updated version originally published in the first edition by William Alvin McElveen and Richard F. Macko.

stroke syndromes can be divided into (a) anterior circulation syndromes—middle cerebral artery (MCA) and anterior cerebral artery (ACA) syndromes, (b) posterior circulation syndromes, (c) lacunar syndromes, and (d) borderzone (or *watershed*) infarct syndromes. A brief description of each of these syndromes is given in the following text.

Middle Cerebral Syndromes

Occlusion of the MCA will present with contralateral weakness, face and arm more than leg associated with sensory loss, visual field cut, and aphasia when the dominant hemisphere is affected and hemineglect when the nondominant hemisphere is involved.

ACA Syndromes

Occlusion of the ACA will present with weakness, leg more than arm and face, behavioral disturbances such as abulia, mutism, anterograde amnesia, grasping and sphincter dysfunction.

Posterior Circulation Syndromes

Strokes in the posterior circulation can present with dizziness, anisocoria, diplopia, dysphagia, ataxia, hemiplegia, quadriplegia, and coma depending on the location of the occlusion. The major posterior circulation syndromes include posterior inferior cerebellar artery (PICA, also known as "Wallenberg") syndrome, anterior inferior cerebellar artery (AICA) syndrome, and posterior cerebral artery (PCA) syndrome. Wallenberg syndrome presents with ipsilateral facial sensory loss, contralateral body sensory loss, dysphagia, dysphonia, ipsilateral ataxia, Horner's syndrome, and nystagmus. Infarction of the AICA territory usually presents with sudden hearing loss, vertigo, vomiting, ipsilateral facial palsy, ataxia, and contralateral sensory loss. Infarction of the PCA territory can present with multiple symptoms depending on the area affected. The most common symptom is visual field loss, and when there is involvement of the P2 branches, patients present with impaired cognition, amnesia, and changes in personality.

Lacunar Syndromes

Most lacunar infarcts are secondary to occlusion of small penetrating arteries; there are five "classic" lacunar syndromes: pure motor hemiparesis, pure sensory stroke, sensorimotor stroke, dysarthria–clumsy hand syndrome, and ataxic hemiparesis. The most common presentation is pure motor and pure sensory stroke.

Watershed Infarct Syndromes

Watershed infarcts are secondary to severely reduced flow in one or multiple vascular territories that leads to infarction of distal areas lying between two vascular territories. The most common are infarcts in the ACA/MCA watershed region, classically described as the *man-in-a-barrel* syndrome because of the especially proximal upper extremity weakness, although most of the time patients present with heterogeneous symptoms.

STROKE RECOGNITION

Rapid recognition of the signs and symptoms of stroke, and timely access to stroke centers, are crucial to optimizing acute care for stroke. Too often, patients develop signs of stroke and wait hours before seeking care, believing that the deficits will go away if they wait long enough. A study by Feldman in 1993 showed that the median time from onset of symptoms to presentation to emergency departments was 13 hours (1). Only 42% of patients presented within 24 hours. During the course of the National Institutes of Health rt-PA Pilot Study, public education and awareness campaigns were conducted to encourage early hospital arrival. Following this campaign, the mean time from symptom onset to hospital arrival declined significantly (3.2 h vs. 1.5 h). The use of 911 increased from 39% in the first quartile of the study to 60% in the fourth quartile. Community forums have also been successful in creating and extending awareness of the need for immediate action. The five most common symptoms of stroke include:

1. Sudden numbness or weakness of face, arm, or leg, especially on one side of the body
2. Sudden confusion, trouble speaking or understanding
3. Sudden trouble seeing in one or both eyes
4. Sudden trouble walking, dizziness, loss of balance, or coordination
5. Sudden severe headache with no known cause

Public education as to the significance of these symptoms and the importance of early evaluation is the goal of any comprehensive stroke program.

Emergency medicine system protocols are also critical in the early treatment of stroke. Proper training of paramedics allows these frontline personnel to obtain crucial information from family or bystanders. This includes obtaining history regarding time of onset and medications the patient might be taking. This historical information, as well as physical findings such as aphasia, motor deficit, and vital signs, can be called to the hospital emergency department so that a stroke alert protocol can be activated, saving significant time in treatment.

EMERGENCY DEPARTMENT MANAGEMENT OF STROKE

Because of the importance of rapid intervention in treating patients with ischemic stroke, it is important that hospitals develop protocols and order sets to be used when a patient with symptoms of stroke arrives. If the patient is transported by emergency medical services that communicate with the emergency department, the hospital can institute the protocol immediately on arrival, but preferably before. Several criteria should be established in the emergency department regarding minimizing delays, including activation of the

stroke team, timely interpretation of studies, and administration of fibrinolytic therapy.

Patient History and Evaluation

The history should focus on determining whether the symptoms are a result of stroke or other medical conditions that can mimic stroke symptoms. The latter include migraine, seizure, syncope, and hypoglycemia. To determine whether the patient may be a candidate for fibrinolytic therapy, it is essential to establish the time of symptom onset, or, if this is unavailable, the time that the patient was last known to be free of stroke symptoms.

As with other critically ill patients, initial evaluation and management should address the ABCs: airway, breathing, and circulation. Patients with hypoxia should be given supplemental oxygen to maintain oxygen saturation >94%. In the emergency care setting, a rapid but thorough neurological assessment is needed. The National Institutes of Health Stroke Scale (NIHSS), shown in Figure 3.1, is an 11-item scale

Ia. Level of Consciousness (LOC)	0 Alert 1 Not alert but arousable by minor stimulation to obey, answer, or respond 2 Not alert; requires repeated stimulation to attend, or is obtunded and requires strong or painful stimulation to make movements 3 Response only with reflex motor or autonomic effects or totally unresponsive, flaccid, and are flexic
Ib. LOC Questions	0 Answers both correctly 1 Answers one correctly 2 Answers neither correctly
Ic. LOC Commands	0 Performs both tasks correctly 1 Performs one task correctly 2 Performs neither task correctly
II. Best Gaze	0 Normal 1 Partial gaze palsy 2 Forced deviation or total gaze paresis
III. Visual	0 No visual loss 1 Partial hemianopia 2 Complete hemianopia 3 Bilateral hemianopia (blind including cortical blindness)
IV. Facial Palsy	0 Normal symmetrical movements 1 Minor paralysis 2 Partial paralysis 3 Complete paralysis of one or both sides
V. Motor Arm Right arm Left arm	0 No drift; limbs holds 90 (or 45) degrees for full 10 seconds 1 Drift; limb drift down before full 10 seconds, does not hit bed or other support 2 Some effort against gravity 3 No effort against gravity 4 No movement
VI. Motor Leg	0 No drift; limbs holds 90 (or 45) degrees for full 5 seconds 1 Drift; limb drift down before full 5 seconds, does not hit bed or other support 2 Some effort against gravity 3 No effort against gravity 4 No movement
VII. Limb Ataxia	0 Absent 1 Present in one limb 2 Present in two limbs
VIII. Sensory	0 Normal 1 Mild-to-moderate sensory loss 2 Severe to total sensory loss
IX. Best Language	0 No aphasia; normal 1 Mild-to-moderate aphasia 2 Severe aphasia 3 Mute, global aphasia
X. Dysarthria	0 Normal 1 Mild-to-moderate dysarthria 2 Severe dysarthria
XI. Extinction or Inattention	0 No abnormality 1 Visual, tactile, auditory, spatial, or personal inattention in one of the sensory modalities 2 Profound hemi-inattention or extinction to more than one modality

that can rapidly quantify the neurological deficits of a stroke patient. The use of standardized assessment tools has proved useful when discussing the patient's condition with the treating primary medical team, and for continuity of rehabilitation care. Training for this, as well as certification for performing the evaluation, can be obtained through several mechanisms such as the American Stroke Association website.

Tissue Plasminogen Activator

Recombinant tissue plasminogen activator (rt-PA) is a serine protease that converts plasminogen to plasmin, a fibrinolytic enzyme (Figure 3.2). Upon administration, rt-PA increases plasmin enzymatic activity, resulting in fibrinolysis. It is used to treat the stroke in the acute stage in an attempt to restore flow to the ischemic area, and should be administered as quickly as feasible, by protocol standards within a 3- to 4.5-hour time period to restore blood supply and optimize recovery.

rt-PA was approved by the FDA in 1996 for the treatment of acute stroke based on findings of the NINDS stroke trial in 1995 (2). This double-blind placebo-controlled trial demonstrated that patients treated with rt-PA within 3 hours of symptom onset had a 30% greater likelihood of having minimal to no disability 90 days following treatment, compared to a placebo-treated group. There was a 6.4% risk of symptomatic intracerebral hemorrhage in the rt-PA treated group, compared to 0.6% in the placebo group. However, even considering the risk of bleeding, the mortality at 90 days was 21% in the placebo group, and only 17% in the rt-PA group. Subsequent analyses have shown that these findings with rt-PA in the NINDS trial hold up for improved outcomes at the one-year time point (3). The benefits of early thrombolytic therapy are corroborated by the results of two European Cooperative Stroke Studies, as well as clinical experience, substantiating the effectiveness of rt-PA when used according to the guidelines of the clinical trials (4).

More recently, the third European Cooperative Stroke Study showed benefit for patients who were treated between 3 and 4.5 hours from symptom onset. Patients treated within this time window were more likely to have a favorable outcome (52.4% vs. 45.2%). However, there was a higher incidence of intracranial hemorrhage in the treatment group. The Food and Drug Administration considered this study to be insufficient to approve the use of rt-PA beyond the three-hour window (5). Current American Heart Association/American Stroke Association guidelines recommend treatment of patients in the 3- to 4.5-hour time period, excluding those who are more than 80 years old, those who are taking oral anticoagulants independent of international normalized ratio (INR), and those with NIHSS > 25, ischemia involving more than one-third of the MCA territory, and those with history of both stroke and diabetes mellitus (6).

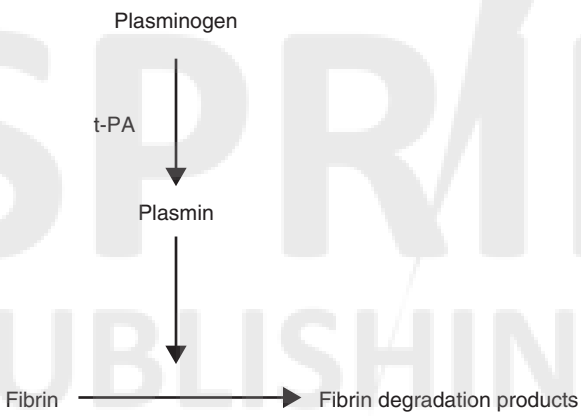

FIGURE 3.2 Diagram showing the site of action of recombinant t-PA to activate plasmin, which mediates fibrinolysis.

If it is determined that a patient's symptoms have been present less than 3 hours, there are other criteria that must be considered to determine if a patient is to be considered for rt-PA administration. These criteria are listed in Figure 3.3. If the patient is brought in between 3 and 4.5 hours after symptom onset, treatment can be considered using the same criteria listed in Figure 3.3 with additional exclusions: age >80 years old, taking anticoagulants, NIHSS > 25, involvement of >1/3 of the MCA territory affected, and history of both stroke and diabetes mellitus.

The consideration of rapidly improving symptoms as they relate to thrombolytic therapy decision making has been somewhat problematic. Improvement over the baseline NIH score is not considered rapid improvement if the patient continues to have a significant deficit. A good rule of thumb has been to assume that the patient is not going to show further improvement in his or her condition. Is the deficit mild enough that the patient can continue to function at a high level? Even mild weakness might be devastating to an individual whose occupation depends on fine motor movements; hence, rt-PA could be a consideration in such patients, even if they have a low NIHSS value. Barber and colleagues noted that one-third of patients deemed to have mild stroke symptoms that excluded them from rt-PA treatment either died or were left in a dependent state (7).

A majority of acute stroke patients have elevated blood pressure at the time of admission and across the initial days after stroke, which must be carefully managed. After rt-PA is administered, the patient should be monitored for at least 24 hours in an intensive care facility. The present recommendations are to keep systolic blood pressure below 185 mmHg and diastolic below 110 mmHg. Labetalol or nicardipine are the recommended agents to lower blood pressure. The lower limits for blood pressure should be a diastolic of 60 mmHg. Serial neurologic examinations are requisite, with appropriate clinical pathways for emergent management of complications such as symptomatic intracranial hemorrhage.

Imaging and Laboratory Studies

Stroke outcome is highly dependent on time; therefore, all eligible patients should be treated with rt-PA within 60 minutes of hospital arrival. Hospitals should determine the delaying steps in their process and work with the different departments to improve the flow.

If any of the following are answered YES, Patient may NOT receive rt-PA

☐ Yes ☐ No Stroke symptom onset more than 3 hours (last time patient was known to be without stroke symptoms)
☐ Yes ☐ No Age 18 or younger
☐ Yes ☐ No Comatose or unresponsive
☐ Yes ☐ No Stroke symptoms clearing spontaneously. Stroke symptoms minor and isolated
☐ Yes ☐ No Intracranial/Subarachnoid hemorrhage (SAH). Clinincal history suggestive of SAH even if CT negative
☐ Yes ☐ No Active internal bleeding or acute trauma (fracture) on examination
☐ Yes ☐ No INR greater than 1.7
☐ Yes ☐ No Platelet count less than 100,000
☐ Yes ☐ No Glucose less than 50
☐ Yes ☐ No HTN uncontrolled despite medication with systolic BP greater than 185 or diastolic BP greater than 110

History of:

☐ Yes ☐ No Active malignancy
☐ Yes ☐ No Recent MI or pericarditis within the past 3 months
☐ Yes ☐ No Recent arterial puncture at noncompressible site within previous 7 days (such as subclavian)
☐ Yes ☐ No Lumbar puncture within 3 days
☐ Yes ☐ No History of GI or urinary hemorrhage within 21 days
☐ Yes ☐ No Pregnancy, lactation, or childbirth within 30 days
☐ Yes ☐ No History of intracranial hemorrhage
☐ Yes ☐ No Major surgery or serious trauma within in past 14 days
☐ Yes ☐ No Seizure with postictal residual neurologic impairment
☐ Yes ☐ No Major ischemic stroke or head trauma within the past 3 months
☐ Yes ☐ No Heparin within 48 hours with PTT greater than upper limits of normal
☐ Yes ☐ No Known AV malformation or aneurysm
☐ Yes ☐ No Known bleeding disorder

FIGURE 3.3 Clinical criteria that must be considered when determining eligibility for rt-PA therapy.

A CT scan should be performed as soon as possible to exclude a hemorrhagic stroke. The CT scan may also demonstrate subtle early signs of infarction. Although the presence of these signs is associated with a poor outcome, this does not preclude the use of rt-PA unless there is evidence of hemorrhage. Only a noncontrast head CT is necessary to treat patients; obtaining advanced imaging is usually associated with delays in treatment.

Further considerations relevant to management in the acute stroke setting include evaluation of glucose, systemic antithrombotic status, and blood pressure. In the acute stroke setting, glucose is important to determine, as hypoglycemia can be associated with focal neurologic deficits, while patients with hyperglycemia have a less favorable prognosis. Partial thromboplastin time (PTT), INR for prothrombin time, and platelet count should be obtained to prevent the use of thrombolytic therapy in patients with coagulation defects. However, for patients without known coagulopathy who are not taking anticoagulants, current guidelines recommend waiting only for finger stick glucose before treatment with rt-PA to avoid delays in treatment (6).

INPATIENT CARE OF ACUTE ISCHEMIC STROKE

Numerous studies have shown that patients admitted to specialized stroke units with multidisciplinary teams have reduced lengths of stay, reduced mortality, and better functional outcomes (8)—findings that have been translated into clinical practice with similar positive results (9). Among the issues that are central to inpatient care are management of blood pressure, blood glucose, fluid balance, close neurologic monitoring to detect any signs or symptoms of clinical deterioration, prevention of common poststroke complications, and initiation of appropriate secondary stroke prevention measures. Early rehabilitation includes assessment for therapy needs with initiation of early mobilization, and comprehensive treatment plans, which should involve the family and caregivers and plans for continuity of care.

Blood Pressure, Fluid, and Glucose Management

Blood pressure management in the acute stroke patient is not the same as for the general population. Normally, cerebral autoregulation results in a constant CBF for mean arterial pressures between 60 and 160 mmHg. However, autoregulation may be lost in the acute stroke setting, and as a result, decreasing blood pressure decreases CBF in the area of ischemia. Extreme hypertension should also be avoided, as it may cause hemorrhagic transformation of the infarct, encephalopathy, and result in systemic complications. The optimal range of blood pressure in the acute stroke setting is not well established. For patients who are not candidates for rt-PA, unless there is a cardiac, renal, or other medical reason for which the pressure must be lowered, the current recommendation is to treat the blood pressure only when it is above 220/120 mmHg. Agents such as

sublingual nifedipine that lower the blood pressure quickly should be avoided. A reasonable decrease in blood pressure would be 15% over 24 hours. For patients who have pre-existing hypertension and are taking antihypertensive medications, it is generally agreed that antihypertensive medications should be temporarily held or reduced, but can be restarted at 24 hours if the patients are neurologically stable, unless a specific contraindication to restarting treatment is known.

Hypotonic and glucose-containing intravenous fluids are not recommended in the acute setting of cerebral infarction. Cytotoxic edema resulting from cellular membrane disruption with resulting swelling of the cell body develops with infarct. The use of these solutions can increase the cellular damage with influx of water into the cell. Normal saline is, therefore, generally utilized in these patients.

Hypoglycemia can mimic stroke symptoms and, if severe, can result in neuronal injury. Blood glucose should be checked immediately in patients presenting with stroke symptoms, with rapid correction of hypoglycemia. Numerous studies have shown that, in addition to hypoglycemia, sustained glucose greater than 140 predicts less favorable stroke outcomes than lower glucose values. Hyperglycemia after acute ischemic stroke has been shown to predict higher mortality and worse 90-day clinical outcomes for individuals with and without preexisting history of type 2 diabetes mellitus (10), and appears to blunt the beneficial effect of early recanalization that accompanies rt-PA therapy (11). Glucose levels should be monitored, and if greater than 140 to 180, treatment with insulin is similar to management in other medical intensive care conditions, with close monitoring to prevent hypoglycemia.

Evaluating and Managing Neurologic Deterioration

Between 15% and 30% of individuals with acute ischemic stroke experience neurologic deterioration during the acute hospitalization period, and this portends a much poorer prognosis (12). Factors linked to early neurological deterioration tend to be neurovascular, including stroke in progression, recurrent stroke, brain swelling, and hemorrhagic transformation (13). Neurologic factors beyond recurrent or progressing stroke that can mediate clinical deterioration in the acute hospital setting include brain swelling with mass effect, herniation syndromes, hemorrhagic transformation of ischemic stroke, and seizures, including subclinical variants that are difficult to diagnose without electroencephalography and can greatly compromise stroke outcomes. A number of other potentially modifiable systemic and medical factors must be considered. They include evaluation of cardiopulmonary and fluid status, glucose and electrolyte status, assessment for infection, and metabolic and toxic abnormalities, as well as consideration of medication side effects. Any neurologic deterioration or signs of fluctuating mental status should trigger rapid assessment for possible etiologies of worsening (12).

Management of Malignant Cerebral Edema

The management of malignant cerebral edema in large infarctions has historically proved problematic. Clinical signs of brain edema from large supratentorial cerebral infarctions typically begin with a decreased level of consciousness, followed by upper brainstem signs and involvement of anterior and posterior cerebral arterial territories. Malignant cerebral edema typically presents within the first 5 days, including one-third of cases within less than 24 hours, and portends a poor prognosis, with fatality approaching 80% regardless of medical management (14–16). Pooled analyses from three European randomized clinical trials showed that decompressive surgery performed within 48 hours of stroke onset reduces mortality (78% vs. 29%) and increases the likelihood of achieving a favorable 1-year outcome, defined as Modified Rankin Score of 4 or less, when compared to usual medical management (75% vs. 24%) (16). To place this in perspective, a modified Rankin of 4 indicates moderately severe deficits: inability to walk or attend to activities of daily living (ADLs) without assistance (17). Early decompressive surgery also led to doubling of chances to recover to a Modified Rankin Score of 3 or less by 1 year; a score of 3 indicates moderate disability, ability to walk without assistance. Notably, chances of surviving with severe disability (Score 5, bedridden, incontinent, requiring constant nursing) were not different for decompressive surgery versus usual medical care (4% vs. 5%). Note that these favorable outcomes for decompressive surgery come from studies that employ strict eligibility and exclusion requirements, including age 60 years or less, NIHSS greater than 15 in the setting of more than 1/2 MCA territory infarction, and with no space-occupying hemorrhagic lesions, fixed dilated pupils, or other major illnesses that could affect outcomes. These factors must be taken into consideration when making decisions regarding early decompressive surgery for individual patients.

Seizures

Any change in mental status, particularly episodic, should trigger evaluation for seizures. Incidence of seizures is reported at 9% for ischemic stroke (18). By contrast, seizures are reported in one-third of intracranial hemorrhage cases, and clinical studies suggest that more than half of these are electrographic only, and are not accompanied by clinical signs or symptoms of seizure (19). Specifically, continuous EEG recording has revealed seizures in up to 36% of lobar intracranial hemorrhage; contrary to conventional thinking, convulsive or nonconvulsive seizures are reported in 21% of subcortical intracranial hemorrhage cases, and they are linked to increased hemispheric mass effect and poorer outcomes (20). Seizures increase cerebral metabolic demands and intracranial pressure; generalized seizures can increase body temperature. All these factors can potentially worsen neurologic status and extend brain infarction in individuals with ischemic or hemorrhagic stroke, conditions in which cerebral autoregulation is already impaired. Hence, seizures must be treated

urgently in the setting of stroke. Likewise, suspicion of subclinical seizures warrants bedside electroencephalography and monitoring, along with rapid and aggressive anticonvulsant therapy, if seizures are diagnosed.

Infection

Infection is known to be a prothrombotic trigger mechanism in as many as 25% to 33% of ischemic strokes, and has long been recognized as an etiology for clinical worsening in the setting of acute stroke (21–23). Therefore, survey for infection is recommended at the time of initial stroke presentation, and comprehensive infection evaluation should be conducted if clinical deterioration occurs. Aspiration pneumonia and urinary tract infections are the most prevalent and must be treated aggressively. Because acute infection is linked to a prothrombotic state, and elevated temperature can accelerate neuroexcitotoxicity, both fever and infection must be aggressively treated in the acute stroke setting to protect the brain from further ischemic damage.

Dysphagia, Aspiration Risk, and Nutritional Management

One of the major dangers following stroke is aspiration, which may be silent, resulting in aspiration pneumonia. Dysphagia occurs in nearly half of hospitalized stroke patients and strongly predisposes to risk for aspiration pneumonia. Notably, the presence of a gag reflex is not indicative of safety in swallowing. Therefore, patients should be kept NPO until a bedside evaluation can be performed. Speech and language therapists play a significant role in this evaluation, and a videofluoroscopy swallowing study is recommended if bedside screening reveals abnormalities. If the patient is deemed to be at risk of aspiration, a dysphagia therapy program should be provided, optimally in consultation with a speech/language professional, as this has been shown to reduce pneumonia in the acute phase of stroke. Individuals at high risk for aspiration pneumonia may require nasogastric feeding tubes or percutaneous endoscopic gastrostomy (PEG). There is controversy regarding which is safer and more effective. While prior reviews provided some initial suggestions that PEG might be more efficacious (24), emerging evidence based on meta-analyses of 15 prospective studies suggests that nasogastric tubes are not associated with higher death rates, as previously believed (25). Hence, best clinical judgment must be used until the results of further clinical research are available. Dysphagia also identifies individuals who are inherently at greater risk for developing malnutrition, which is reported in 15% of stroke cases at the time of initial presentation, and doubles to 30% across the first week of hospitalization (26). Because malnutrition is linked to poorer clinical outcomes, ongoing monitoring of nutritional as well as hydration and electrolyte status becomes an important component of clinical pathways for stroke, particularly in individuals with dysphagia and compromised oral intake (27).

Antithrombotic and Anticoagulant Therapy

Aspirin is the antiplatelet agent that has been most extensively studied in the management of acute stroke. The combined results of two large acute stroke trials demonstrated a modest benefit in mortality and disability when aspirin therapy was initiated within 48 hours of stroke (28,29). This led to a recommendation of instituting aspirin at a dose of 325 mg within the first 48 hours after stroke. For patients who have received rt-PA, aspirin is not recommended within 24 hours of rt-PA administration.

The efficacy of other antiplatelet agents as monotherapy or in combination with aspirin is not well established for acute stroke. A 2007 study compared clopidogrel plus aspirin to aspirin alone given within 24 hours of onset of minor stroke (NIHSS < 4) or transient ischemic attack (TIA) (30). There was a 7% recurrent stroke incidence in the combined group, compared to 11% in the aspirin group. However, this did not reach statistical significance. The recent CHANCE trial demonstrated that the combination of aspirin and clopidogrel initiated within 24 hours of stroke or TIA was superior to aspirin alone in preventing recurrent stroke, without an increase in hemorrhagic complications, in a Chinese population (31). A similar study (POINT) comparing the combination of aspirin and clopidogrel to aspirin alone is currently underway in North America. Combinations of antithrombotic agents are generally not recommended for long-term secondary stroke prevention, as they are linked to increased bleeding risks (32–34).

Anticoagulants are generally avoided in the treatment of acute stroke. Numerous studies have shown that although the use of heparin or heparinoids in the management of acute stroke results in a decrease in the risk of early recurrence of stroke, there is an increased risk of hemorrhagic complications, including symptomatic intracerebral hemorrhage, with the use of anticoagulants (29). An example of this is seen in Figure 3.4. Historically, heparin had often been used acutely in patients with suspected cardioembolic stroke, such as those

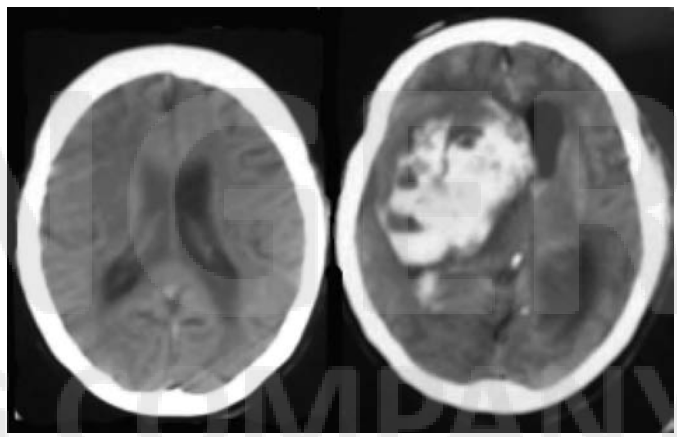

FIGURE 3.4 Patient presents at 10 a.m. with left hemiparesis, and the scan on the left is obtained. Heparin was started. At 4 p.m., the patient becomes obtunded, and the scan on the right is obtained.

with atrial fibrillation, to prevent early recurrence. However, in randomized clinical trials, no subgroup or arterial distribution has been identified in which urgent anticoagulation has demonstrated a significant benefit, when also considering the risk of bleeding. In an observational study, bridging with heparin for patients initiating oral anticoagulant therapy did not reduce the rate of early recurrent stroke (35). Acute anticoagulation may be used in certain high-risk patients, such as those with intracardiac thrombus or intra-arterial thrombus with or without arterial dissection, though the evidence to support its use is limited. As with antiplatelet agents, anticoagulants should not be utilized within 24 hours of rt-PA administration.

Early Rehabilitation Care and Mobilization

Consensus recommendations support early mobilization in appropriate medically stable subjects (36). While medical instability can limit the scope of rehabilitation early on, there are numerous physiological reasons for early care emphasizing mobility, including prevention of deep venous thrombosis, pressure ulcers, autonomic deconditioning, skin and lung infections, contracture formation, and muscular wasting. Muscular wasting can be rapid and devastating for functional recovery, particularly in frail elderly subjects. For those patients incapable of volitional muscle activation because of altered consciousness or severe motor deficits, early range-of-motion exercises and/or appropriate splinting as indicated to reduce contracture development, along with change of body positioning and other strategies to minimize skin pressure and friction, are recommended to minimize common post-stroke complications of contractures and pressure ulcers, respectively. For individuals with cardiopulmonary stability with higher neurologic function, resumption with appropriate supervision and training in basic mobility, self-care, and socialization skills is fundamental to early comprehensive rehabilitation care (36). Involvement of family and caregivers, including provision of structured written materials mapping rehabilitation plans and issues, is strongly recommended.

Prevention of Deep Venous Thrombosis

Patients with stroke often have deficits that impair their ability to ambulate safely, or even cause them to be confined to bed. This immobilization, along with elements of the prothrombotic state that are associated with acute ischemic stroke, increase the risk for deep venous thrombosis and associated pulmonary embolism. Therefore, measures should be taken to prevent this complication. Consensus recommendations strongly support the use of subcutaneous low-dose unfractionated heparin or low molecular weight heparin or heparinoids (37). Some evidence exists that the latter may have greater efficacy. For example, a study by Sherman and Alpers indicated a 43% improvement in venous thromboembolism in patients treated with the heparinoid enoxaparin given 40 mg subcutaneously daily, compared to subcutaneous unfractionated heparin given twice a day (38). This is consistent with meta-analyses concluding that both unfractionated heparin and low molecular weight heparin/heparinoids are partially effective in reducing deep venous thrombosis, but some evidence suggests that low molecular weight heparinoids may be more effective (39). As previously stated, heparin should not be used during the initial 24 hours of postthrombolytic therapy. Intermittent pneumatic compression devices (or elastic stockings) can also be used to help prevent deep vein thrombosis in patients with contraindications to anticoagulants, and for individuals presenting with acute intracranial hemorrhage; stable patients with intracranial hemorrhage may be switched over to low-dose subcutaneous heparin as early as the second day postevent. Aspirin may provide some mild benefit, and is safe to use in combination with low-dose heparin. Regardless of the medical coverage, early mobilization (preferably in collaboration with physical therapy consultation) and walking are important and can significantly reduce the risk for venous thrombosis (37).

Skin Care and Prevention of Pressure Ulcers

Pressure ulcers occur in approximately one-tenth of hospitalized stroke patients and one-fourth of those in nursing homes. Individuals at particular risk are those with mobility deficits of greater severity and medical conditions that compromise skin vascular integrity (including diabetes and peripheral arterial occlusive disease), those with urinary incontinence, and frail elderly patients with low body mass. Nursing pathways for stroke employ daily monitoring of skin integrity, and scheduled care including turning, proper positioning, and other appropriate methodologies to reduce the pressure and friction that propagate pressure ulcer formation (37,40). This includes the use of pressure-relief ankle-foot orthoses as a means to prevent contractures and pressure sore development. Consistent with clinical rehabilitation practice guidelines, early physical therapy assessment and care to optimize recovery of mobilization are also recommended to reduce the longitudinal risk profile for skin breakdown and pressure ulcer development.

Incontinence

Urinary incontinence is a prevalent early problem after stroke, occurring in about half of hospitalized cases, and decreasing in prevalence to 20% in the chronic poststroke recovery period. Factors increasing the predisposition to urinary incontinence are similar to those for pressure ulcers: greater stroke severity, diabetes, and advanced age. Because of the extremely high prevalence of urinary incontinence (and often fecal incontinence) in individuals with moderate to severe stroke, indwelling catheters are often used during the acute stage. This can facilitate fluid management and reduce the risk for skin breakdown. However, continued indwelling catheter usage for more than 48 hours predisposes to infection. During acute stroke hospitalization, assessment for urinary retention should be conducted via catheterization or bladder scan, urinary volume and control assessed, and dysuria documented. Some evidence exists that

silver alloy-coated catheters may have fewer complications. Regardless, it is optimal to discontinue indwelling catheter use after 48 hours, and to employ an individualized bladder training program with prompted voiding training for appropriate cases (37). Similarly, bowel incontinence is common after stroke and can be associated with an increased risk for skin breakdown and infection complications. Patients should be carefully assessed for presence, pattern, and etiology of fecal incontinence, including consideration of mental status and neuromotor control of sphincter function, diarrhea, or constipation with diarrhea around a hardened stool mass, medication, and potential infectious complications that can increase the risk for fecal incontinence. Physical therapy to optimize mobility recovery can be useful, as physical activity can influence gastrointestinal transit time. Maintaining skin cleanliness and integrity of the perineal area is crucial, along with attention to dietary fiber content, and implementation of a time-structured regular bowel program and associated medications as clinically indicated.

Cognitive Function and Communication

Global alterations in mental status, as well as a spectrum of specific neuropsychologic syndromes, are highly prevalent during the acute phase of stroke. Approximately one-third of stroke patients have a globally altered mental status during their acute hospitalization that can influence all other cognitive and communication assessments and limit early rehabilitation participation. The first item of the NIHSS categorically documents consciousness level. Those with stupor (or coma), or who fluctuate between drowsiness and stupor, regardless of cardiopulmonary stability, are best managed in a more intensive care setting, with frequent examinations documenting the specific stimuli needed to produce arousal. This enables a more rapid detection of fluctuating or progressing strokes and triggers urgent evaluation pathways. All patients with adequate alertness require evaluation for visual, motor, and sensory hemineglect syndromes, aphasia and apraxia, memory deficits, and impaired executive function—all factors that influence acute and longitudinal rehabilitation care pathways.

Some symptoms, such as denial of deficit and hemineglect syndromes, particularly in visual and motor domains, also lead to challenges for the therapist and safety concerns, as the patient may not realize there is a dysfunction. These and other prevalent poststroke neuropsychologic syndromes should optimally be identified during the acute hospitalization period and their significance explained to caregivers and future rehabilitation providers to optimize continuity of care. Assessment of communication skills, including speech, comprehension, repetition, reading, and writing, with speech/language therapist consultation is a standard of care. Early initiation of speech therapy, including visual communication aids, may be useful to facilitate patients' interaction with staff for routine care, and for socialization with family.

Other elements of neurocognitive health that are often overlooked during the acute hospitalization stage are mood and sleep integrity. Approximately one-third of stroke survivors develop some form of depression, which in many cases can be identified even during acute care hospitalization. Early recognition and management of depression is requisite to optimizing long-term rehabilitation outcomes. Sleep disordered breathing is also highly prevalent after stroke, particularly during the acute and subacute stroke recovery period, where fragmented sleep architecture and/or apnea have been reported in more than half of patients (41,42). A particular concern is obstructive sleep apnea that is linked to increased stroke risk and prothrombotic state, and may be associated with or exacerbate other neuropsychologic issues such as fatigue, depression, and memory impairment: factors that can complicate rehabilitation and recovery (43,44). Individuals fitting the profile for sleep disordered breathing may be screened using nocturnal pulse oxymetry, or further evaluated by polysomnography as clinically indicated. Many acute stroke patients have a disturbed sleep–wake cycle, particularly when in intensive care units. Approaches to improving sleep hygiene include transferring the patient from the intensive care unit as soon as possible, and providing a quiet environment with dark during the night and sunlight during the day to facilitate return of more normal circadian patterns. Selected medications properly timed may be used to facilitate sleep (e.g., trazadone, chloral hydrate), to try to avoid regular use of major sedative-hypnotics and antipsychotics, which can contribute to confused states, particularly in the elderly, and may further alter sleep architecture. Because abnormal sleep architecture is common in acute stroke, and given increasing evidence suggesting that sleep is critical to memory consolidation and, hence, may facilitate sensorimotor recovery in the rehabilitation setting, careful attention to sleep hygiene should be addressed early on (42–44).

In summary, a diversity of neurocognitive and communication deficits, as well as sleep disturbances, can complicate early stroke management and ongoing rehabilitation care. A summary of all cognitive and communication deficits and neuropsychologic syndromes, including depression and sleep disorders, that are diagnosed during acute hospitalization should be discussed with the family and outlined to subsequent care providers to optimize continuity of stroke care.

Screening for Risk Factors

Risk factors for stroke include hypertension, which increases both small and large vessel arterial atherothrombotic risk, atrial fibrillation, and selected other cardiac arrhythmias, extracranial carotid and intracranial large vessel stenosis, cardiomyopathy, hyperlipidemia, vasculitis, cigarette smoking, hypercoagulable states, diabetes, syphilis, elevated C-reactive protein, and elevated homocysteine levels. A timely evaluation of these risk factors is recommended in patients with acute stroke and TIA. Here we present a brief overview of a few of these risk factors and secondary stroke prevention measures, which are covered in more detail in later chapters.

Carotid artery stenosis is an important cause of ischemic stroke. Carotid ultrasound may be used for screening patients, as it has a sensitivity of approximately 85%, compared to digital arteriography. In combination with MR angiography, the sensitivity of detecting carotid stenosis improves to close to 100%. CT angiography is also helpful in assessing carotid lesions, with a sensitivity of 88% to 98% depending on the study. If a question remains regarding the lesion, catheter arteriography may be necessary. These studies are also needed to evaluate for less common conditions such as arterial dissection.

In patients with carotid stenosis greater than 70%, the North American Symptomatic Carotid Endarterectomy Trial indicated that carotid endarterectomy reduced the risk of ipsilateral stroke from 26% to 9%, compared to medical management at 2 years (45). There was no significant change between the groups for less severe stenosis. The surgical/arteriographic risk for these procedures was less than 3%. For patients who are at higher risk, the benefits of endarterectomy compared to medical therapy would be less, perhaps indicating that medical management would be preferable. The greatest benefit occurred when surgery was performed within two weeks of symptom onset.

Carotid artery stenting is an alternative, less invasive method of revascularization. The CREST trial compared stenting to endarterectomy in patients with asymptomatic and symptomatic carotid stenosis, and found no difference in the composite endpoint of stroke, myocardial infarction, or death (46). There was a higher risk of stroke in the stenting group, and a higher risk of myocardial infarction in the endarterectomy group. Notably, younger patients had fewer events with stenting, whereas older patients did better with endarterectomy. Carotid artery stenting is also suitable for patients who have contraindications to surgery, such as prior radiation treatment to the neck or lesions that cannot be approached surgically.

Hyperlipidemia is a risk for cardiovascular disease and, to a lesser degree, cerebrovascular disease. Current guidelines recommend treatment with HMG-CoA reductase inhibitors (statins) for patients with clinical atherosclerotic cardiovascular disease, including stroke or TIA. High-dose atorvastatin has been shown to decrease the risk of recurrent stroke (47). The benefit of statins after stroke may not be due solely to cholesterol reduction, as they also have effects on CBF, endothelial function, and anti-inflammatory properties. The use of statins for neuroprotection is currently being investigated in humans.

Cardiac monitoring is essential for stroke patients for detection of atrial fibrillation and other cardiac arrhythmias, at least for the first 24 hours after stroke. The risk of atrial fibrillation increases with age and comorbid conditions such as congestive heart failure, hypertension, and diabetes. More prolonged monitoring on an outpatient basis increases the chances of detecting paroxysmal atrial fibrillation. The use of anticoagulants significantly decreases the risk of thromboembolism in patients with atrial fibrillation. Warfarin decreases the risk of thromboembolic events by two-thirds (48), and the newer oral anticoagulants, such as dabigatran, rivaroxaban, and apixaban, have similar, or reduced, rates of thromboembolic events compared to warfarin (49–51). Aspirin decreases the risk slightly, but is significantly less effective than warfarin.

Cigarette smoking is another major modifiable risk factor. All smokers should receive counseling and education regarding the importance of smoking cessation. Several agents and techniques are available to help patients with this endeavor. They include nicotine patch and gum, hypnosis, and pharmacological agents such as varenicline and bupropion.

DISPOSITION AND DISCHARGE PLANNING

Decisions regarding the level of care for ongoing rehabilitation, particularly whether intensive inpatient rehabilitation is needed, should be made by the primary medical or neurologic team in consultation with rehabilitation providers. Three criteria influence the triage decision:

1. The premorbid and current functional statuses of the stroke survivor
2. The psychosocial and financial systems to support the stroke survivor in the community
3. The conditions of third-party reimbursement

The first criterion is heavily weighted by the recommendations of the physical, occupational, and speech/language therapists. Consideration must be given to whether the candidate has adequate physical and neurocognitive capacity to perform basic ADL functions, including mobility with safety using the appropriate assistive device and/or orthosis. For individuals with mobility deficits and elevated fall risk, a home assessment may be recommended to optimize safety and facilitate ADL functionality. Some individuals may require the capacity to maintain their own instrumental ADL functions, such as banking, shopping, and cooking, for independent functioning. This involves higher levels of communicative and cognitive skills for home management, community living, health management, and the ability to react safely and correctly to emergency situations. Hence, instrumental ADL status must be ascertained prior to discharge, and a follow-up plan for repeated assessment made in the event of discharge to the community.

Psychosocial and financial systems are essential to support the stroke survivor if he or she wishes to return to the community. If the caregivers are ready, willing, and able to assist or supervise the stroke survivor in the community, the stroke survivor may be admitted to an inpatient rehabilitation facility. If the stroke survivor has inadequate support systems to return to the community, it may be prudent to transfer him or her to a less intensive environment, to give the individual more time for spontaneous improvement. If the stroke survivor remains at an assisted functional level

that cannot be supported in the community, he or she will ultimately be transferred to a long-term care facility.

The final component of the rehabilitation triage decision rests, ultimately, upon the type of third-party payer policy under which the stroke survivor is covered. Although most insurance policies carry contingencies for different levels of rehabilitation care, some may limit the amount of inpatient and/or outpatient coverage per diagnosis. Some may not have provisions for specific levels of rehabilitation. Some may force the stroke survivor to pay for a portion of his or her rehabilitation hospital bills. Some may limit their networks to specific inpatient rehabilitation facilities. In any case, it is imperative for the stroke survivor and his or her caregiver to review the insurance policy to ensure proper coverage in the event of a catastrophic event such as stroke. It is equally essential for the case manager to review the policy and confirm benefits before transferring a stroke survivor to an inpatient rehabilitation facility, to ensure that the third-party payer will pay for the rehabilitation stay and to minimize the financial liability for the stroke survivor and caregiver.

A comprehensive rehabilitation follow-up plan should be set in motion before any community discharge. Attention should be given to therapeutic modalities and prevention of poststroke complications. Other factors such as return to work, driving, sexual function, adaptive equipment, social adjustments, and planning free-living physical activity and health-promoting exercise are generally managed in the outpatient environment and are dealt with in other chapters.

TRANSIENT CEREBRAL ISCHEMIA OR MILD STROKE SYMPTOMS

TIAs were previously defined as stroke symptoms that subsided within 24 hours. With the advent of rt-PA treatment, which requires treatment within 3 hours, that definition has been modified. Indeed, MRI studies with diffusion weighted imaging have indicated that more than half of the patients whose symptoms lasted more than 60 minutes actually have areas of infarction despite resolution of symptoms. Although the clinical symptoms in TIA may have subsided, it is important that the patient be thoroughly evaluated. Emerging guidelines for evaluation and acute medical management of TIA are now moving toward paralleling those of acute ischemic stroke (52). This approach toward the rapid management of TIA is being driven by an increasing recognition that many clinical events formerly classified as TIAs do, indeed, result in structural damage to the brain, and because the cerebrovascular event rate following TIA is dangerously high (52,53). Hence, TIA should be considered a medical emergency, with an imperative to optimize comprehensive secondary prevention strategies immediately.

Meta-analyses of 11 prospective studies suggest that, following a TIA, the risk for recurrent stroke is 3.5%, 8%, and 9.2% at 2, 30, and 90 days post-TIA, respectively (53). Twenty-one percent of these strokes are fatal, with another 64% resulting in disability. Rapid evaluation and management of patients with TIA, therefore, offer an opportunity to intervene and prevent a significant number of strokes. Indeed, studies from Paris and Oxfordshire, United Kingdom, have indicated that early evaluation may decrease the risk of stroke in the 90-day period by as much as 80% (54). Notably, the mean time to comprehensive clinical evaluation in the EXPRESS prospective study of stroke prevention following TIA was less than one day, which underscores the importance of rapid care (54). The development of dedicated clinics that see the patient immediately and institute the evaluation of the TIA patient has been possible in some communities. This approach also allows for the timely evaluation and institution of appropriate treatment, but is not widely available.

CONCLUSIONS

The efficient management of acute stroke requires emergent and structured protocols for efficient patient management. When the patient has had an ischemic stroke, early treatment can result in improved clinical outcomes. Proper medical management, even in patients who are not candidates for thrombolytic or neurointerventional procedures, results in better outcomes. Studies have demonstrated a significant decrease in the number of patients with severe disability when treated in a dedicated stroke unit, compared to those treated in a general medical ward. Many hospitals are now developing programs such as Primary and Comprehensive Stroke Centers, and accreditation for these programs has been established. These programs also stress early rehabilitation plans for the patient. Evaluation of dysphagia to prevent aspiration, nutritional assessment and planning, early patient mobilization, cognitive and communication assessment and speech/language therapy, and measures to prevent skin breakdown and deep vein thrombosis are important components of these programs. The institution of timely rehabilitation measures can improve daily living function for the stroke patient.

Neuroimaging of Acute Stroke

Daniel J. Boulter, Govind Mukundan, and Pamela W. Schaefer

For acute care of stroke patients, a number of computed tomography (CT) and magnetic resonance (MR) techniques are essential. Noncontrast CT excludes other causes of acute neurologic deficits and intracranial hemorrhage. CT and MR angiography can identify intravascular clots, and the CT angiography source images improve detection of acute infarction over plain CT. Diffusion MRI estimates the size, location, and age of infarcted core more precisely, and perfusion imaging estimates the ischemic penumbra. These new modalities play a critical role in determining which patients should undergo thrombolytic therapy.

Acute stroke imaging is rapidly advancing. Twenty years ago, state-of-the-art CT and MRI techniques were insensitive in detecting early acute stroke, and the diagnosis was usually presumptive. In the 1990s, diffusion-weighted MRI provided the first highly sensitive technique for visualizing acutely ischemic brain tissue. More recently, the development of CT and MR perfusion imaging has allowed the visualization of additional hypoperfused tissue at risk of infarction. The development, in concert, of CT and MR angiography has allowed highly reliable detection of proximal intravascular thrombus. Concomitant advances in stroke treatment provide a unique opportunity to direct and revolutionize stroke triage and management through imaging (1).

In this chapter, we review how conventional and advanced CT and MR imaging techniques are used to provide four types of information that are essential to the care of acute stroke patients (Table 4.1):

1. They establish the diagnosis of ischemic stroke and exclude other potential causes of an acute neurologic deficit.
2. They identify intracranial hemorrhage.
3. They identify the vascular lesion responsible for the ischemic event.
4. They provide additional characterization of brain tissue that may guide stroke therapy by determining the viability of different regions of the brain and distinguishing between irreversibly infarcted tissue and potentially salvageable tissue.

NONCONTRAST COMPUTED TOMOGRAPHY

CT is based on the measurement of x-ray beam attenuation through a region of interest, which is proportional to its density. Its low cost and accuracy in the detection of acute intracranial hemorrhage still make it the first-line diagnostic examination of choice in the emergency room setting in the United States. In addition to being performed to exclude hemorrhage, noncontrast CT (NCCT) is obtained primarily to exclude hypodensity in more than one-third of the middle cerebral artery territory and to exclude other causes of acute neurologic deficits, such as an intracranial mass lesion that would preclude the patient from receiving anticoagulation, thrombolytic therapy, or aggressive hypertensive therapy. One large study found that, among patients with symptoms of acute stroke, NCCT achieved a sensitivity and specificity of 90% and 99%, respectively, in detecting intracranial hemorrhage (2).

Noncontrast CT findings of acute stroke syndrome are subtle when present and include: loss of cortical, basal ganglia, or insular gray–white matter differentiation; loss of cortical sulci and reduction in sylvian fissure and basal cistern size caused by mild swelling; subtle parenchymal hypodensity; and hyperdensity within an intracranial vessel, such as the MCA, from acute thrombus (3) (Figure 4.1, Table 4.2). CT hypodensity is, in general, thought to be secondary to increased total tissue edema. Cytotoxic edema develops within 30 minutes of an acute embolic event caused by failure of Na^+K^+-ATPase and other ion pumps. Vasogenic edema develops at approximately four to six hours, secondary to disrupted endothelial tight junctions and reperfusion. Because cytotoxic edema results in net shift of water from the extracellular to the intracellular space, not an increase in total water, and CT hypodensity may appear before the onset of vasogenic edema, some authors have proposed that decreased blood volume causes early CT hypodensity (4).

Reported sensitivities of NCCT in the detection of acute infarction vary widely in the literature, secondary to dependence on time between symptom onset and imaging, the vascular territory involved, the generation of CT scanner, CT technique, viewing methodology, knowledge of clinical

TABLE 4.1 Critical Questions in the Imaging Evaluation of Acute Stroke

1. Is there hemorrhage?
2. Is the proximal intravascular thrombus a target for therapy?
3. Is there an infarct (or core) of irreversibly ischemic tissue?
4. Is there severely ischemic, but potentially salvageable, tissue (the penumbra)?

TABLE 4.2 NCCT Findings in Acute Ischemic Stroke

Parenchymal hypodensity
Hyperdense vessel sign
Loss of gray–white matter differentiation
Mild sulcal effacement
Exclusion criteria for receiving thrombolytic therapy
Intracranial hemorrhage
Hypodensity in greater than one-third of the MCA territory
Predictors of intracranial hemorrhage
Hypodensity in more than one-third of the MCA territory
ASPECTS score < 7

history, and reader experience. In one large retrospective study, in which the mean time from symptom onset to scanning was 2.3 hours and neuroradiologists blinded to clinical history interpreted the scans, the sensitivity in detecting acute infarction was 38% (5). The sensitivity improved to 52% when clinical history was provided. In another study of 30 patients, the sensitivity in detection of acute ischemia was 57% using standard windows (window 40 HU, level 80 HU) but improved to 71% with narrow windows (window 36 HU, level 30 HU) (5). (Radiodensity in CT is defined in Hounsfield Units—HU.) Reported specificities are high, ranging from 89% to 95% (6). In addition, one study found that the hyperdense middle cerebral artery sign was 100% specific for middle cerebral artery occlusion, but only 27% sensitive (7).

The hypodensity in NCCT has a number of important clinical implications. Multiple studies have confirmed that hypodensity on NCCT in the acute stroke setting almost always represents infarcted tissue. One study demonstrated that hypodense tissue on NCCT becomes necrotic with a probability of 97% (8). Hypodensity on NCCT correlates with stroke severity (8). The ECASS study demonstrated that hypodensity in more than one-third of the MCA territory correlates with an increased risk of hemorrhage following the administration of intravenous TPA; hypodensity in more than one-half of the MCA territory is associated with brain herniation (9).

The Alberta Stroke Program Early CT Score (ASPECTS) represents one effort to improve intra- and inter-rater reliability, by partially quantifying the extent of hypodensity on NCCT scans (10). In ASPECTS, 10 regions in the MCA territory are assigned a binary score of zero or one depending on the presence (one) or absence (zero) of hypodensity, and the total number of ischemic regions is subtracted from ten.

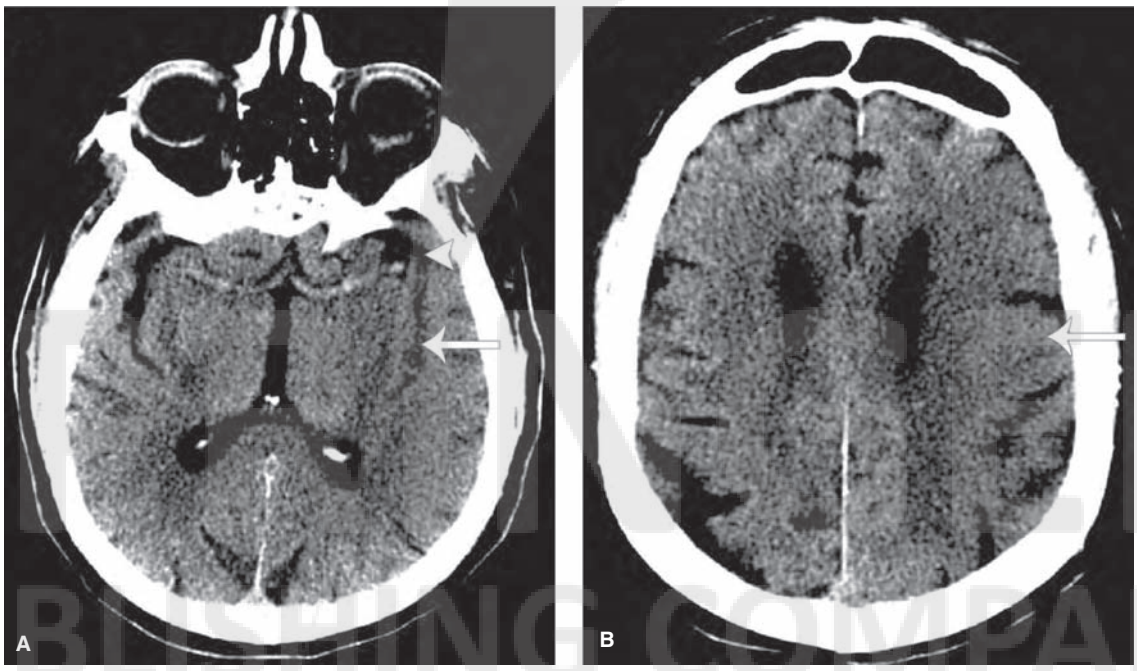

FIGURE 4.1 Early left MCA infarction. Sixty-year-old female with onset of left hemiparesis and aphasia four hours prior to imaging. There is hypodensity, loss of gray–white differentiation, and mild sulcal effacement throughout the visualized MCA territory (arrows). There is hyperdensity in the left MCA stem, consistent with acute thrombus (arrowhead).

ASPECTS may be helpful in deciding whether thrombolytic therapy should be initiated. One large study found that ASPECTS scores of seven or less are associated with a substantially increased risk of thrombolysis-related parenchymal hemorrhage (11). Reanalysis of data from another large study, the Pro-Urokinase for Acute Cerebral Thromboembolism II (PROACT-II) trial of patients randomized to intra-arterial thrombolysis within six hours of symptom onset, revealed that patients with an M1 or M2 occlusion and ASPECTS score greater than seven were three times more likely to have independent functional outcome compared with controls; patients with ASPECTS scores of seven or less were less likely to benefit from treatment (12). Neurointerventionalists who use NCCT to triage patients for intra-arterial reperfusion therapy typically do not treat patients with an ASPECTS score of less than five.

CONVENTIONAL MR IMAGING

T2 and FLAIR images, like NCCT, are capable of detecting parenchymal changes caused by vasogenic edema in acute ischemic stroke. However, because little vasogenic edema is present in the first six hours after stroke onset, parenchymal hyperintensity may be weak or absent. Furthermore, volume averaging of ischemic parenchyma and CSF can obscure small lesions. In one study, the sensitivity of T2 weighted images in the first 6 hours was only 18% (13). By suppressing the CSF signal, FLAIR has improved detection of infarctions in brain parenchyma adjacent to CSF such as cortex and periventricular white matter. The sensitivity of FLAIR imaging in the detection of parenchymal injury, however, is still as low as 29% in the first 6 hours (14). Besides parenchymal hyperintensity, other signs of acute stroke on MRI include the following: in T2 weighted images, loss of vascular flow voids; in FLAIR images, arterial hyperintensity in the clot and in collateral vessels because of slow flow; in gadolinium-enhanced T1-weighted images, vascular contrast enhancement in collateral vessels caused by slow flow; in gradient echo/T2* and susceptibility-weighted images (SWI) images, intravascular susceptibility (blooming) in the region of the acute thrombus; in SWI, prominent asymmetric hypointense cortical veins within the acutely ischemic region; and effacement of sulci, cisterns, and ventricles caused by mild swelling (Table 4.3, Figure 4.2). Gradient echo/T2* images and SWI are also highly sensitive in detecting hemorrhage.

TABLE 4.3 Appearance of Acute Arterial Infarcts on Conventional MRI

1. T2—loss of *arterial* flow void, subtle parenchymal hyperintensity
2. FLAIR—increased arterial signal, subtle parenchymal hyperintensity
3. Gradient echo/T2*—intravascular blooming in the region of the thrombus and hemorrhage
4. Susceptibility-weighted imaging—asymmetrically increased hypointensity of cortical draining veins, intravascular blooming in region of thrombus and hemorrhage
5. T1 postcontrast—arterial enhancement without parenchymal enhancement

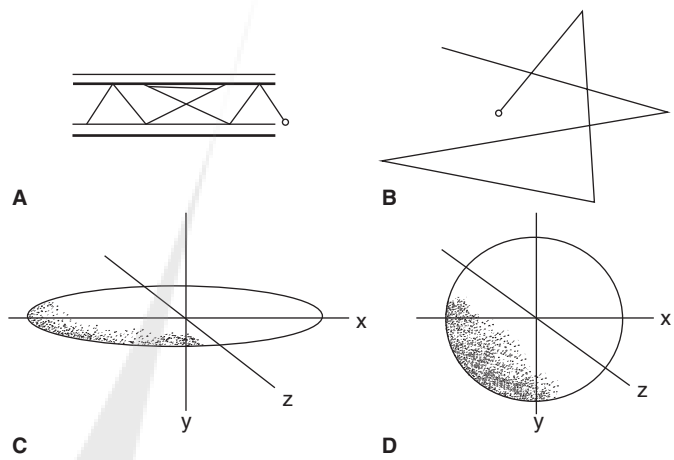

FIGURE 4.2 Anisotropic and isotropic diffusion of water molecules. Diagrammatic path of a water molecule within highly organized tissue such as white matter (A) and the associated three-dimensional representation of diffusion of water molecules in this system (C). Diagrammatic path of water in a non-bounded environment (B) and the associated three-dimensional representation of diffusion of water molecules in this system (D).

MRI DIFFUSION-WEIGHTED IMAGING

Diffusion-weighted imaging is an MR sequence with image contrast dependent on the magnitude of the relative motion or diffusion of water molecules. This property is particularly useful in the setting of acute strokes. Acute ischemia induces a cascade of metabolic and molecular changes that, within minutes, ultimately act to decrease the relative mobility of tissue water molecules in the affected parenchyma (15,16). The decrease in energy metabolism that leads to the failure of Na^+/K^+ ATPase and other ion pumps (15) results in loss of ionic gradients and net translocation of water from the extracellular to the intracellular compartment, where water movement is relatively more restricted. With cellular swelling, there is also a reduction in the extracellular space volume and increased tortuosity of extracellular space pathways (17). In addition, there are significant reductions in intracellular metabolite apparent diffusion coefficients (ADCs) that may be caused by increased intracellular viscosity from dissociation of microtubules and fragmentation of other cellular components, increased tortuosity of the intracellular space, and decreased cytoplasmic mobility.

Physical Principles and Diffusion MR Maps

MR is based on the principle of adding energy to the spins of hydrogen atoms in water molecules (referred to as *spins*)

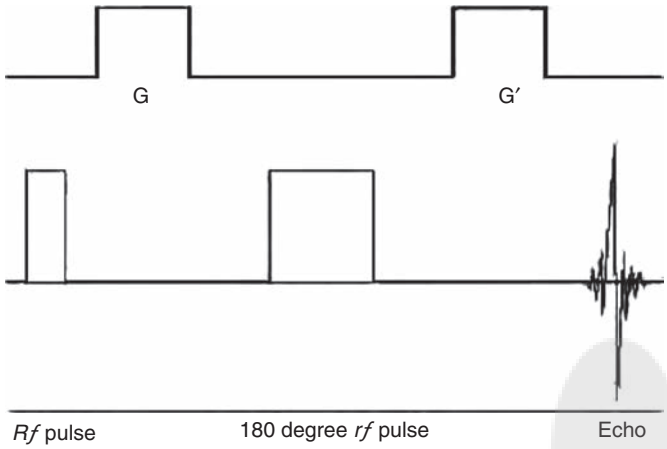

FIGURE 4.3 Fundamental Stejskal-Tanner diffusion MR scheme. During the first gradient lobe (G), the proton spins acquire phase shift. The 180-degree radio frequency (rf) pulse inverts all the spins. The second gradient lobe (G′) induces a second refocusing phase shift that is opposite to the first (caused by all spins inverted). Water protons that have not translocated have their phase shifts cancelled and lose no net signal (bright on image). Water protons that have migrated in space result in incomplete refocusing and incomplete cancellation of phase shift leading to loss of signal (dark on image).

and listening to the energy that is emitted back as the spins relax from their higher energy state to a lower basal state. The basic diffusion pulse sequence (Figure 4.3) consists of two equal applications of magnetic gradients with a 180-degree refocusing pulse in between (18). The first gradient causes the spins to go out of phase and lose signal. The 180-degree pulse inverts the phase of the spins. The second gradient refocuses the spins. Because the magnitudes of the gradients are identical, relatively immobile spins such as those in ischemic parenchyma are exposed to equal but opposite gradient-induced phase shifts, leaving their initial signal intact. This results in a relatively larger signal on the resultant diffusion-weighted MR image. However, the more the spins wander between the two gradient applications (e.g., with the diffusion of water in normal brain parenchyma), the more unequal the cancellation of their accumulated phase, resulting in loss of signal. Thus, normal parenchyma appears relatively hypointense compared to ischemic tissue.

Image Interpretation

Diffusion-weighted images (DWIs) and exponential images or apparent diffusion coefficient (ADC) maps should be available for review (Figure 4.4). It is important to understand that the DWIs indicate T2 signal differences as well as differences in diffusion. To remove the T2 contrast (called "shine-through"), the DWI can be divided by the echoplanar T2 image (or b 0 image) to give an exponential image. Alternatively, an ADC map, whose signal intensity is equal to the magnitude of the ADC, can be created. On DW images, regions with decreased diffusion (as in acute ischemia) are hyperintense. Regions with elevated diffusion (as in vasogenic edema) may be hypointense, isointense, or hyperintense, depending on the strength of the diffusion and T2 components. On exponential images, regions with decreased diffusion are hyperintense whereas lesions with elevated diffusion are hypointense. On ADC maps, regions with decreased diffusion are hypointense, whereas regions with elevated diffusion are hyperintense. For lesions with decreased diffusion, the DW images have superior lesion conspicuity. However, because hyperintense signal abnormality on DWI could result from the T2 component rather than from abnormal diffusion, review of the ADC maps or the exponential images is important.

Regardless of the mechanism, DWIs are highly sensitive and specific in the detection of hyperacute and acute stroke (19–21). Reported sensitivities and specificities are in the greater-than-90% range. The rare infarcts not identified on DWIs are typically very small lacunar brainstem or deep gray nuclei infarctions. False-positive DWIs may occur in patients with a subacute or chronic infarction because of T2 shine-through. In such cases, a lesion appears hyperintense on the DWI because of an increase in the T2 signal. This pitfall is easily avoided by interpreting the DWI in combination with ADC or exponential images (as described earlier). False-positive DWIs can also occur with decreased diffusion as a result of ion pump failure (seizures or hypoglycemia), high viscosity (abscess), dense cell packing (some tumors), and myelin vacuolization (Creutzfeldt Jakob disease, demyelinative lesions, or diffuse axonal injury). When these lesions are reviewed in combination with routine T1, T2, and gadolinium-enhanced T1-weighted images and clinical history, they can usually be readily differentiated from acute ischemic infarctions.

The DWI lesion is thought to represent tissue that is destined to infarct. Indeed, reversibility (abnormal on initial DWI but normal on follow-up images) of DWI hyperintense lesions is very rare and usually seen only in the setting of very early reperfusion following intravenous thrombolysis and/or intra-arterial recanalization procedures (22,23). Even with intravenous thrombolysis and intra-arterial recanalization procedures, the amount of DWI abnormal tissue that recovers is usually relatively small and typically more often involves white matter than gray matter. However, judging whether tissue with a diffusion abnormality is normal at follow-up is complicated. Such lesions may appear normal on follow-up DW, ADC, or T2-weighted images, but this may not reflect complete tissue recovery. Kidwell et al. reported a decrease in size from the initial DWI abnormality to the follow-up DWI abnormality immediately after IA thrombolysis in 8 of 18 patients (22). However, despite the initial apparent recovery, a subsequent increase in DWI lesion volume was observed in five patients. Furthermore, a number of studies have demonstrated that ADCs are significantly higher in DWI reversible tissue compared with DWI abnormal tissue that progresses to infarction. Mean ADCs

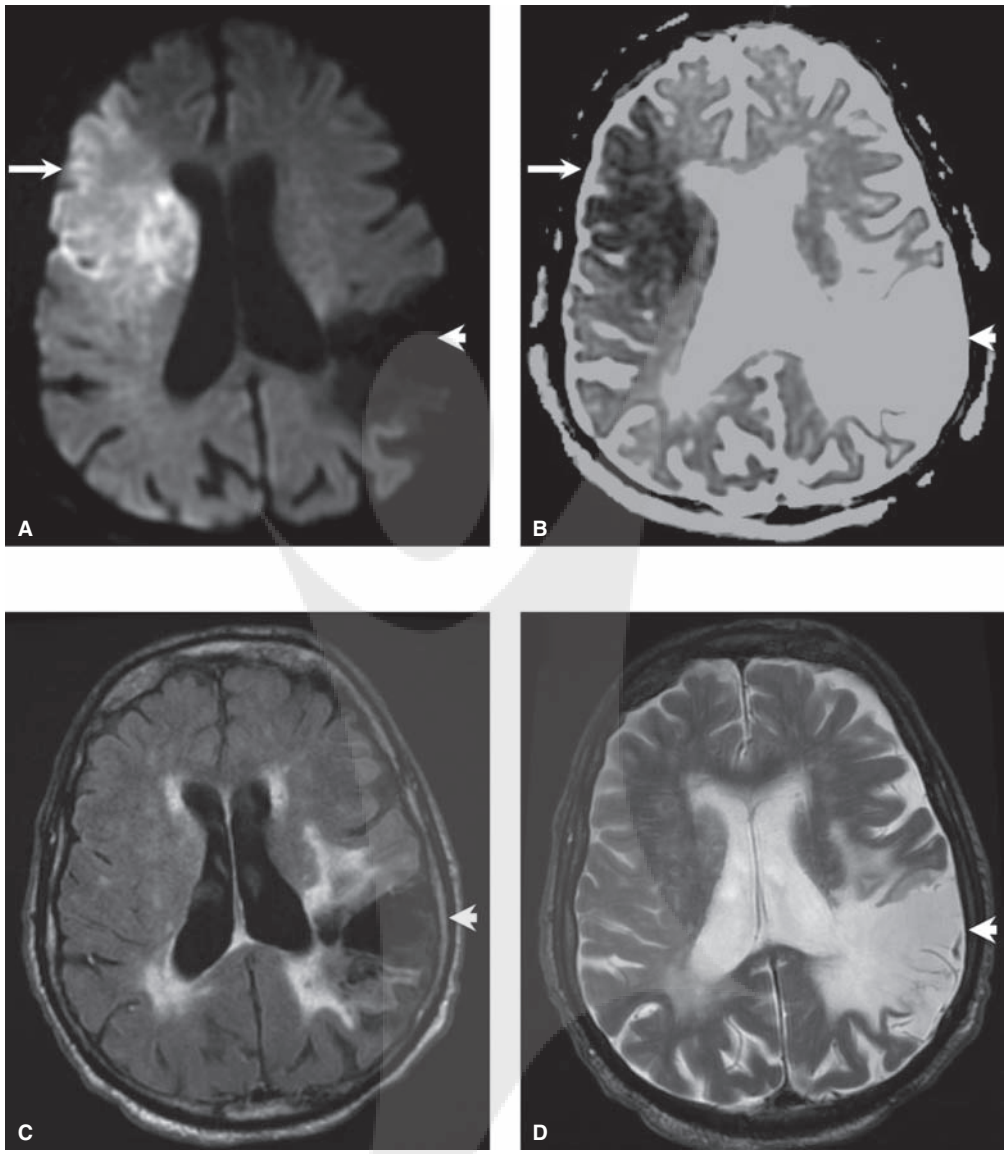

FIGURE 4.4 Acute and chronic infarction. Eighty-six-year-old male with atrial fibrillation with sudden onset of left hemiparesis four hours prior to MR imaging. There is restricted diffusion consistent with acute right MCA infarction, which is hyperintense on DWI (A) and hypointense on ADC map (B) images (arrows). FLAIR (C) and T2-weighted images (D) demonstrate no definite parenchymal abnormality in the region of the acute infarction. There is a chronic left parietal infarction, characterized by tissue cavitation and gliosis (arrowheads).

range from 663 to 732 × 10^{-6} mm^2/sec in DWI reversible regions, compared with 608 to 650 × 10^{-6} mm^2/sec in DWI abnormal regions that progress to infarction (22,24).

The temporal evolution of acute infarcts on DW imaging is of paramount importance, from both diagnostic and therapeutic standpoints (Figure 4.5, Table 4.4). The literature reports appreciable reduced diffusion as early as 30 minutes after an ischemic event. The ADC then decreases until it reaches a nadir at one to four days. This is reflected in marked signal hyperintensity on DWIs and exponential images, and marked signal hypointensity on ADC maps. Thereafter, with cell membrane disruption and the development of vasogenic edema, the diffusion coefficient begins to rise and returns to baseline at one to two weeks. At this point, a stroke is usually mildly hyperintense from the T2 component on the DWI and isointense on the ADC images (25). Thereafter, the ADC values continue to rise because of gliosis and/or cavitation with increased extracellular water. There is hypointensity, isointensity, or hyperintensity on the DWI (depending on the strength of the T2 and diffusion components) and increased signal intensity on ADC maps. Whereas multiple variables, including patient age, type of infarct, and infarct location, can influence the general time course of these ADC changes, it is generally true that infarcts with low ADC and little or no associated abnormality on T2-weighted images are less than approximately six hours in age. Recent evidence suggests

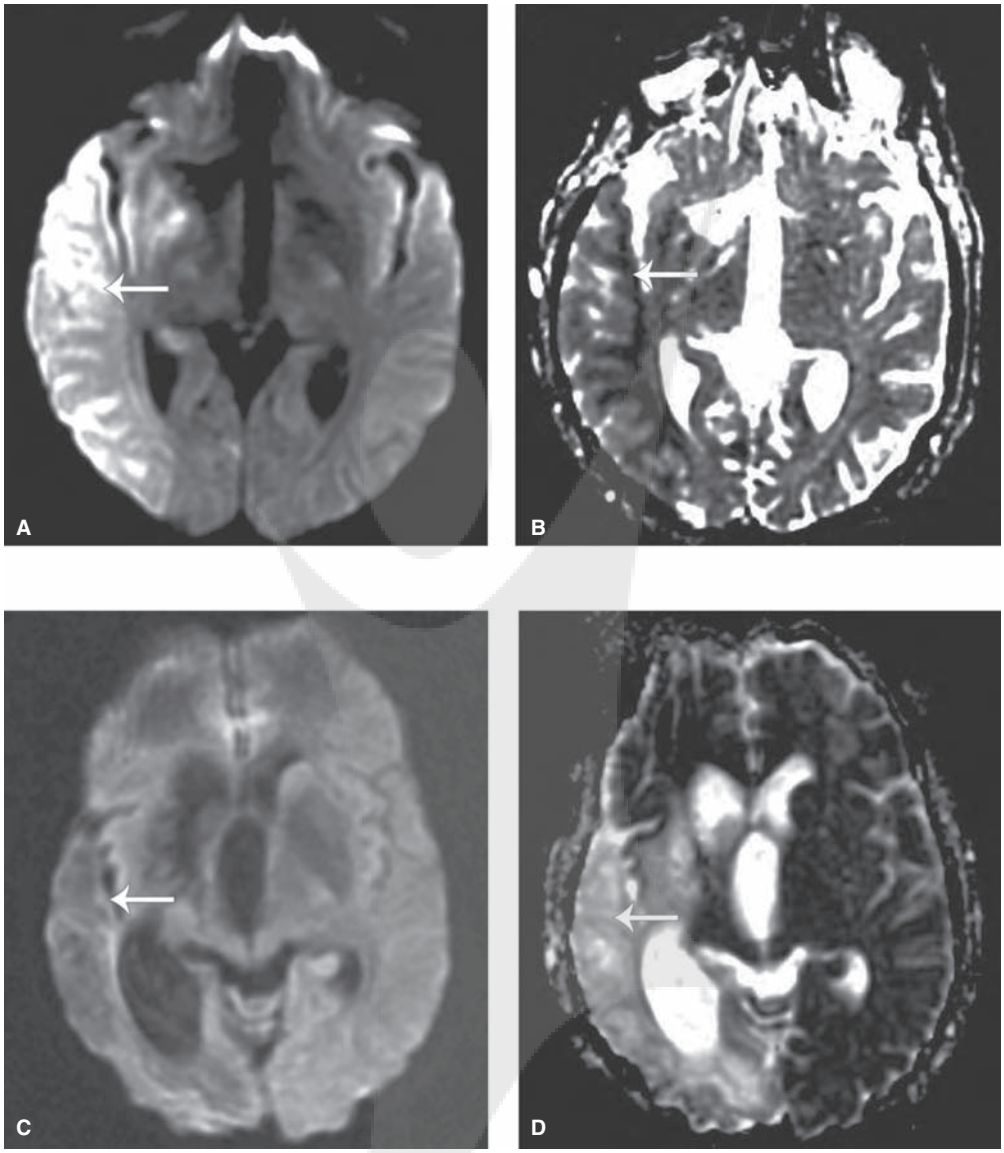

FIGURE 4.5 Evolution of DWI changes in an infarction. Sixty-four-year-old female with sudden-onset left facial drop, left-sided weakness, and slurred speech. In the acute stage, the infarction (arrow) is hyperintense on DWI (A) and hypointense on ADC (B) maps from decreased diffusion. In the chronic stage two years later, the infarction is characterized by tissue cavitation and volume loss with associated dilatation of the lateral and third ventricles. There is now more free movement of water molecules, with elevated diffusion characterized by decreased signal on the DWI (C) and increased signal on the ADC (D) maps.

TABLE 4.4 Temporal Changes in DWI, ADC, and Exponential Maps

PULSE SEQUENCE	HYPERACUTE (0–6 HOURS)	ACUTE (6–24 HOURS)	EARLY SUBACUTE (1–7 DAYS)	LATE SUBACUTE (1–4 WEEKS)	CHRONIC
Reason for ADC change	Cytotoxic edema	Cytotoxic edema	Cytotoxic edema + smaller vasogenic edema component	Cytotoxic and vasogenic edema	Vasogenic edema and then gliosis and neuronal loss
DWI	Hyperintense	Hyperintense	Hyperintense	Hyperintense (mostly T2 component)	Isointense to hypointense
ADC	Hypointense	Hypointense	Hypointense	Isointense	Hyperintense
EXP	Hyperintense	Hyperintense	Hyperintense	Isointense	Hypointense

that this phenomenon may be a useful imaging surrogate for estimating infarct age in patients with "wake-up" strokes of unclear onset times, who have traditionally been precluded from thrombolytic therapy. One study found that DWI hyperintense infarcts with little or no FLAIR hyperintensity predicted a symptom onset within 4.5 hours with a sensitivity of 62%, a specificity of 78%, and a positive predictive value of 83% (26). In addition, infarcts that are FLAIR hyperintense but have lower-than-normal ADC are usually less than approximately two weeks in age (27,28).

DWI lesions have been found to be highly predictive of patient outcomes and of likelihood of response to treatment. Larger DWI lesion volumes are strongly associated with poor patient outcomes, and may help predict which patients are unlikely to benefit from recanalization therapy. In one study, all patients with DWI lesion volumes greater than 70 mL had a poor outcome despite recanalization therapy (29). Another study found a diminishing effect of recanalization with increasing baseline DWI lesion size, with little treatment benefit for lesions more than 25 mL (30). Lesion location is also likely an important determinant of outcome, because not all brain regions contribute equally to clinical deficits. One study showed that a location-weighted, atlas-based method provided better prediction of clinical deficit severity than volume-based estimates alone in the subacute period (31).

CT ANGIOGRAPHY

Information about the intracranial and cervical vessels is an important part of the imaging evaluation because the bulk of acute stroke therapy targets intraluminal thrombus. However, thrombolytic therapy carries a significant risk of intracranial hemorrhage, so it is important to exclude patients with conditions that do not benefit from therapy, such as lacunar infarcts or postseizure deficits.

CTA has many attractive features that have made it the first-line diagnostic test for imaging intracranial vasculature in patients with signs and symptoms of acute stroke. CTA is widely available in the emergency setting and is a quick extension of the nonenhanced CT scan. Fast, high-resolution CTA techniques have become possible largely because of the advent of the helical CT scanner and the multidetector design of the scanner array. Helical scanning technology, developed in the 1990s, uses 360-degree rotation of the x-ray tube, scanning continuously with table progression. This results in the acquisition of a three-dimensional helical ribbon of data. The development of multislice or multidetector CT has led essentially to the acquisition of a larger ribbon of data per gantry rotation, allowing larger coverage at higher speeds. Thus, with a single bolus of contrast, high-resolution angiographic images of the major vessels from the arch to the vertex can be obtained within a minute.

Furthermore, the required postprocessing can be performed rapidly. For example, three-plane, orthogonal, maximal intensity projection (MIP) images can be reconstructed at the scanner by a technician in less than three minutes. The combination of the source axial images and the three-plane MIPS nearly always allows adequate evaluation of the arterial vasculature for the purposes of triage for thrombolytic therapy. In addition, the speed of CTA makes CTA images relatively resistant to degradation by artifact related to patient motion. With CT scanners, unlike MRI scanners, it is safe to bring metallic equipment into the scanner room, permitting easier monitoring of potentially unstable acute stroke patients. A significant percentage of stroke patients have cardiac diseases that require pacemakers, and they cannot undergo MR scanning. Also, CTA is less susceptible to other artifacts often encountered in MR angiography, including susceptibility artifact from calcified atherosclerotic plaque, air (e.g., within the petrous apices and sinuses), and metal clips.

Multiple studies have shown that CTA can detect large vessel intravascular clots with a sensitivity and specificity of greater than 95% (32) (Figure 4.6). Thus, CTA plays a critical role in directing acute therapy by detecting occlusion of proximal intracranial arteries that are accessible by endovascular microcatheterization and may be treated by intra-arterial thrombolysis or mechanical clot disruption. Indeed, studies using CTA suggest that proximal occlusions should be treated with intra-arterial recanalization procedures rather than, or in addition to, intravenous thrombolysis, because intravenous thrombolysis is less effective in treating proximal lesions than in treating distal ones (33,34). Also, detection of large vessel clots may be important in determining prognosis. One CTA study found that occlusion of a large intracranial artery was one of two factors that independently predicted poor outcome in acute stroke patients (The other was poor initial neurologic status.) (35). Another found a four-and-a-half-fold increased odds of death and a three-fold reduction in odds of good outcome in patients with large vessel occlusion (36). From worst outcome to best were occlusions of the basilar artery, internal carotid artery, M1, and M2 segments. The presence of large vessel occlusion is also highly correlated with mismatch on perfusion imaging (37), suggesting that it may be useful in selecting for reperfusion therapy. Indeed, in a post hoc analysis of perfusion mismatch selected patients from the desmoteplase in acute stroke (DIAS), desmoteplase in acute ischemic stroke (DEDAS), and DIAS-2 trials (described in more detail later), the presence of a proximal arterial occlusion on CTA was associated with a clinically beneficial effect of intravenous administration of the plasminogen activator desmoteplase (38). An additional CTA study showed that in the setting of proximal arterial occlusion, the recanalization status determines which clinical parameters are most important in determining clinical outcome; time was most important in patients with complete recanalization, whereas NIHSS was more important in those who incompletely recanalize (39). CTA has also been shown to predict the need for advanced neurointerventional services (40).

The Boston Acute Stroke Imaging Score (BASIS) is an instrument developed to integrate the useful information gained from CTA with that of NCCT and represents

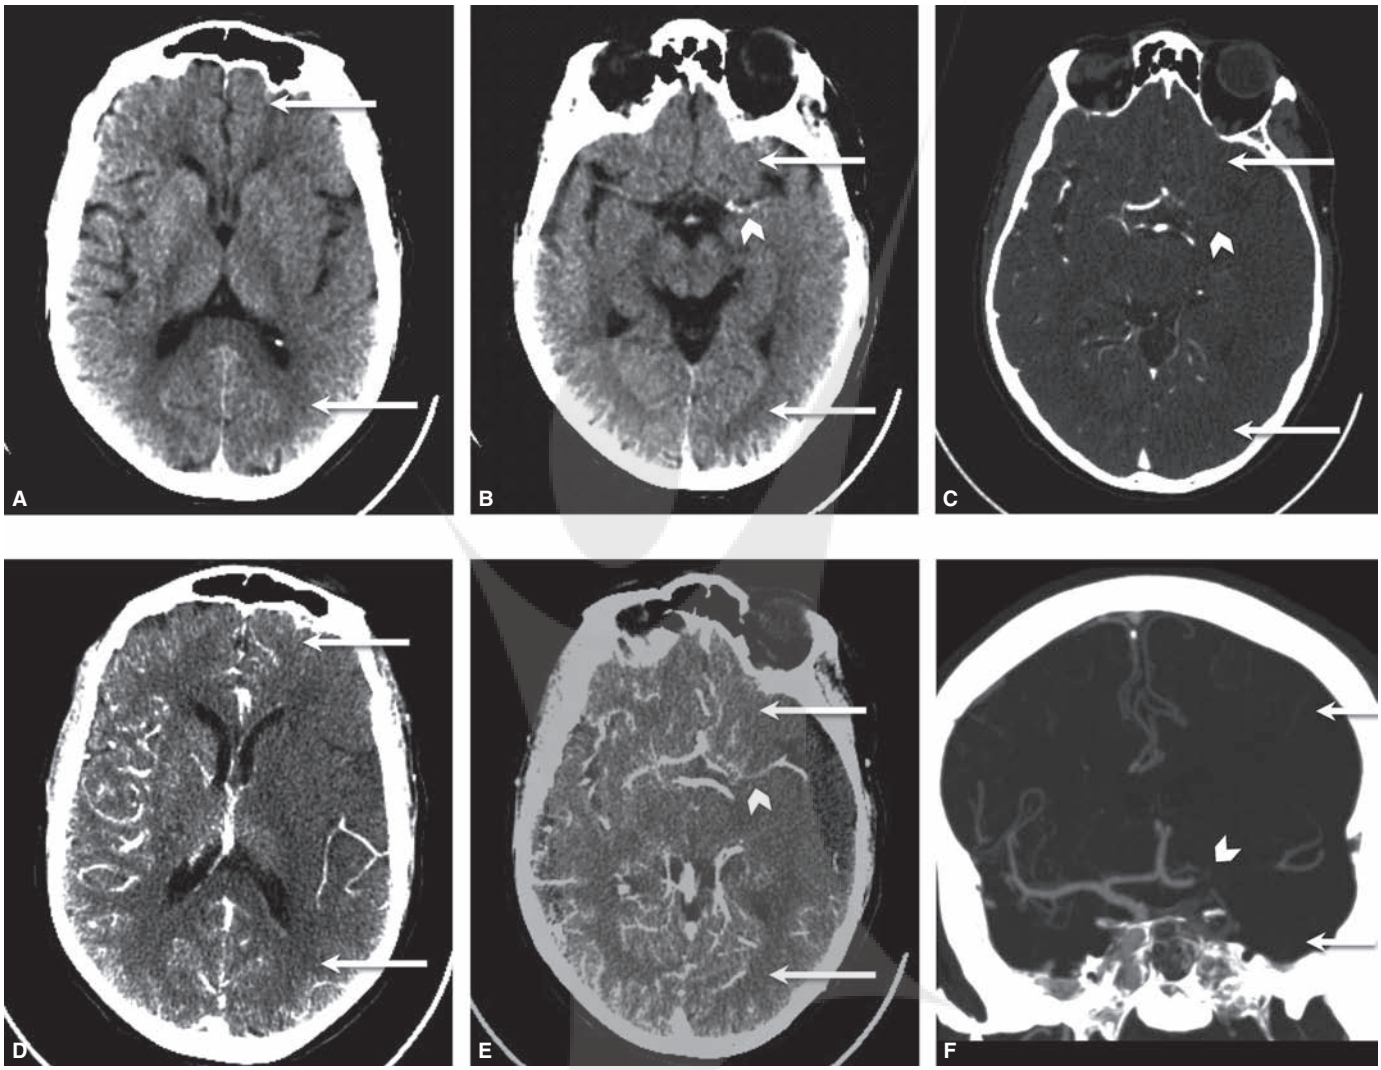

FIGURE 4.6 Embolic left MCA occlusion. Sixty-two-year-old male with known left ventricular thrombus following myocardial infarction awoke with right hemiparesis and aphasia, last seen normal 13 hours prior to imaging. Noncontrast CT (A and B) reveals a hyperdense clot in the left MCA stem (arrowhead), with subtle sulcal effacement and loss of gray–white matter differentiation throughout a large portion of the left MCA territory (delineated by arrows). Thin-section CTA source images (C) show absent enhancement within the occluded left MCA stem (arrowhead) as well as the distal left MCA branches and arterial collaterals (delineated by arrows). Thick-section (5 mm) CTA source images (D and E) more clearly demonstrate a large area of hypoperfused brain tissue in the left MCA territory (delineated by arrows). Coronal MIP CTA image (F) clearly depicts the absent enhancement of the left MCA stem caused by embolic occlusion (arrowhead), as well as the absent enhancement in the distal left MCA branches and arterial collaterals. (*Continued*)

an augmentation of the ASPECTS noncontrast CT scoring system that is superior in predicting outcomes (41). In one large trial, the Improved Outcome Prediction Using CT Angiography in Addition to Standard Ischemic Stroke Assessment (STOPStroke) study, BASIS+ was one of two independent outcome predictors; the other was NIHSS (42). In this trial, patients were classified as BASIS+ if proximal anterior circulation artery occlusions were observed on CTA or if the NCCT ASPECTS score was seven or less in patients without proximal artery occlusions.

CTA has a number of other advantages. In the neck, it allows evaluation of stroke etiology (Figure 4.7). CTA can demonstrate atherosclerotic plaque with thrombus at the internal carotid artery bifurcation. It can differentiate thrombosis from hairline residual lumen, and it can identify dissection. In the head, CTA source images (CTA-SIs) greatly improve the detection of subtle, early parenchymal ischemic changes compared to NCCT (43,44) (Figure 4.6). In the early days of CTA, a steady-state level of contrast was reached during scanning and the CTA-SIs could be considered whole-brain perfused blood volume images. Furthermore, the CTA-SI lesion size correlated with the DWI lesion size and could help to identify the infarction core. However, with current, faster CTA protocols, a steady state is not reached, the CTA-SI are more blood

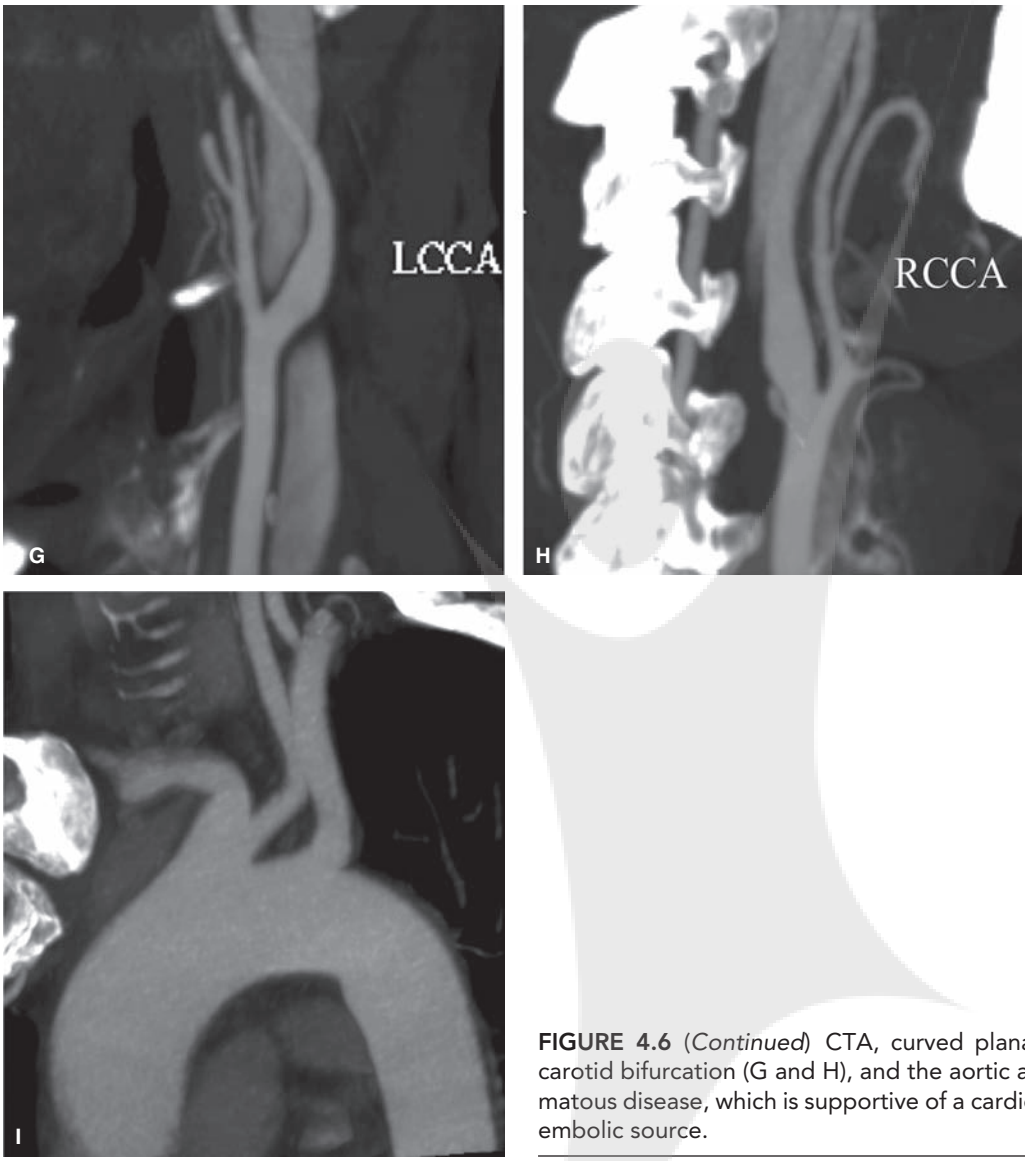

FIGURE 4.6 (*Continued*) CTA, curved planar reformats of the left and right carotid bifurcation (G and H), and the aortic arch (I) reveal no significant atheromatous disease, which is supportive of a cardioembolic rather than a large vessel embolic source.

flow weighted, and they frequently overestimate infarct core relative to the DWI lesion volume (45). The CTA-SI technique may also be important in risk stratification and in determining patient prognosis. In one study, CTA-SI increased the utility of the ASPECTS metric in predicting the clinical outcomes of acute stroke patients (46). In another, the degree of hypoattenuation on CTA-SI correlated with the likelihood of hemorrhagic transformation (47).

The extent of leptomeningeal arterial collateral supply can be noninvasively assessed in the acute setting using CTA (48). A robust collateral circulation supports the tissue surrounding the infarct core and decreases the extent of final ischemic injury in stroke patients with large vessel occlusion. Several studies have identified a malignant profile of collateral circulation on CTA that stratifies patients who are likely to do poorly (49,50). One study found that a malignant collateral profile in the setting of a proximal arterial occlusion was highly specific for large admission DWI lesion size and poor functional outcome (49), while another found high mortality and poor outcome despite early intravenous thrombolysis (50). Studies have also shown that the extent of CTA collaterals can predict both the final infarct volume following (51), and the clinical response to, endovascular therapy (52).

CTA does have some disadvantages. One of the most significant is the risk of contrast nephropathy (53,54). This is especially heightened in patients with reduced renal function, diabetes, or both. However, a recent large study of acute stroke patients who received CTA and CT perfusion (CTP) within 24 hours of admission found no increased risk of contrast-induced nephropathy compared with unexposed patients (55). These findings support the practice in many institutions of deferring a creatinine level in order to save valuable time for patients being considered for urgent intra-arterial recanalization procedures. In addition, a risk of contrast-induced allergic reactions does exist. Although

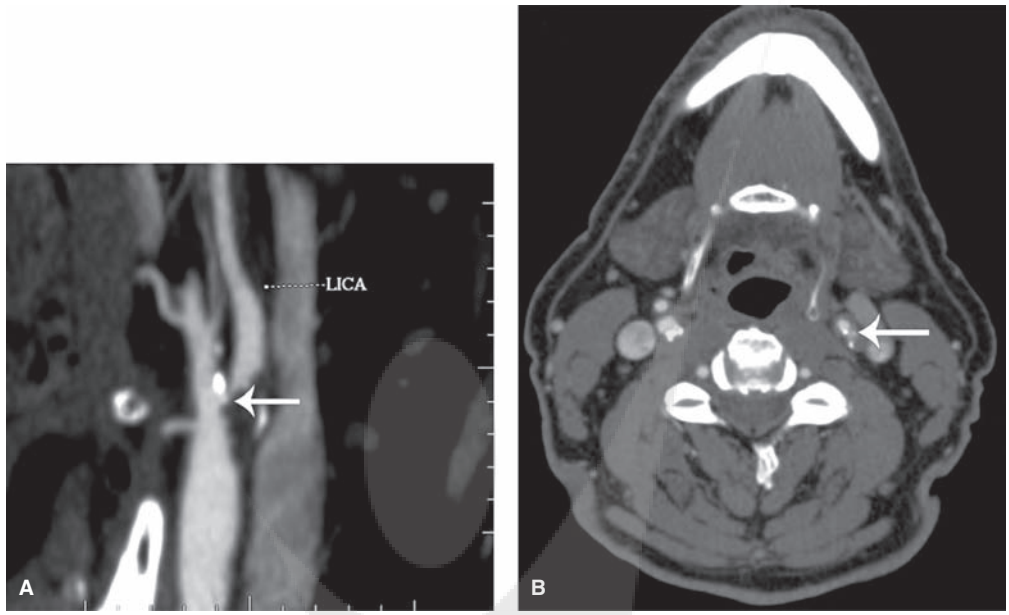

FIGURE 4.7 Carotid stenosis on CTA. Sixty-four-year-old male presenting with acute left hemiparesis. CTA, sagittal reformatted (A), and axial source (B) images demonstrate a large hypodense asymmetric plaque at the left carotid bifurcation extending into the proximal left ICA, causing severe stenosis (arrows). This disease was likely the site of the patient's embolus.

nonionic contrast agents have decreased the overall risk of contrast-induced reactions, there is a 0.03% risk of an anaphylactic reaction for nonionic, iodinated contrast agents (56). CTA also imparts a radiation dose, a particularly important fact to consider when imaging children and pregnant women. Multiple CTA examinations can result in a large cumulative dose.

MR ANGIOGRAPHY

MR angiography (MRA) techniques utilized in stroke imaging include noncontrast-enhanced time-of-flight (TOF) imaging as well as gadolinium-enhanced MRA. The physical principles underlying both techniques are complicated and are beyond the scope of this chapter. Briefly, TOF techniques utilize a gradient-echo sequence that saturates signal from the stationary spins within a volume of tissue. This is accomplished by multiple radio frequency pulses, followed by dephasing and rephasing gradients. Thus, the only unsaturated spins (signal) are within blood flowing from outside into the volume of interest. Generally, the contrast is proportional to the velocity of flow (57). A saturation band decreases signal from venous flow, which is usually in the opposite direction from the arterial flow. Two-dimensional TOF MRA is generally performed for evaluation of the cervical arterial vasculature with the acquisition of multiple, contiguous, thin slices of tissue. Three-dimensional TOF MRA is usually used to evaluate the intracranial vasculature. This technique, as its name implies, acquires a volume of tissue and, with an additional phase-encoding step, partitions the volume into thin slices (Figure 4.8).

Three-dimensional TOF MRA provides an increased signal-to-noise ratio and a higher spatial resolution versus the two-dimensional TOF technique. However, the volume covered is restricted by vascular saturation artifact, thus limiting it largely to the intracranial vasculature. Both techniques, particularly the two-dimensional TOF technique, are susceptible to signal loss from turbulent flow. From a diagnostic standpoint, this tends to cause overestimation of vascular stenoses. A combination of the two techniques called multiple overlapping thin slab acquisition (MOTSA) exists. It allows larger volumes of coverage with decreased saturation effects and increased spatial resolution.

Phase contrast techniques, based on quantitation of the differences in the transverse magnetization between stationary and moving spins, are not typically performed in the evaluation of stroke patients because of the much longer acquisition times that make this technique vulnerable to motion artifact. However, this technique can be used for the evaluation of flow in collateral vessels because, unlike TOF MRA, the technique can measure flow direction.

Contrast-enhanced MRA techniques, based on a short rapid gradient-echo sequence, image a bolus of intravenous gadolinium contrast in the arterial phase. The contrast agent shortens the T1 within vessels. This allows good separation of vessels from surrounding longer T1 soft tissues (57). Compared to TOF techniques, contrast-enhanced MRA provides coverage of a larger volume with a shorter acquisition time and less vulnerability to patient motion. In addition, this technique generally provides better signal-to-noise ratios than TOF techniques and has fewer artifacts related to dephasing from turbulence and saturation effects. For these

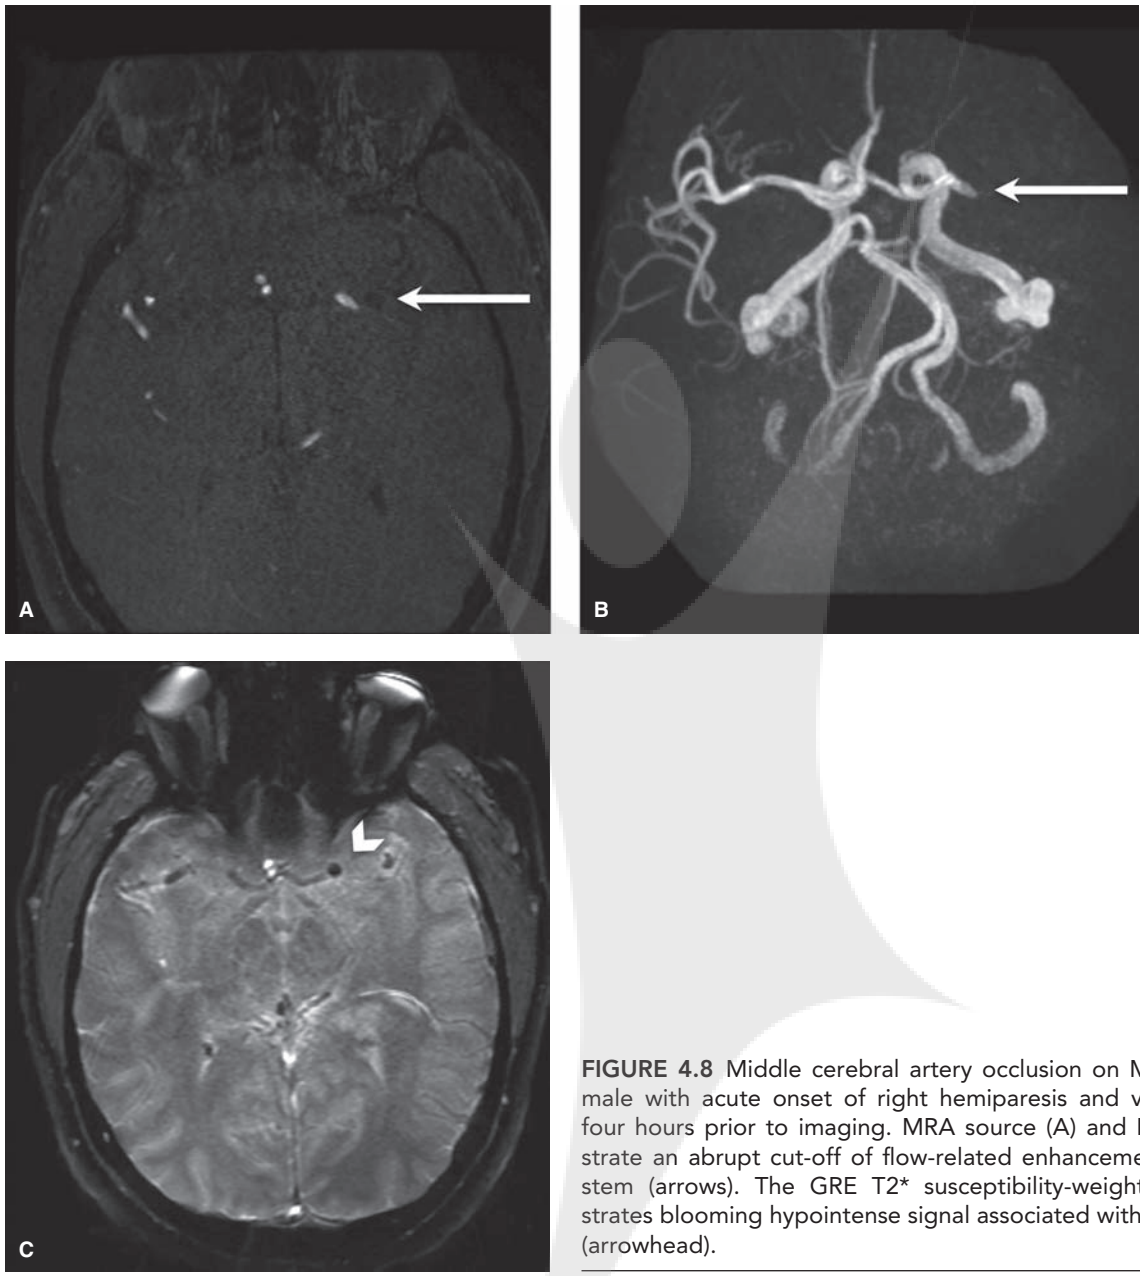

FIGURE 4.8 Middle cerebral artery occlusion on MRA. Forty-five-year-old male with acute onset of right hemiparesis and verbal unresponsiveness four hours prior to imaging. MRA source (A) and MIP (B) images demonstrate an abrupt cut-off of flow-related enhancement within the left MCA stem (arrows). The GRE T2* susceptibility-weighted image (C) demonstrates blooming hypointense signal associated with the left MCA thrombus (arrowhead).

reasons, contrast-enhanced MRA is often used to image the arteries of the neck (Figure 4.9). This can be accomplished in approximately one to two minutes. However, contrast-enhanced MRA has worse spatial resolution compared to noncontrast MRA, making the technique less suitable for imaging the smaller vessels of the head.

Multiple studies have demonstrated that contrast-enhanced MRA is highly accurate in differentiating surgical from nonsurgical carotid artery stenoses (58). Other studies have suggested that MRA is also highly accurate in detecting proximal intracranial occlusions (59,60). However, from a practical standpoint, MRA images of the head and neck are generally inferior to CTA images for scanning acute stroke patients on an emergency basis because motion artifact is a common problem (Table 4.5). Also, compared to CTA, contrast-enhanced MRA images have a narrower window for acquiring images during peak contrast enhancement. Consequently, inadequate arterial enhancement and venous contamination are common problems. Thus, in the acute stroke practice at the Massachusetts General Hospital, MRA is generally utilized only to evaluate patients with allergies to CT contrast agents, patients with renal failure, and patients such as children and pregnant women who are particularly vulnerable to radiation. However, gadolinium-enhanced MRA techniques cannot be used in patients with renal failure because of the increased risk of their developing nephrogenic systemic fibrosis (NSF) (61). Also

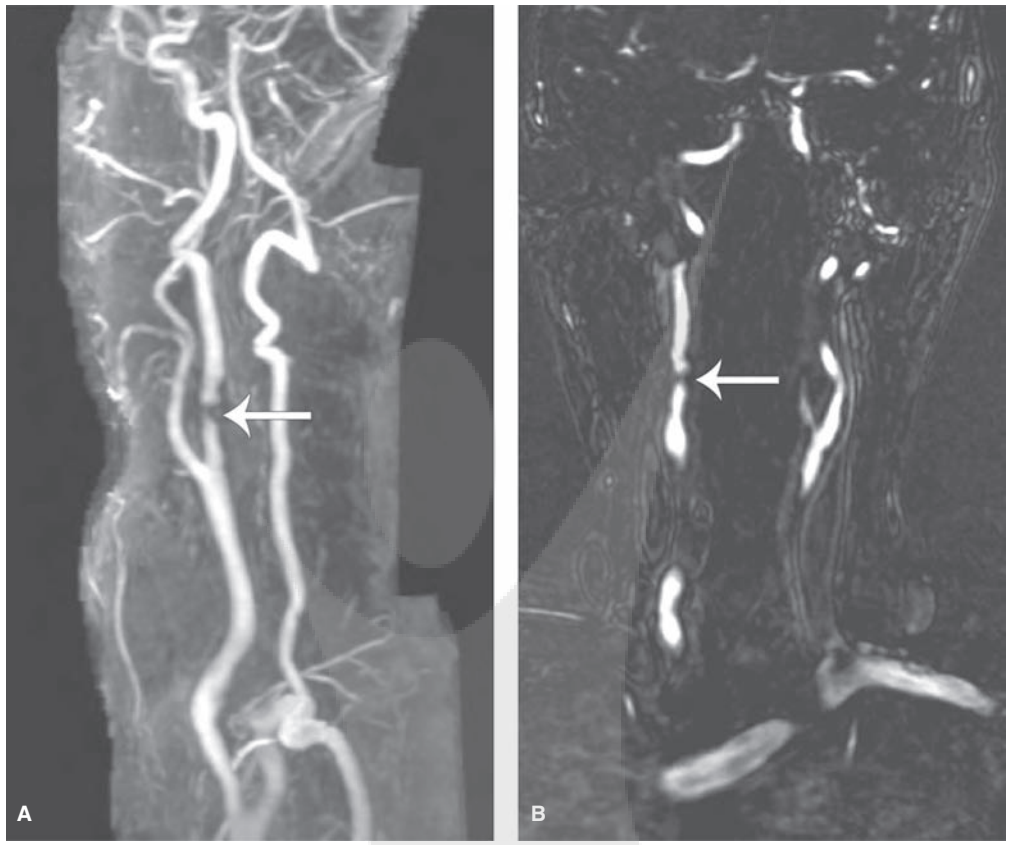

FIGURE 4.9 Carotid stenosis on MRA. Gadolinium-enhanced MRA of the neck MIP (A) and source (B) images demonstrate signal dropout, consistent with a focal severe stenosis of the proximal right internal carotid artery (arrow).

TABLE 4.5 CTA and MRA Comparison in the Acute Stroke Setting

	CTA	MRA
Advantages	• Rapid acquisition speed, resulting in decreased motion artifact and greater coverage • Cost and availability: Cheaper physical plant and wider dissemination in the acute setting • Accuracy: Nonflow-dependent technique with higher spatial resolution • Higher accuracy for detection of proximal vessel occlusion • Better collateral flow assessment • CTA source images of value in infarct detection • Can be utilized where MR is contraindicated, for example, patients with non-MR-compatible implantable devices	• Good for patients with allergic contraindications to iodinated contrast • Can provide velocity and flow direction data
Disadvantages	• Contrast-dependent techniques in patients with allergies and renal failure • Radiation dose cumulative effect, especially in repeated imaging	• More susceptible to motion artifact • High cost and less accessibility of equipment • Inferior accuracy • Contrast-dependent techniques in patients with renal abnormalities, such as nephrogenic systemic fibrosis (NSF) (56)

present is a relative contraindication to gadolinium contrast utilization in pregnant patients (62).

In addition, gadolinium contrast agents are associated with a small (0.01% or less) risk of anaphylactic reactions (63), although the risk is lower than for iodinated contrast agents in CTA.

CONVENTIONAL ANGIOGRAPHY

Although potentially a front-line diagnostic tool, the risks associated with this invasive procedure, such as stroke, the relatively long preparation time, and relative cost preclude the use of this modality in most diagnostic acute stroke evaluations. However, catheter-guided therapy using digital subtraction angiography has an important role in acute stroke management. The use of intra-arterial thrombolytic agents, mechanical clot disruption, and clot retrieval for the treatment of acute stroke are discussed in subsequent chapters.

PERFUSION IMAGING

The circulation of blood through a vascular bed defines tissue perfusion. In the acute stroke setting, perfusion imaging is generally performed with a bolus tracking technique in which a contrast agent is injected rapidly (5–7 cc/sec) into a peripheral intravenous catheter and images are obtained repeatedly as the contrast agent passes through the brain. The technique takes approximately one to two minutes and is performed such that it is sufficient to track the first pass of the contrast bolus through the intracranial vasculature without recirculation effects. The images obtained in the examination are converted by a computer to contrast agent concentration versus time curves. The cerebral blood volume (CBV) is proportional to the area under the curve. The cerebral blood flow (CBF) and mean transit time (MTT) are computed by deconvolution using an arterial input function. Cerebral perfusion parameters are related according to the central volume theorem, that is, MTT = CBV/CBF. Other frequently used transit time parameters are T_{max} (the time at which the deconvolved residue function reaches its maximum) and time to peak contrast concentration (TTP).

Several variants of MR perfusion broadly employing endogenous and exogenous labeling of blood exist (Figure 4.10). The primary method is a dynamic susceptibility (T2*) contrast sequence that relies on the decrease in signal caused by the magnetic susceptibility effects of gadolinium as it passes through the intracranial vasculature (64). Because blood passes through the brain parenchyma rapidly, the most commonly used sequence is a single-shot gradient-echo echo-planar sequence (EPI) capable of multiple slice acquisition from a single repetition time (TR). Approximately 60 images are obtained for each 5-mm brain slice, and the whole brain is covered. Historically, the arterial input was typically chosen from the ipsilateral or contralateral MCA, but currently is frequently chosen automatically using cluster analysis (65).

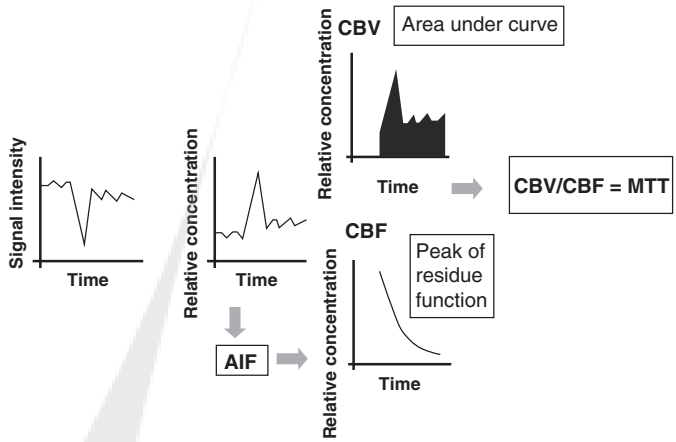

FIGURE 4.10 MR perfusion scheme. For each pixel in each image slice, a graph of signal intensity as a function of time is converted into a change in rate of susceptibility (T2* effect) caused by gadolinium, which is proportional to the gadolinium contrast agent given. This curve can then be used to compute relative CBV, which is proportional to the area under the curve. Using a deconvolution technique, where an arterial input function (AIF) that describes the contrast left in the arteries is used, cerebral blood flow (CBF) can be calculated. CBV/CBF gives mean transit time (MTT).

For CT, brain tissue increases and then decreases again in density as an iodine-based contrast agent passes through the brain. Briefly, the technique utilizes a standard cine protocol that obtains approximately 60 sequential images for each scan location over a given volume of coverage (slab). The slab is 4 cm for 64 detector scanners and up to 16 cm for the latest 256 and 320 detector scanners. On current-generation scanners, the volume of coverage can also be increased above the physical detector limit, on the order of 6 to 16 cm, through the use of vendor-specific techniques such as adaptive spiral scanning or simultaneous scanning of two slabs in a single acquisition (shuttle mode). The volume of tissue imaged is divided into 5-mm-thick slices. The arterial input function is usually chosen from the anterior cerebral artery or the top of the internal carotid artery, or may be automatically chosen by the vendor software using a summation of large vessels. The venous output function, which is required for CT but not for MRI, is usually chosen from the superior sagittal sinus.

A number of studies have demonstrated that lesion volumes on CT perfusion (CBV, CBF, and MTT) maps correlate highly with those obtained from similar MR perfusion maps (66,67). However, the degree of correlation depends strongly on the volume of anatomical coverage of CTP (68). Compared to MRP, CTP offers wider availability in the acute setting, lower cost, higher speed of acquisition, higher spatial resolution, and quantitative perfusion estimates. Also, CTP can be readily performed in patients with contraindications to MR imaging, such as pacemakers. Compared to CTP, however, MRP generally offers a larger volume of coverage and avoids a relatively large dose of radiation.

In addition, MRP avoids iodinated contrast-related risks, including contrast allergy and contrast-induced nephropathy, particularly important in older patients at higher risk for stroke syndromes.

CBV, CBF, and MTT relate to acute ischemia as follows. With the onset of acute ischemia, loss of cerebral perfusion pressure (CPP) exceeds the autoregulatory capacity of the cerebral vasculature, and CBF begins to fall. There is compensatory vasodilatation and capillary recruitment that increases the effective vascular cross-sectional surface area, resulting in a lower blood velocity and an increase in MTT. A decrease in the velocity of blood as it passes through the capillaries is adaptive, as it allows time for a greater oxygen extraction fraction (OEF). With a modest impairment of blood flow, this mechanism allows for preservation of blood volume and of oxidative metabolism without alteration in electrical function. However, when CPP and, therefore, CBF are sufficiently low, OEF reaches a maximum and cannot increase further. Brain tissue ceases to function electrically, resulting in a neurologic deficit. If the oxygen supply falls low enough, the tissue dies. The amount of time it takes for tissue to suffer irreversible damage is inversely related to the severity of the ischemic insult. Tissue that is completely deprived of blood will die within a few minutes, but less severely hypoperfused tissue may survive for many hours and may be saved by therapeutic intervention.

It has been suggested that when CPP becomes very low, microvascular collapse occurs and CBV falls. However, the early studies on which the current understanding of cerebral hemodynamics is based offer little direct evidence of decreased CBV. These studies focused more often on the CBV/CBF ratio (i.e., MTT), rather than CBV itself (69). In fact, early studies often found that CBV was elevated, although these measurements were usually made in subacute infarcts (70–72).

Imaging the Infarct Core and Ischemic Penumbra

In the clinical setting, radiologists and neurologists evaluate the diffusion and perfusion images to determine the infarct core and ischemic penumbra (Table 4.6). Operationally, for MRI, the DWIs (depicting changes from cytotoxic edema) are thought to represent the infarct core or tissue that is severely ischemic, is irreversibly damaged, and is unlikely to survive in spite of acute intervention. For CT, definition of the infarct core is controversial. Some investigators choose thresholded CBV maps to represent infarct core. Others have shown that CBV can be elevated or decreased in infarct core and choose thresholded CBF maps to represent the infarct core.

With proximal emboli, MTT and other transit time (T_{max}, TTP) lesion volumes are generally much larger than the DWI or thresholded CBV/CBF lesions. Tissue that appears normal on the DWIs and thresholded CBV/CBF images but abnormal on the MTT and other transit time images is thought to represent the ischemic penumbra. The ischemic penumbra usually surrounds the core where collateral vessels supply some residual perfusion. The penumbra represents tissue that may progress to infarction or may recover, depending on the timing of reperfusion and the degree of collateralization. It is tissue that can potentially be salvaged with reperfusion therapy.

TABLE 4.6 Summary of Perfusion-Weighted Parameters and Prediction of Tissue Viability

PARAMETER	INFORMATION
DWI	Infarct core, generally irreversible and highly predictive of final infarct volume
CBV	Thresholded CT CBV used by some investigators to define infarct core. Thresholds vary depending on vendor
CBF	Thresholded CT CBF used by some investigators to define infarct core. Thresholds vary depending on vendor Nonthresholded CBF yields operational penumbra. For proximal occlusions, nonthresholded CBF is usually much larger than DWI
MTT, T_{max}, TTP	Yield operational penumbra. Thresholded maps may separate benign oligemia from tissue at risk. For proximal occlusions, MTT, T_{max}, and TTP are usually much larger than DWI

A number of investigators have tried to establish CT and MR perfusion parameter thresholds that define the infarct core and penumbra. Unfortunately, reported thresholds are highly variable, as highlighted in a recent article by Dani et al., who reviewed 20 CT perfusion and 49 MR perfusion studies. CT perfusion parameter ranges for penumbra included MTT 6.53–7.0 seconds; relative MTT 1.45–2.2; and relative CBF 0.50–0.63. MR perfusion parameter ranges for penumbra were MTT 1.78–8.1 seconds; TTP 4–7 seconds, and relative CBF 0.58–0.61 (73). Recently, authors and trials evaluating MR-PWI as a selection criterion for thrombolytic therapy have used various MR-T_{max} thresholds, with values ranging from more than 2 seconds to more than 6 seconds for penumbra and more than 6 seconds to more than 10 seconds for infarct core (74–79).

The variability in perfusion thresholds likely results from a number of different factors. Most importantly, the data obtained represent only a single time point in a dynamic process. In addition, postprocessing techniques are inconsistent between manufacturers and introduce a significant source of variability in defining appropriate and generalizable thresholds. For example, one CTP study found that CT-CBF maps most closely approximated the DWI lesions, but that the thresholds varied up to two-fold among various postprocessing software (80). Another found that CT-MTT maps best distinguished benign oligemia from tissue at true risk; however, the precise thresholds depended upon whether the postprocessing software used a delay-corrected or standard algorithm (81). Yet another source of variability appears to be the timing of reperfusion therapy relative to initial perfusion imaging. One study found lower CBF thresholds for infarction in tissue that was reperfused earlier (82). Jones et al. demonstrated that both severity and duration of CBF reduction of

up to four hours define an infarction threshold in monkeys (83). The CBF threshold for tissue infarction with reperfusion at 2 to 3 hours was 10 to 12 mL/100 g/min, while the threshold for tissue infarction with permanent occlusion was 17 to 18 mL/100 g/min. Another factor is that normal average cerebral blood flow in human parenchyma varies greatly, from 21.1 to 65.3 mL/100 g/min, depending on age and location in gray matter versus white matter (84,85). Indeed, one study demonstrated variable regional ischemic vulnerability of the brain to hypoperfusion on CTP, suggesting that location-specific rather than whole-brain thresholds may provide a more accurate assessment of infarct core and penumbra (86). Other factors include variability in initial and follow-up imaging times, and in postischemic tissue responses.

Although somewhat controversial, the assumption that the DWI-MTT mismatch (MR perfusion) and the thresholded CBV/CBF-MTT mismatch (CT perfusion) represent the ischemic penumbra implies that patients with a large mismatch are most likely to benefit from intravenous thrombolytic therapy and endovascular procedures because they have the largest volume of threatened tissue that may be salvaged (Figures 4.11–4.14, Table 4.7). If these patients cannot be treated with intravenous thrombolytic therapy or intra-arterial procedures, then they should be treated aggressively

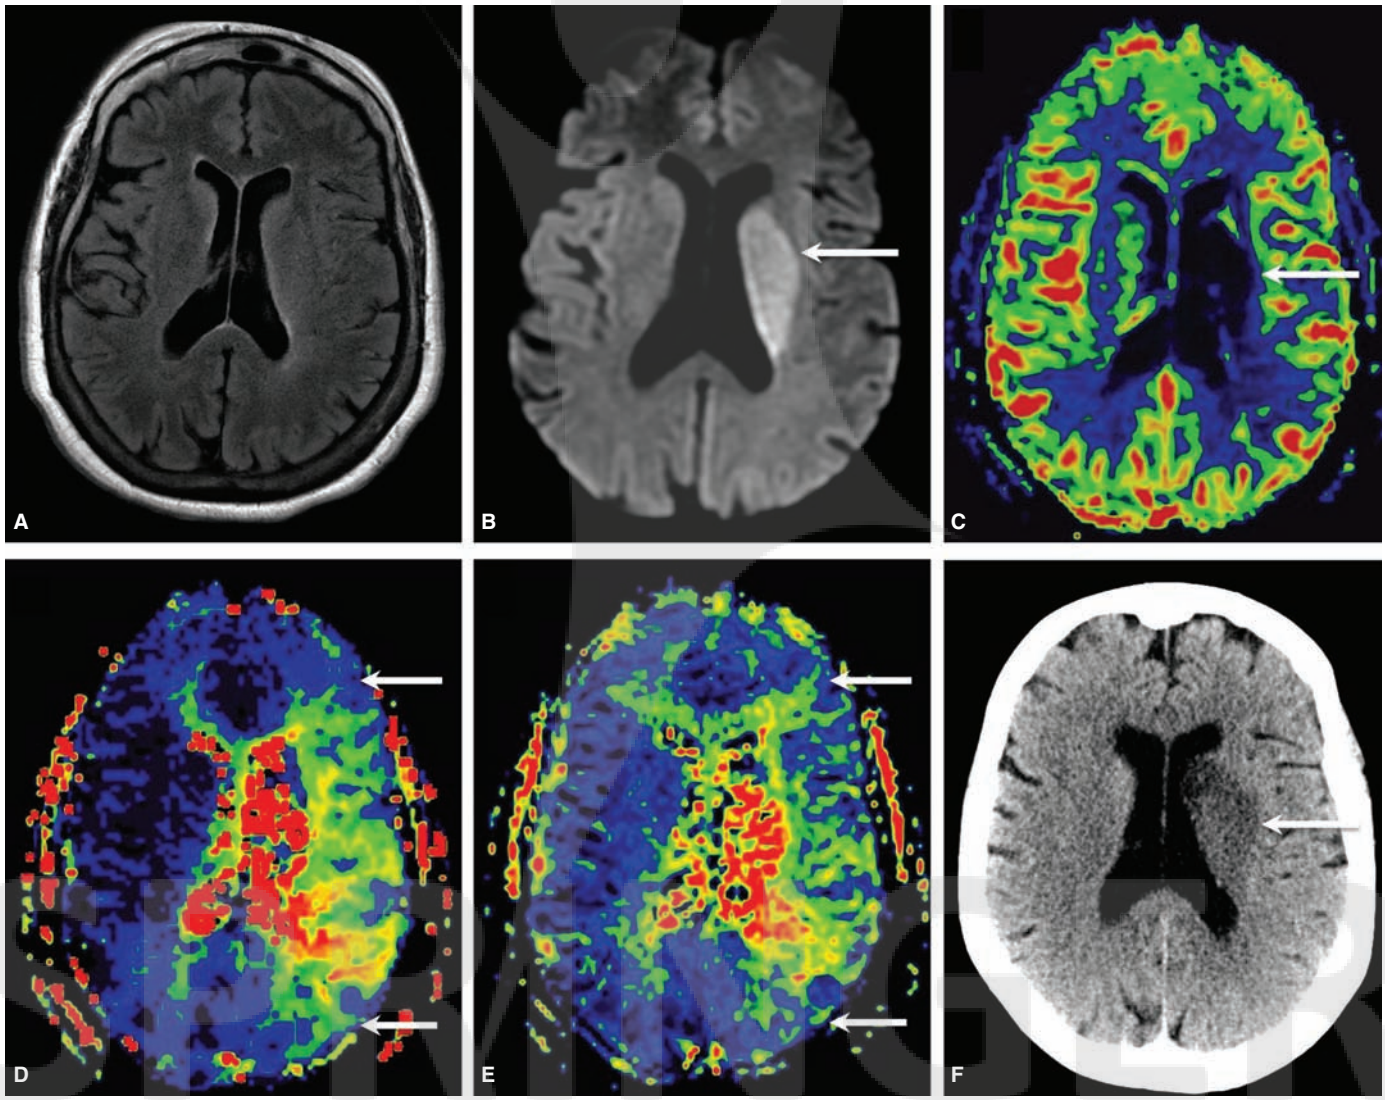

FIGURE 4.11 A 71-year-old male developed acute-onset aphasia and right hemiparesis two hours prior to MR imaging. There are no significant parenchymal findings on FLAIR (A) to suggest a completed infarction. DWI (B) shows restricted diffusion within the left basal ganglia and corona radiata (arrow), consistent with acute infarction. MR perfusion CBF map (C) shows severely decreased blood flow within the left basal ganglia (arrow) corresponding to the area of acute infarction on DWI. There is increased T_{max} (D) and MTT (E) within a large portion of the left MCA territory (delineated by arrows), without corresponding abnormality on diffusion. The large area of diffusion–perfusion mismatch within the left MCA territory suggests tissue at risk for infarction without recanalization (penumbra). A follow-up CT (F) performed 48 hours following successful intra-arterial recanalization of the occluded left MCA reveals hypodense infarct that matches the area of acute infarction on the admission MRI, suggesting salvage of the ischemic penumbra.

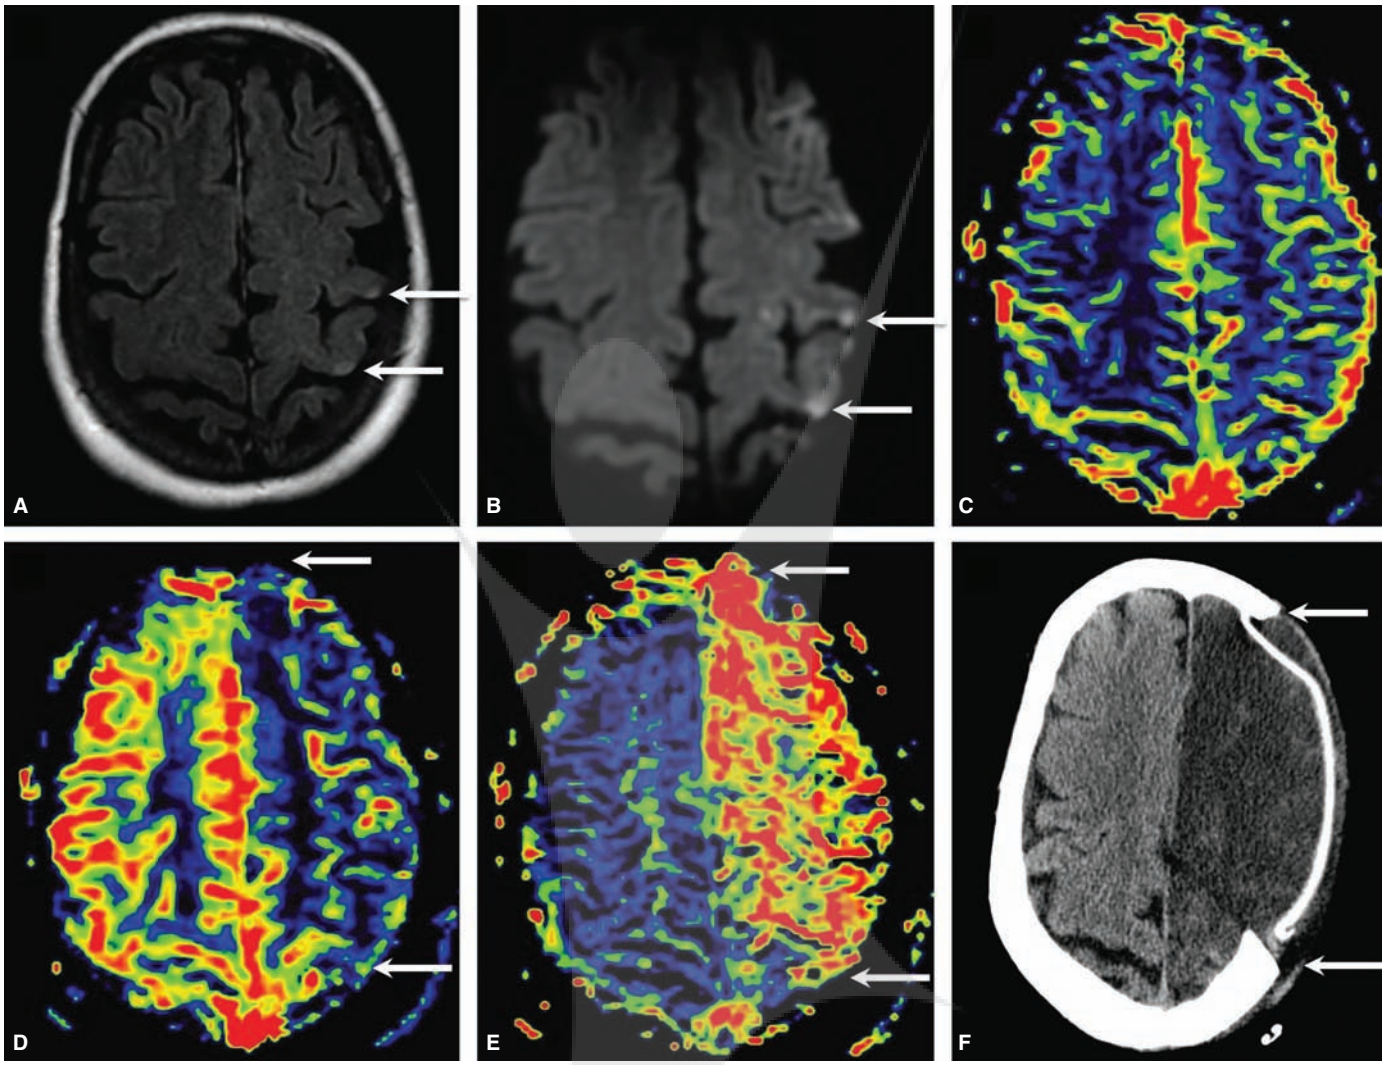

FIGURE 4.12 A 76-year-old woman developed acute-onset right hemiparesis 2.5 hours prior to MR imaging. There are a few tiny foci of FLAIR hyperintensity (A) and restricted diffusion (B) within the left precentral and middle frontal gyri (arrows), consistent with acute infarction. MR perfusion shows markedly decreased CBF (D) and increased MTT (E) within the entire visualized left MCA and ACA territories (delineated by arrows), involving a much larger area than the diffusion abnormality. CBV (C) is approximately symmetric. The extensive area of diffusion–perfusion mismatch is suggestive of tissue at risk for progressing to infarction without treatment. CTA (not shown) demonstrated thrombosis of the left internal carotid artery and proximal anterior and middle cerebral arteries. Attempted intra-arterial recanalization was unsuccessful. Follow-up head CT performed one week after symptom onset shows hypodense infarction of the entire left MCA and ACA territories (delineated by arrows), with postsurgical changes related to left hemi-craniectomy and duraplasty performed for cerebral edema. This is an example of a large diffusion–perfusion mismatch with subsequent infarction of tissue at risk.

with hypertensive therapy. Conversely, patients with little or no diffusion–perfusion mismatch should not receive aggressive therapies because their infarctions are unlikely to increase in size, and they should be spared the associated risk of hemorrhage (Figure 4.15).

The concept that the mismatch represents the ischemic penumbra and should be used as a selection criterion for intravenous thrombolysis and endovascular procedures is supported by studies demonstrating that patients with larger mismatches have more lesion growth (87). More importantly, a number of studies have shown that intravenous thrombolysis may be beneficial more than three hours after stroke onset, provided that only patients with a significant diffusion–perfusion mismatch are treated. Ribo et al. found that patients with a more than 50% diffusion–perfusion mismatch could be treated safely and effectively with IV-tPA in the three- to six-hour time period (88). In phase II of the DIAS trial, patients with diffusion–perfusion mismatch were treated with desmoteplase up to nine hours after stroke onset and showed better outcomes than patients given placebo, with only a minimal incidence of symptomatic hemorrhage (89). Similar success was achieved in the same time window

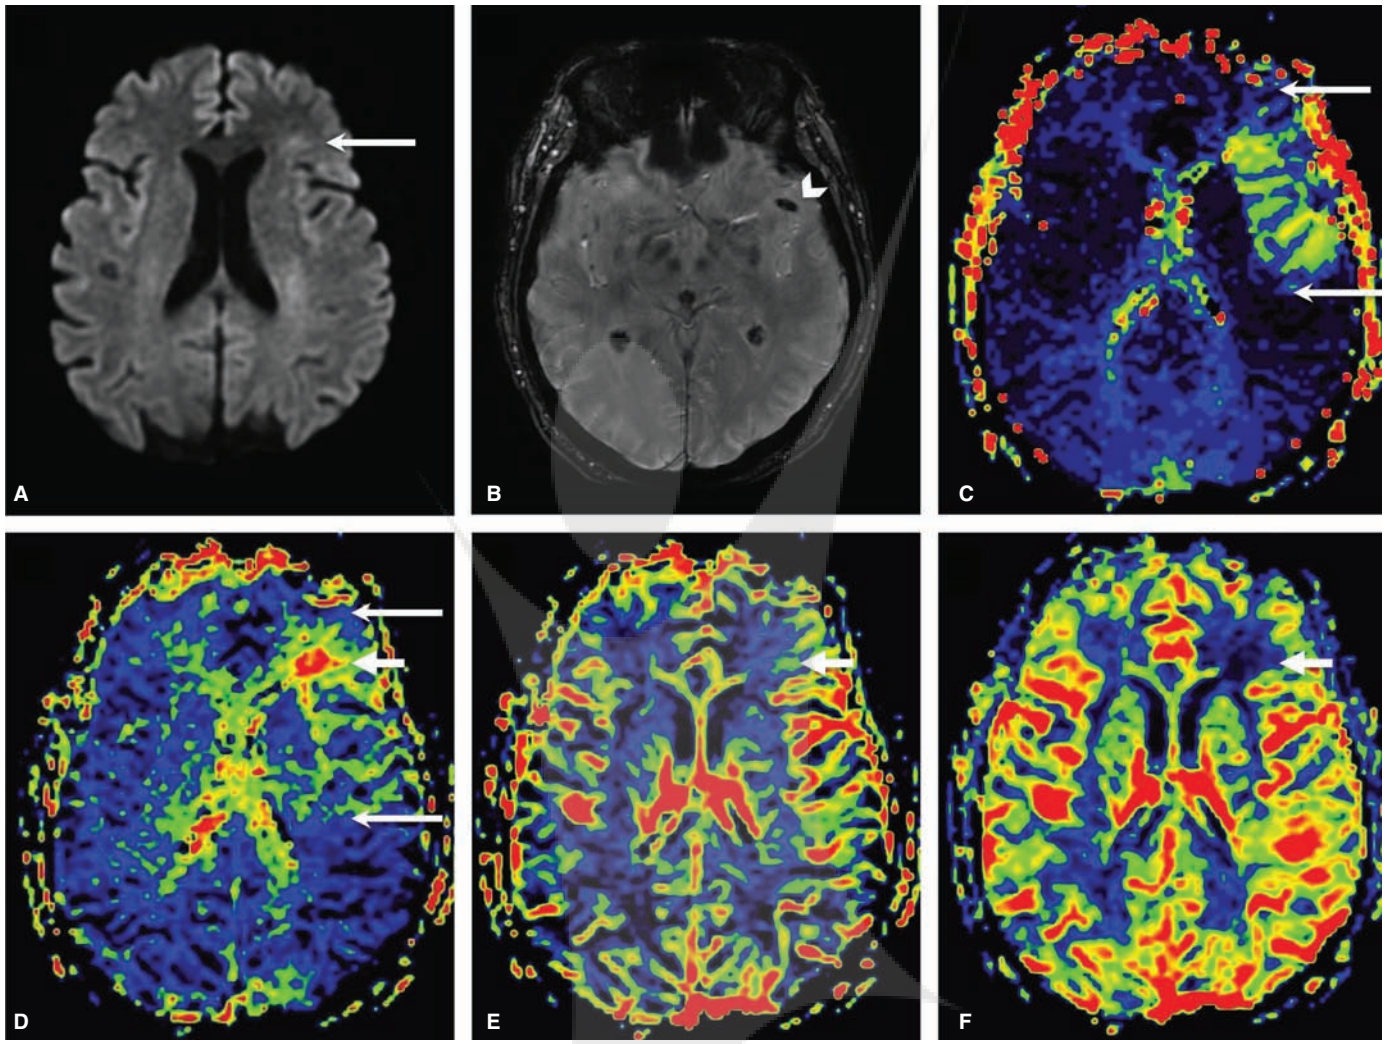

FIGURE 4.13 A 77-year-old man developed acute-onset aphasia and right hemiparesis five hours prior to MR imaging. DWI (A) shows mild focal hyperintensity within the left frontal operculum consistent with early ischemia (arrow). Susceptibility-weighted image (B) shows focal blooming hypointense signal, consistent with embolic clot within a proximal left M2 branch of the MCA (arrowhead). There is transit time delay with prolonged T_{max} (C) and MTT (D) involving a large portion of the left MCA territory (delineated by arrows), which corresponds to the territory supplied by the occluded left M2 branch. Within this region, there is a smaller area of more severely elevated MTT, mildly increased CBV (E), and decreased CBF (F) (short arrow), which corresponds to the region of diffusion abnormality. (*Continued*)

by the dose escalation study of DEDAS (90). In contrast, these early positive results were not replicated in the larger DIAS-2 phase III trial that followed, in which patients with diffusion–perfusion mismatch treated with desmoteplase between three and nine hours after stroke onset showed no benefit compared with placebo (91). The study authors speculate that the unexpectedly high placebo response rate may have been because of a higher proportion of mild strokes than in the previous trials, with smaller DWI lesion volumes, fewer proximal vessel occlusions, and lower NIHSS. In addition, a post hoc analysis of pooled data from DIAS, DEDAS, and DIAS-2 showed a positive treatment effect of desmoteplase in both the pooled sample and in the DIAS-2 patients when a mismatch volume of 60 mL or greater was used, rather than the visually apparent mismatch criteria (approximately >20% mismatch) used in these trials. The study showed no treatment effect relative to placebo for patients with mismatch volumes less than 60 mL in both DIAS-2 and pooled data, suggesting that higher minimum mismatch volumes may be required to detect treatment benefits in future trials (92).

Additional more recent trials also support the DWI/PWI mismatch model for selection of patients for reperfusion therapies. In both the diffusion and perfusion imaging evaluation for understanding stroke evolution (DEFUSE) trial and the DEFUSE-2 trial, patients receiving reperfusion therapy (intravenous tPA and endovascular therapy, respectively) between three to six hours were stratified based on predefined DW-PW imaging profiles, and both showed a favorable clinical response in the patients with "target mismatch" that had early reperfusion relative

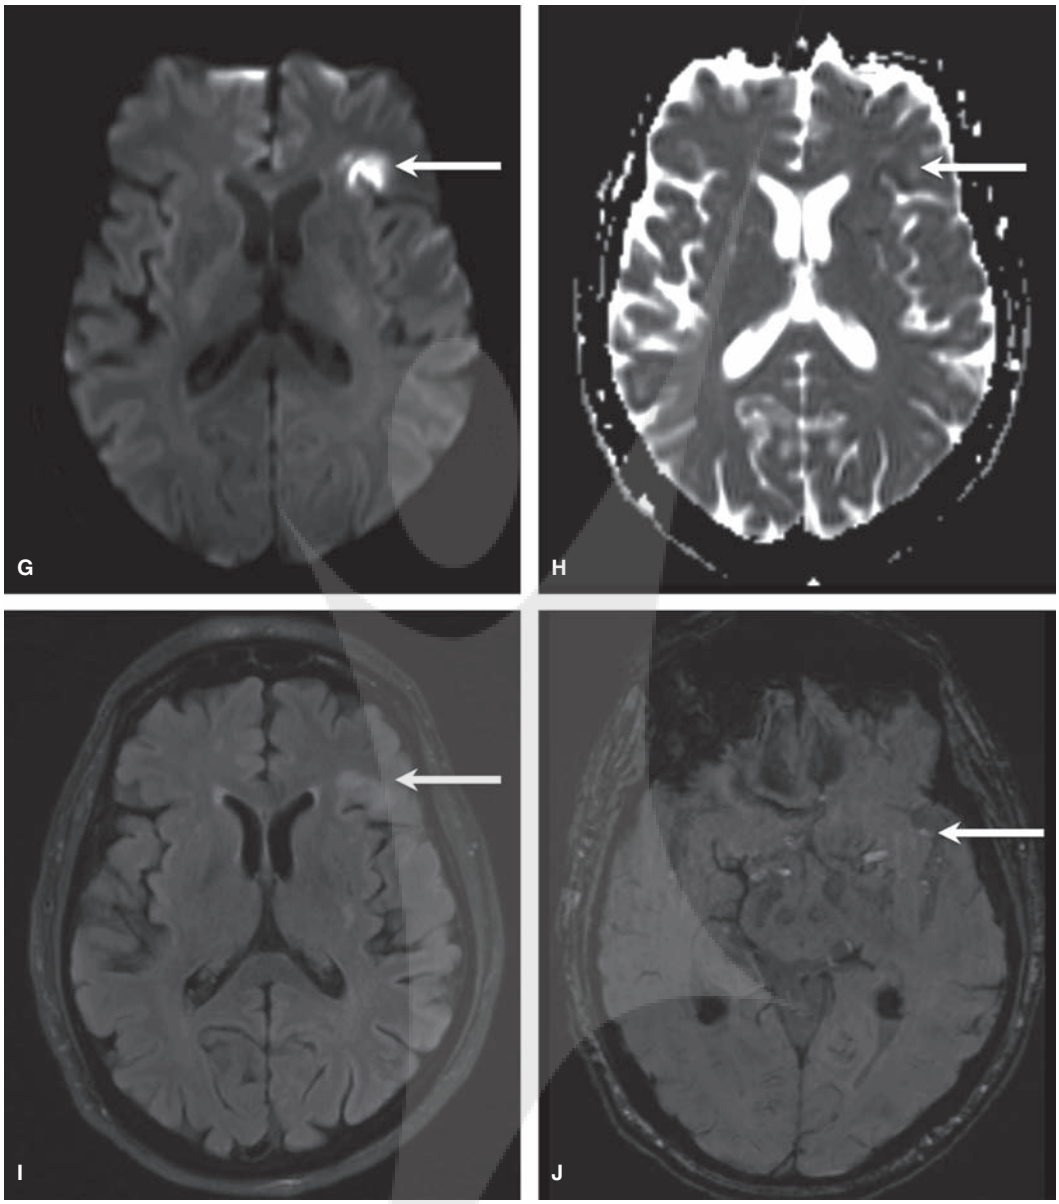

FIGURE 4.13 (*Continued*) The combination of findings suggests a small area of early infarction in the left frontal operculum, with a larger area of diffusion–perfusion mismatch suggesting tissue that may be at risk for progressing to infarction without recanalization. Follow-up MRI performed three days following symptom onset shows acute infarction on DWI (G), ADC map (H), and FLAIR (I) images (arrows) involving the region of most severely increased MTT on the initial MRI scan, with preservation of the remaining diffusion–perfusion mismatched tissue that was at risk for infarction. Follow-up susceptibility-weighted image (J) shows interval recanalization of the left MCA, with resolution of the blooming hypointense clot seen on the initial MRI scan (arrow).

to those with "no mismatch" or "malignant" profiles (78,79). In the more recent DEFUSE-2 trial (endovascular therapy), a "target mismatch" profile was defined as (a) a ratio between the volumes of critically hypoperfused tissue (T_{max} > 6 s) and an ischemic core (ADC < 600 × 10^{-6} mm^2/s) of 1.8 or more, with an absolute difference of 15 mL or more; (b) ischemic core volume less than 70 mL; and (c) less than 100 mL of tissue with severe delay in bolus arrival (T_{max} > 10 s). Early reperfusion was defined as more than 50% reduction in volume of the perfusion lesion (T_{max} > 6 s) between baseline and early follow-up. The adjusted odds ratio for a favorable clinical response associated with reperfusion was 8.8 in the target mismatch group, and only 0.2 in the no target mismatch group. These studies raise the possibility that, one day, imaging-based treatment protocols may allow for intravenous thrombolysis and endovascular reperfusion therapies in selected patients well outside the now-accepted three- and six-hour time windows, respectively, and could allow treatment of a much larger number of patients.

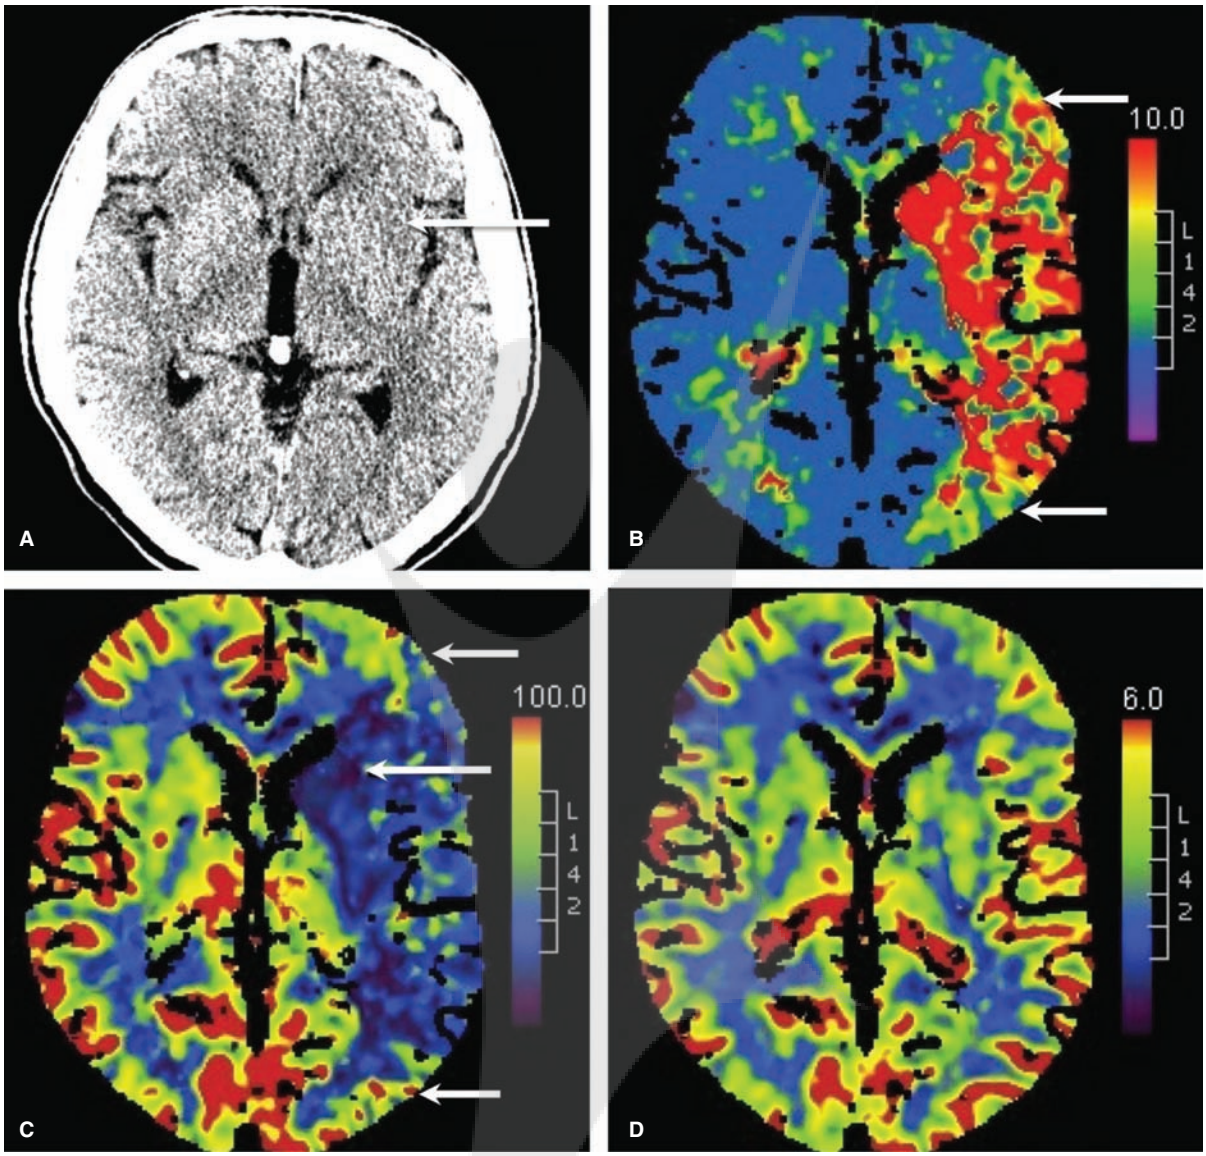

FIGURE 4.14 Fifty-seven-year-old female presented with right hemiparesis and aphasia, last seen normal 2.5 hours prior to imaging. Noncontrast CT (A) reveals subtle loss of gray–white matter differentiation within the left lateral putamen (arrow), which is faintly visible with narrow window level settings. CT perfusion maps reveal a large area of increased MTT (B) and decreased CBF (C) involving the entire left MCA territory (delineated by short arrows), with preserved CBV in this region (D). There is a small focal area of more severely decreased blood flow (C) within the anterior left putamen (long arrow), which was confirmed to represent infarction core on follow-up MRI (not shown). The large mismatched region with increased MTT and decreased CBF, but normal CBV and noncontrast CT findings, may represent the penumbra, ischemic but viable, tissue at risk for infarction.

Even when an acute stroke patient is not a candidate for intravenous thrombolytic or endovascular therapy, perfusion-weighted imaging should be considered. For patients who cannot undergo MR imaging, CTP increases the detection of acute ischemia. In one study, CTP increased the sensitivity in detecting acute stroke by 18% compared with NCCT alone, and by 12% compared with NCCT and CTA-SI (93). For patients with an acute neurologic deficit and a normal DWI, perfusion imaging can help determine whether or not the acute deficit is ischemic; a wedge-shaped perfusion deficit suggests that the patient has ischemic but viable tissue, whereas normal perfusion suggests a nonvascular etiology for the patient's symptoms. In a patient with a DWI abnormality in one vascular territory, perfusion imaging can help determine stroke etiology; for example, PWI demonstrating abnormalities in multiple vascular territories suggests a cardioembolic or vasculitic etiology. Perfusion imaging also contributes to general patient outcome prediction models. One study including patients who received heparinization alone or intravenous thrombolytic and/or endovascular therapy showed that a combination of MR-MTT and DWI lesion volumes improved outcome prediction over NIHSS alone, with MTT volume less than 47 mL and

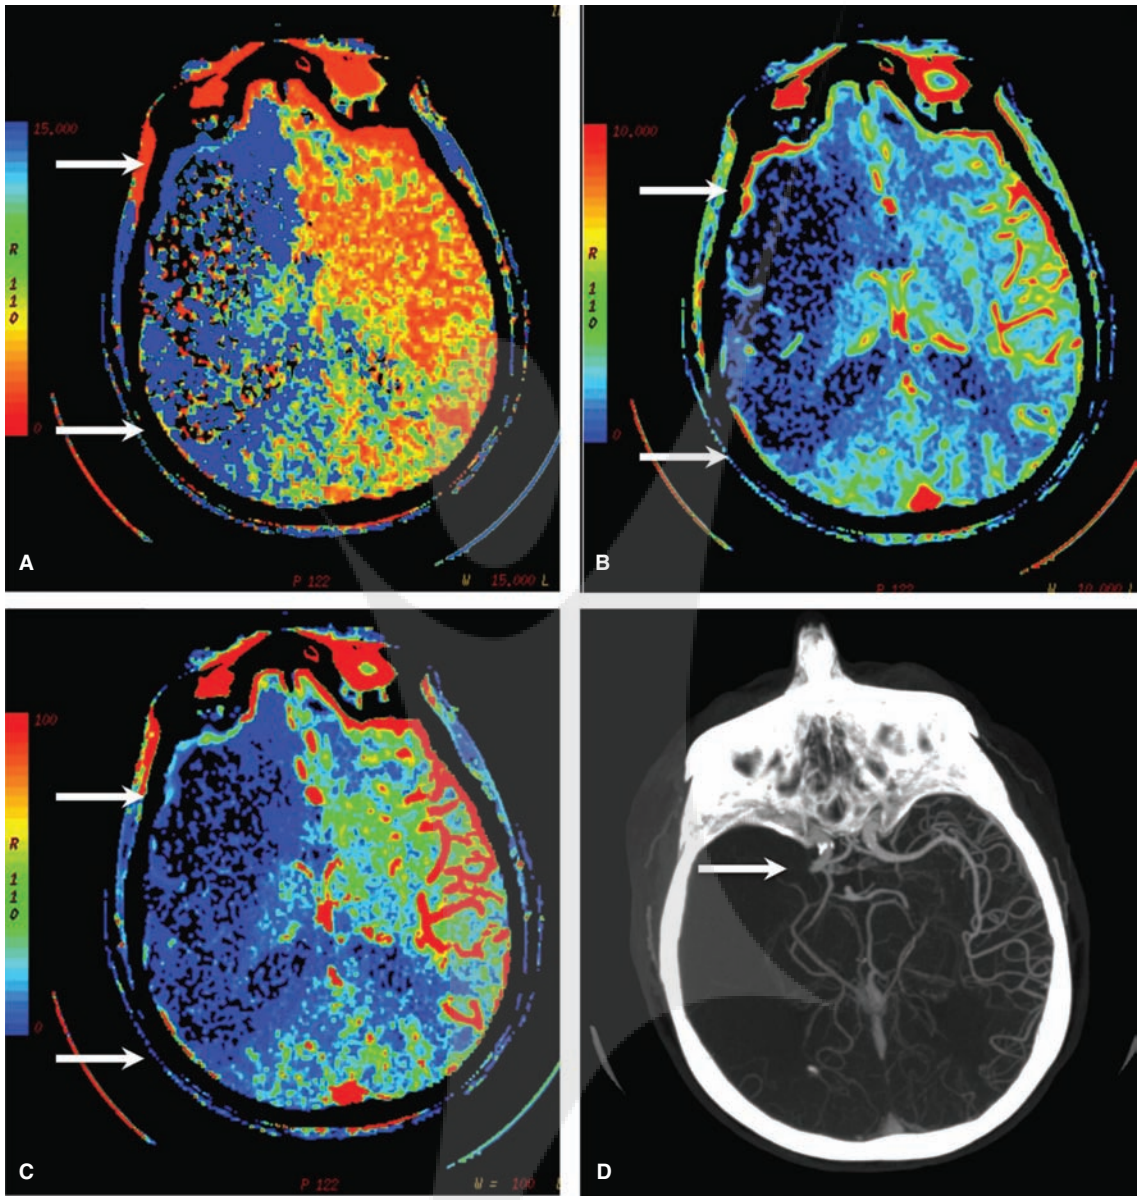

FIGURE 4.15 Eighty-eight-year-old female with atrial fibrillation with sudden onset of left hemiparesis, 1 hour and 20 minutes before imaging. CT perfusion maps demonstrate severely decreased CBV (B) and CBF (C) throughout the visualized right MCA territory, consistent with infarction core. There is also prolonged MTT (A) throughout the same region. There is no mismatch between the MTT images and regions of severely decreased CBV and CBF, suggesting that there is no tissue that is at increased risk for further infarction. The CTA MIP image (D) demonstrates occlusion of the right M1 segment of the MCA without significant collateral vasculature.

NIHSS less than 8 predicting good patient outcome and DWI volume more than 72 mL and NIHSS more than 20 predicting poor outcome (94). Perfusion imaging may also predict malignant middle cerebral artery territory infarction, as was demonstrated in one CTP study that showed an association between the area of increased blood–brain barrier permeability and those patients ultimately requiring hemicraniectomy (95). In addition, preliminary studies have demonstrated that location-weighted CT perfusion analysis may be helpful in predicting motor and language recovery (96,97).

HEMORRHAGIC TRANSFORMATION OF ACUTE STROKE

Hemorrhagic transformation is a major complication of acute stroke. It is commonly thought that reperfusion into severely ischemic tissue leads to hemorrhagic transformation (Figures 4.16 and 4.17). However, some investigators have shown that it can occur distal to permanently occluded vessels and suggest that collateral flow into ischemic tissue can lead to hemorrhage (98). Furthermore, thrombolytic agents increase the risk of hemorrhage. They are thought

TABLE 4.7 DWI and PWI Lesion Volumes and Associated Prediction of Ischemic/Infarct Tissue Behavior

PATTERN	CAUSE	COMMENT
MTT but no DWI	Frequently, proximal occlusion or critical stenosis with penumbra perfused via collaterals	DWI abnormality may develop, depending on collateral supply and timing of reperfusion. Good candidate for reperfusion therapy.
MTT > DWI	Frequently, proximal occlusion or critical stenosis with penumbra perfused partially by collaterals	Infarct may expand into part or all of the MTT abnormality, depending on collateral supply and timing of reperfusion. Good candidate for reperfusion therapy.
MTT = DWI	Usually, distal occlusions or lacunar infarcts, but can involve proximal occlusions as well	Entire territory has infarcted. No additional tissue at risk and no need for aggressive therapy.
MTT < DWI	Proximal, distal, or lacunar infarct	Ischemic tissue has reperfused. No additional tissue at risk and no need for aggressive therapy.
DWI but no MTT	Proximal, distal, or lacunar infarct	Ischemic tissue has reperfused. No additional tissue at risk and no need for aggressive therapy. Also, tiny infarcts below resolution of perfusion imaging.

to aggravate microvascular damage by activation of the plasminogen-plasmin system with the release of metalloproteinases that cause degradation of the basal lamina (99,100).

CT is considered the gold standard for detecting hemorrhagic transformation. However, T2* sensitive gradient-echo MR sequences (GRE) that have increased sensitivity to blood breakdown products, because of their paramagnetic properties, are as sensitive as CT in the detection of hemorrhage associated with acute stroke (101) (Figure 4.17). Furthermore, following thrombolysis, both contrast extravasation and hemorrhage are hyperdense and may be difficult to differentiate on CT. GRE images can easily differentiate between the two. Hemorrhage has susceptibility effects, whereas iodinated contrast does not.

Estimation of blood–brain barrier permeability (BBBP) with MRI or CT perfusion imaging may help predict the likelihood of hemorrhagic transformation. Permeability can be estimated from the standard dynamic susceptibility (T2*-based) MRI perfusion by measuring the relative recirculation of contrast. In one study of 84 patients, pretreatment BBBP derangement was 98% specific for hemorrhagic transformation, although it was only 29% sensitive (102). CT perfusion can also be used to assess permeability by measuring the rate of contrast material extravasation from the intravascular to the extravascular space through a disrupted BBB. An early study used a first-pass 60-second acquisition CTP protocol and found a sensitivity of 100% and specificity of 89% for prediction of hemorrhagic transformation (103). Subsequent studies, however, found that first-pass CTP data overestimate true tissue permeability (104), and that longer acquisition times of at least 210 seconds are required to generate accurate permeability values with CTP (105). In one recent study using a delayed-acquisition CTP protocol, a permeability surface product threshold of 0.23 mL × min^{-1} × 100 g^{-1} had 77% sensitivity and 94% specificity for detection of HT (106).

A number of additional imaging parameters have been found to be predictive of hemorrhagic transformation. These parameters are thought to reflect more severe ischemia and breakdown of the blood brain barrier and include the following:

1. Hypodensity in more than one-third of the MCA territory on CT (107)
2. Early parenchymal enhancement on gadolinium-enhanced T1-weighted images (108)
3. Larger volume of the initial DWI abnormality (compared to infarctions that do not hemorrhage) (109)
4. A higher percentage of pixels with ADC less than 550×10^{-6} mm^2/sec (compared to infarctions that do not hemorrhage) (110)
5. A more severe decrease in CBV and CBF versus the entire perfusion abnormality (compared to infarctions that do not hemorrhage) (111)
6. A relative CBF value less than 0.48 or relative MTT more than 1.3 compared to the contralateral side (112)
7. At least 126 voxels with CBV less than 5% of contralateral normal gray matter in patients who received intravenous tPA (113)

Conversely, it has been shown that preexisting microbleeds detected on T2* gradient echo do not signify risk for hemorrhagic transformation following thrombolytic therapy (114).

THE FUTURE: EMERGING TRENDS AND TECHNIQUES

The techniques and modalities employed in imaging acute stroke patients are rapidly evolving. Multidetector CT scanners with larger numbers of detectors have shortened scanning times, increased perfusion CT coverage, and require smaller contrast boluses. In addition, higher field strength MR magnets coupled with parallel imaging coils promise even faster, higher signal-to-noise ratio MR images

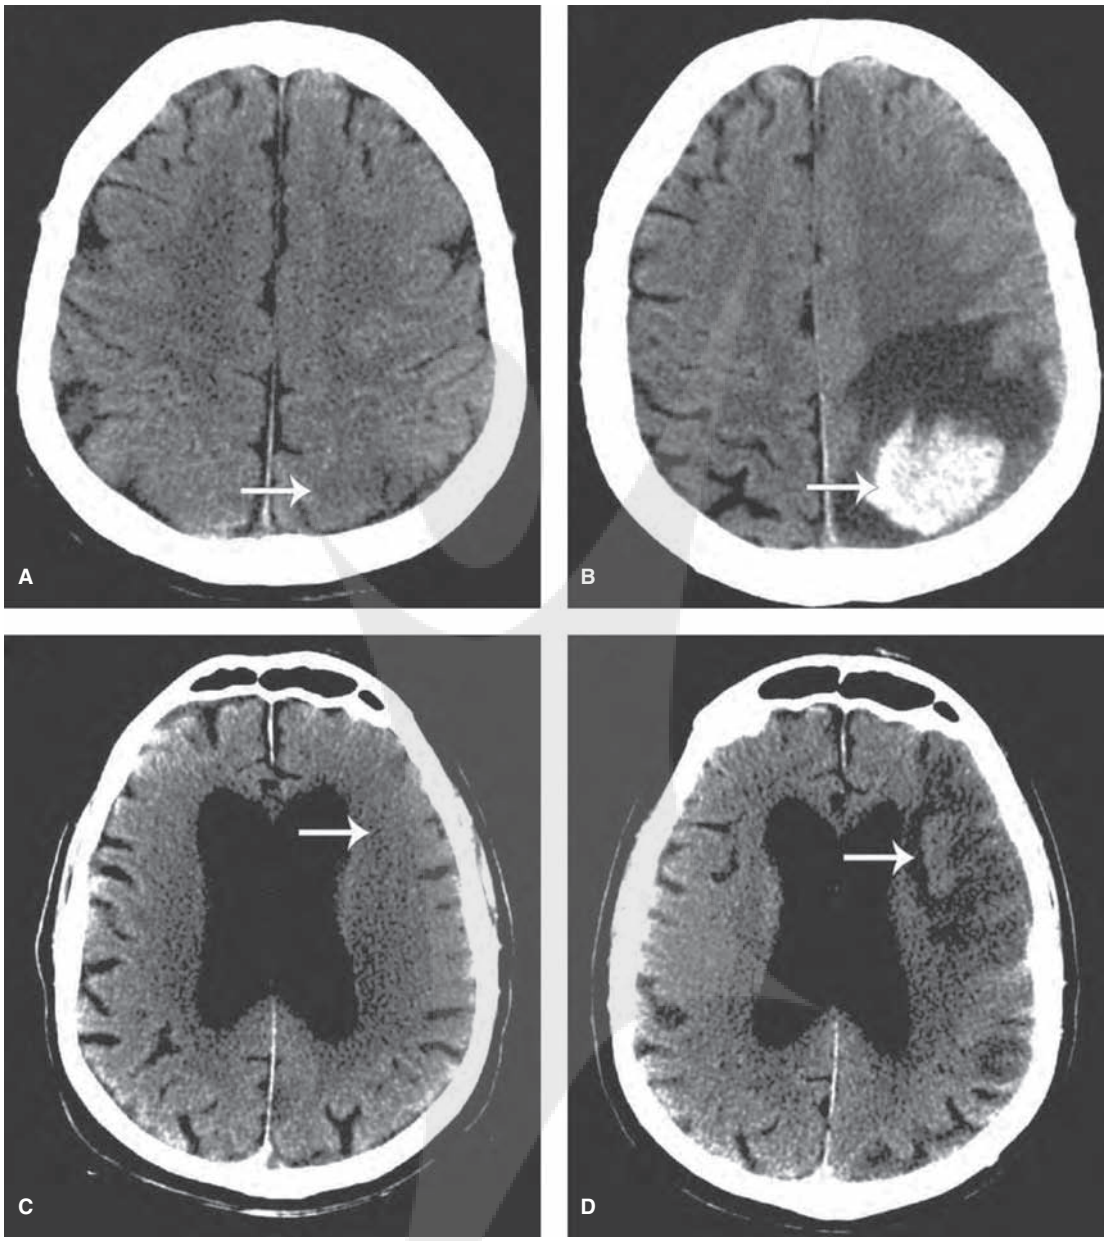

FIGURE 4.16 Hemorrhagic transformation on CT. Fifty-year-old male shown below. Initial noncontrast CT examination (A) demonstrates a small infarction within the left parietal region (arrow). On the follow-up study 14 days later (B), there is expansion of the infarction with a relatively large intraparenchymal hemorrhage (PH2 by ECASS classification scheme) (arrow). In a second patient with right hemiparesis, initial noncontrast CT (C) demonstrates a left MCA infarction (arrow). On follow-up CT (D), there is petechial hemorrhage within the infarction (HI1 by ECASS classification scheme) (arrow).

and MR angiograms. The physiologic evaluation of the acute stroke patient is moving from a largely subjective to an objective quantitative approach.

The search for imaging biomarkers and profiles that can individualize treatments based on specific physiology, rather than a generalized guideline or time window, has intensified. Sodium concentration in brain tissue can be calculated with high field strength MR scanners. In the unperturbed state, brain tissue maintains sodium ion homeostasis via energy-dependent mechanisms. This homeostasis is disrupted in ischemia, and there is evidence that tissue sodium concentrations can be used as a tool to predict ischemic tissue viability (115). Optical imaging (near-infrared spectroscopy) is being used to study both infarct progression and neuroplasticity following ischemia. Blood oxygen level-dependent (BOLD) MRI has been used to assess the cerebral metabolic rate of oxygen ($CMRO_2$), a marker of brain function that may enable a more precise evaluation of tissue at risk for progressing to infarction (116,117). MRI pH-weighted imaging is sensitive and specific for tissue

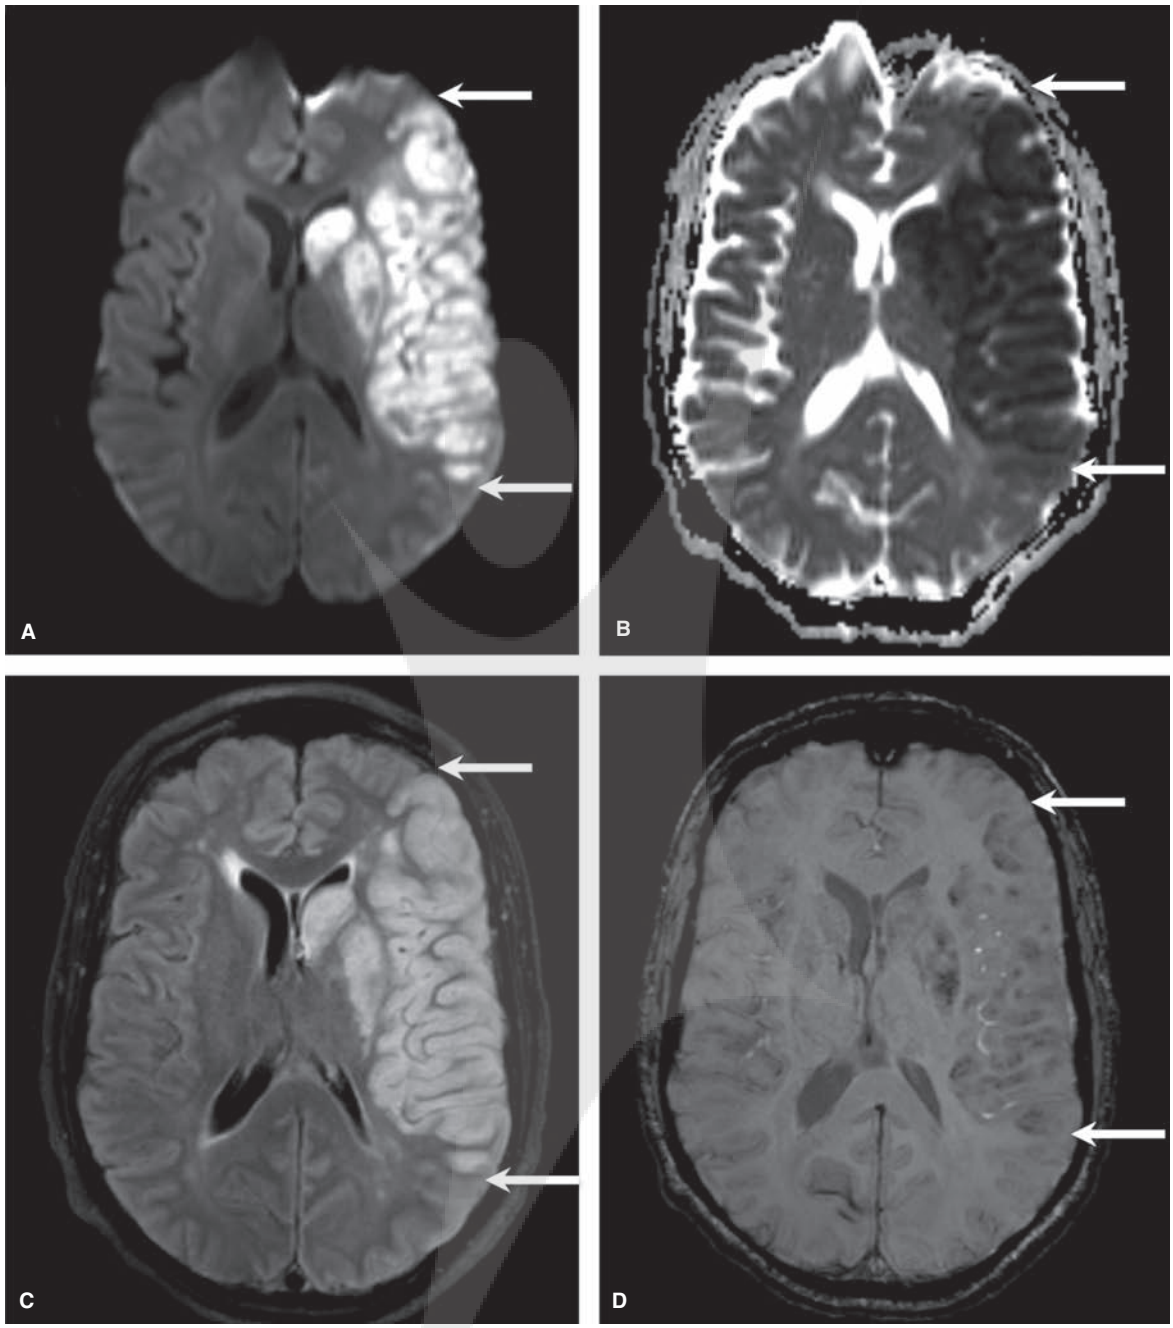

FIGURE 4.17 Hemorrhagic infarction on MRI. Follow-up MRI of the patient depicted in Figure 4.6 confirms infarction in the majority of the left MCA territory, which is hyperintense on DWI (A), hypointense on ADC (B) maps, and hyperintense on FLAIR (C) (delineated by arrows). Susceptibility-weighted images (D) reveal multifocal patchy hypointense signal throughout the area of infarction (delineated by arrows), consistent with confluent petechial hemorrhagic infarction (HI2 according to ECASS classification scheme).

lactic acidosis and is also under investigation as a way to quantify ischemic tissue at risk for infarction (118). Diffusion kurtosis imaging is an advanced diffusion imaging technique that may improve our understanding of the microstructural changes that occur during acute stroke. One recent article suggested that diffusion kurtosis lesions might more accurately define the infarct core versus diffusion-weighted imaging (119).

CONCLUSION

This chapter hopes to inform the reader about the current state of the art and future of acute stroke imaging and its impact on stroke triage. The advent of evaluation of the stroke patient using physiologic stroke parameters, in concert with the advances in stroke therapy, promises better clinical outcomes in the near future.

Cerebral Stroke Syndromes

Richard L. Harvey

The main purpose of the neurologic examination in stroke rehabilitation is to identify physical, cognitive, and communicative impairments, and to determine their impact on functional activity. By understanding these activity limitations, meaningful therapeutic goals can be derived. This contrasts with the neurologic examination performed in acute care, which informs the diagnosis and localizes the injury. In the rehabilitation setting, the lesion location is usually known, so the neurologic examination focuses on identifying *expected* impairments characteristic of a particular stroke syndrome. Understanding stroke syndromes helps target the examination, which improves the practitioner's efficiency and the accuracy of the neurologic assessment.

This chapter covers the stroke syndromes that occur in brain regions above the tentorium, including the anterior cerebral artery (ACA), middle cerebral artery (MCA), posterior cerebral artery, and others. In addition, the lacunar syndromes characteristic of infarcts within the territories of subcortical branches originating from these main arteries are reviewed. The syndromes described are those typical of arterial and branch occlusions rather than hemorrhagic rupture. This chapter is not intended to be an exhaustive review of cerebrovascular and neurologic anatomy, but rather a general anatomical overview that facilitates understanding of common clinical stroke syndromes.

CLINICAL NEUROANATOMY

The two cerebral hemispheres are divided, by convention, into four lobes: frontal, parietal, occipital, and temporal (Figure 5.1).

The frontal lobe is separated from the parietal lobe by the central sulcus. All behavioral motor output, including mobility, object manipulation, directional eye movement, and verbal expression, originate in the frontal lobe and are assisted by the basal ganglia and cerebellum. In contrast, processing of all sensory input, including visual, auditory, and somatosensory, is integrated by the thalamus, and the parietal, occipital, and temporal lobes. However, there is rich neural integration between frontal lobe systems and primary sensory areas. There are also significant interconnections between the primary motor cortex and somatosensory cortex, premotor and ventral motor areas, as well as connections from the thalamus to the motor cortex and the motor cortex to basal ganglia, superior and inferior colliculi, and cerebellum.

Cortical Areas of the Frontal Lobe

Primary Motor Cortex (M1)

The primary motor or M1 cortex is located in the precentral gyrus, just anterior to the central sulcus, in both hemispheres. It extends from the medial portion of the frontal lobe at the paracentral lobule, around the lateral convexity, and into the frontal operculum (the frontal lobe cortical surface tucked within the sylvian fissure). The motor cortex contains large pyramidal neurons (Betz cells) that constitute the "upper motor neurons" of the primary motor system and that supply axons for the cortical spinal tract. It is somatotopically organized in the form of the classic "homunculus" described by Penfield, where motor control for the feet is located in medial frontal regions; shoulder, arm, and hand are located along the superior lateral convexity; and face, tongue, and throat are located along the inferior convexity and the operculum (Figure 5.1). Lesions of the M1 cortex result in hemiplegia, often without spastic dystonia.

Broca's Area

Named after Paul Broca (1824–1880) (1), Broca's area is one of the two primary cortical language areas. Broca's area is located in the inferior lateral convexity and within the operculum of the dominant (usually left) frontal lobe (2,3). Interestingly, it is located in the premotor area anterior to M1 cortical representation for face, mouth, tongue, and throat. Thus it makes sense that lesions in this area would result in impaired oral motor communication, characterized by nonfluent speech production, apraxic errors, and problems with syntax. However, lesions in Broca's area often result in mild to moderate loss of auditory comprehension, characterized by failure to understand the syntax of complex sentences. Broca's area is important for facilitating the production of motor activity given on command, especially commands given verbally. Injury to Broca's area results in limb apraxia in both right and left limbs (4).

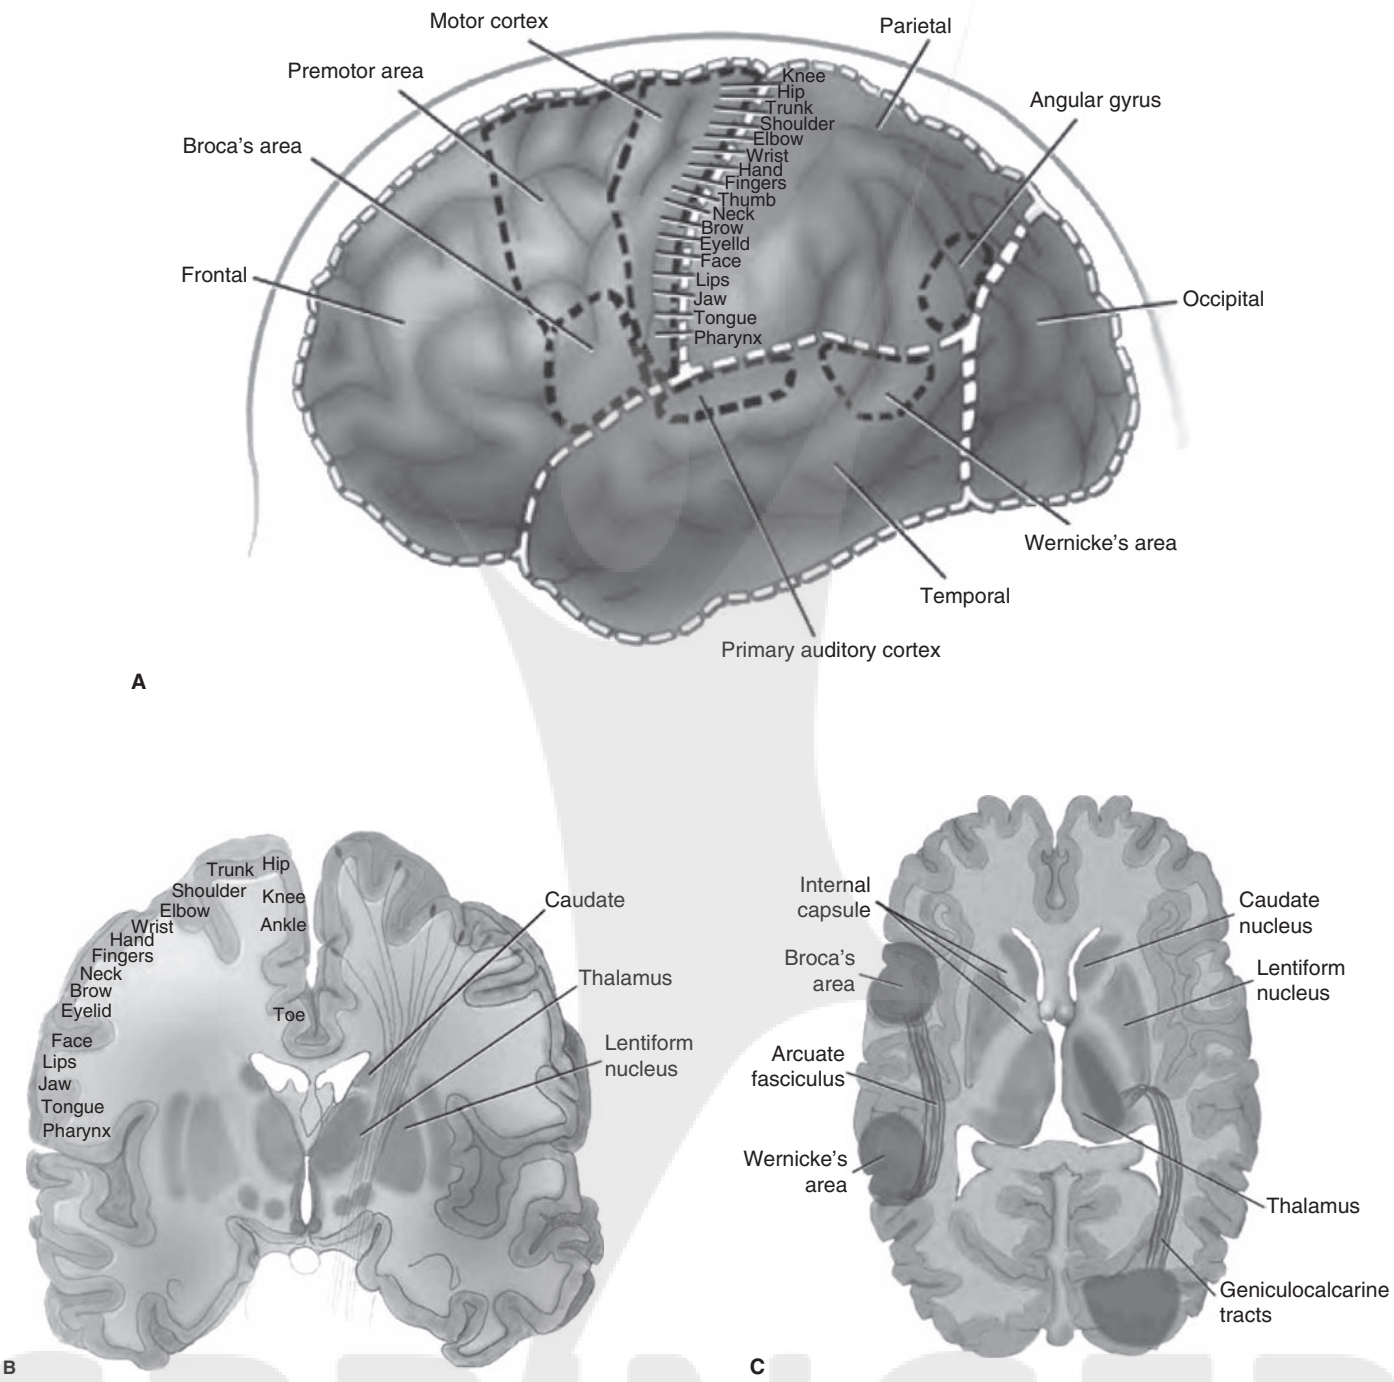

FIGURE 5.1 Cortical and subcortical neuroanatomy of the human brain. (A) Lobes of the cerebral hemisphere and identified cortical structures. (B) Coronal view of frontal lobe. (C) Horizontal view with highlighted language and visual areas and associated tracts.

Frontal Eye Fields

Although the prefrontal area of the frontal lobe is complex and poorly understood, it is accepted that this area plays an important role in executive decision making. Within this context, there are cortical regions in the prefrontal area that are important in directional and exploratory eye movements, called the frontal eye fields. Within each hemisphere are located two eye fields. One is known as the "eye field of the dorsomedial frontal cortex," and the other, located dorsolaterally, is the "frontal eye field" (5). A unilateral lesion of either eye field causes a gaze preference and frequently head-turning toward the side of the lesion, away from the hemiplegic side. Patients with such lesions have reduced saccadic gaze and visual pursuit toward the contralateral visual field. Often these symptoms are transient, but sometimes they may be long-lasting. In addition, injury to the nondominant (usually

right) prefrontal area impairs exploratory eye movements to the left and contributes to the attentional deficits seen in neurologic neglect syndrome (6). Head- and eye-turning associated with nondominant prefrontal lesions is often more persistent, whereas these symptoms usually resolve within days to a few weeks with dominant lobe lesions.

Primary Cortical Sensory Areas

Primary Somatosensory Cortex (S1)

The postcentral gyrus is located anteriorly in the parietal lobe, behind the central sulcus, and contains primary somatosensory representation. Like M1, it is somatotopically organized with roughly the same anatomic organization as the primary motor cortex. Lesions in S1 result in loss of two-point discrimination and stereognosis in the contralateral body. If subcortical sensory structures such as sensory tracts and thalamus are involved as well, there may also be loss of pain, temperature, and joint position sense.

Primary Visual Cortex

Located on the medial surface of the occipital lobe, within the longitudinal fissure, is the calcharine or primary visual cortex, a critical structure for vision. Unilateral hemispheric lesions of the visual cortex result in a contralateral homonymous hemianopsia, meaning loss of half the visual field to an equivalent extent in both eyes. Symptoms of homonymous hemianopsia are not limited to lesions of the primary visual cortex; they may also occur with lesions involving subcortical structures of the temporal lobes. This is because visual tracts extend from the ventral posterior lateral thalamus, radiate posterolaterally into the temporal lobes, and then arch medially to the occipital cortex (Figure 5.1). Any lesion along this tract will also cause a contralateral homonymous hemianopsia.

Primary Auditory Cortex

Pure tone recognition is processed in the primary auditory cortex, located on the superior temporal gyrus in the temporal lobe. This is also known as Heschel's gyrus and is more prominent in the dominant hemisphere (7). Auditory cortex is tonotopically organized by sound frequency (8,9). A lesion to the superior temporal lobe on or near Heschel's gyrus does not result in deafness; however, in the dominant hemisphere, such a lesion can cause complex auditory perceptual problems, such as pure word deafness (10).

Cortical Sensory Association Areas

Cortical association areas are local networks connected by extensive reciprocal monosynaptic connections to other cortical areas, as well as to certain subcortical structures. These interconnected local networks make up large-scale networks for distributed processing of neurocognitive activities such as attention, language, and memory. Thus, lesions in associated areas can negatively affect complex perceptual, cognitive, and communicative behaviors (6).

Posterior Parietal Cortex

Located behind the primary somatosensory cortex, the posterolateral parietal area integrates neural information from somatosensory, visual, and auditory cortices to construct a cohesive perception of three-dimensional space and the body's position within the surrounding environment (11). Current theory suggests that in humans, the nondominant parietal cortex is oriented to bilateral space, whereas the dominant hemisphere is strongly oriented to the contralateral (usually right) hemispace. As such, lesions in the left parietal cortex usually cause only transient right hemineglect syndrome. In contrast, lesions in the right parietal cortex cause clinically significant left hemineglect syndrome. The neglect syndrome is characterized by reduced recognition of and attention to visual, somatosensory, and auditory stimuli in the contralateral hemispace. In addition, patients with lesions in the right parietal hemisphere have visual perceptual deficits resulting in spatial disorientation. Clinically, they are unable to draw figures accurately, to use blocks to build a simple structure, and to orient their clothing to their body while dressing (12). Clinical terms such as *constructional apraxia* and *dressing apraxia* have been applied to this syndrome. However, it is important to note that these problems result from deficits in perception and are not true motor apraxias.

Wernicke's Area

Named after Carl Wernicke (1848–1905) (13), Wernicke's area is located posteriorly to Heschel's gyrus in the dominant hemisphere and is a language-association area functioning as a local neural network, situated between the primary auditory and visual cortices. Wernicke's area processes spoken and written symbolic language into meaning and comprehension (2,3). Along with Broca's area in the frontal operculum, Wernicke's area participates in a larger network for distributed processing of language (6). Lesions in Wernicke's area result in impaired language comprehension and a fluent aphasia mixed with multiple paraphasic errors. Patients with Wernicke's aphasia lack insight about their comprehension deficits, which can complicate care and participation in rehabilitation.

Angular Gyrus

Immediately posterior to Wernicke's area, in the posterior superior temporal lobe, is the angular gyrus, which receives visual input from the occipital lobe and the posterior inferior temporal lobe (14). The angular gyrus is an important region for processing written language; lesions here can cause alexia (3).

Subcortical Structures

Posterior Limb of the Internal Capsule

Axons that constitute the cortical spinal tract descend from the M1 cortex subcortically into the internal capsule. The anterior portion of the posterior limb, beginning at the genu,

contains these fibers. This portion of the internal capsule passes between the thalamus and the globus pallidus, into the cerebral peduncle, and then into the midbrain as the ventral crus cerebri (Figure 5.1). The posterior limb of the internal capsule is somatotopically organized with face, hand, arm, and shoulder anterior to trunk, thigh, leg, and foot. Lesions in the internal capsule result in contralateral hemiplegia.

Thalamus

Located between the third ventricle and the posterior limb of the internal capsule, the thalamus functions as a sensory hub for somatosensory, visual, and auditory inputs (Figure 5.1). Lesions here can result in mild hemiplegia or hemiataxia, sensory deficits, pain syndromes, mild aphasia, and neglect syndrome.

Arcuate Fasciculus

Another important structure in the large-scale language network is the arcuate fasciculus, which is a cortico-cortical white-matter tract passing reciprocally between Wernicke's and Broca's areas along an arched pathway (6). Lesions along the arcuate fasciculus can cause problems with repetition of language as well as limb apraxia bilaterally (3,4).

Corpus Callosum

The large arch-shaped bundle of white matter connecting the two cerebral hemispheres is the corpus callosum (Figure 5.1). Lesions within this structure can contribute to a disconnection between the right and left hemisphere, resulting in various clinical manifestations depending on the location of the lesion.

CEREBROVASCULAR ANATOMY

The Circle of Willis

In his book *Cerebri Anatome*, published in 1664, Thomas Willis provided the first complete description of the cerebral arterial circle, now commonly known as *the circle of Willis* (15). The circle is supplied by three intracranial arteries. The right and left internal carotid arteries supply the circle anteriorly, and the basilar artery provides the posterior supply (Figure 5.2).

The last branch of each internal carotid before entering the circle of Willis is the ophthalmic artery, which passes into the orbit and supplies the retinal tissue. Small branches of the ophthalmic artery anastomose with branches from the external carotid. After releasing the ophthalmic artery, the internal carotid artery enters the circle of Willis at the point where the posterior communicating artery (PComA) branches posteriorly. The internal carotid then provides a deep perforating cerebral artery, the anterior choroidal artery (AChA), before bifurcating into the middle cerebral artery (MCA) and the anterior cerebral artery (ACA). The basilar artery bifurcates into both posterior cerebral arteries (PCA). The circle is completed by anastomosis of the PComA with the PCA, and the anterior communicating artery (AComA) with both ACAs (Figure 5.2).

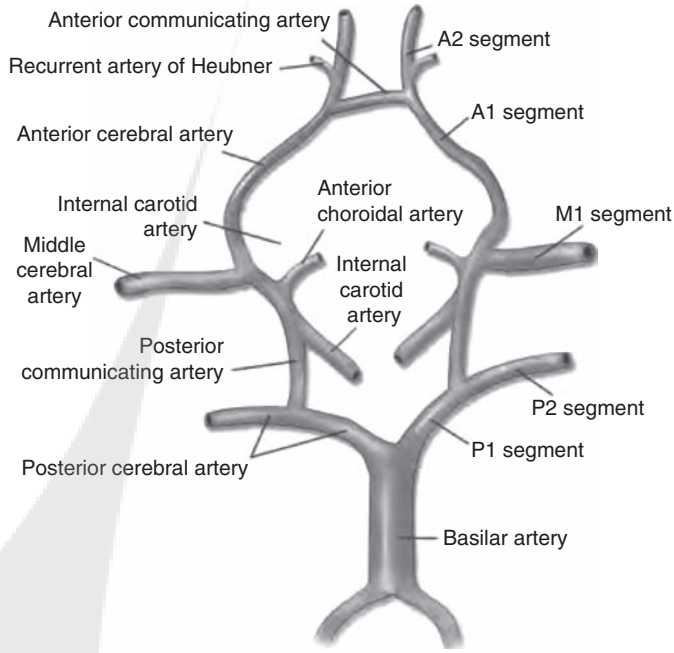

FIGURE 5.2 The circle of Willis and associated branches.

This "typical" anatomy of the circle is present in only 35% of human specimens. Anatomical variations are numerous, including hypoplastic portions of the circle as well as absent portions, the most common being an absent PComA on one side. In the presence of atherosclerotic disease, the intact circle of Willis can provide important collateral supply of blood flow to the ACA, MCA, PCA, and deep perforating arteries. Another important collateral supply to the circle of Willis, in the presence of atherosclerotic occlusion of an internal carotid, is retrograde blood flow from the external carotid artery through the ophthalmic artery. Finally, leptomeningeal arteries provide another helpful, but limited, source of collateral blood supply to the cerebral cortex.

The Anterior Choroidal Artery

The last branch of the internal carotid artery before the MCA–ACA bifurcation is the AChA. It is a major deep perforating artery that supplies the optic tract, globus pallidus, anterior hippocampus, and parts of the thalamus including a branch to the lateral geniculate nucleus (16,17). In addition, the AChA provides blood supply to the deep white matter of the temporal lobe, including the geniculocalcarine tract and the lower portion of the posterior limb of the internal capsule in the cerebral peduncle. As the name of the AChA implies, the terminal branches supply the choroid plexus of the temporal horn.

The Anterior Cerebral Artery

The ACA originates from the carotid bifurcation and extends in an anteromedial direction to the anastomosis of the AComA. This portion of the circle of Willis is called the A1 segment. The A2 segment continues after the AComA anastomosis, along the medial frontal lobe within the medial longitudinal fissure between the cerebral hemispheres (Figure 5.3).

It then passes superiorly and posteriorly around the corpus callosum to supply the medial frontal lobe, the corpus callosum, the cingulate gyrus, the paracentral lobule, and portions of the medial parietal lobe (18). Tributaries from the ACA transverse over the convexity of the cerebral hemisphere and anastomose with tributaries from the MCA in a watershed region.

The recurrent artery of Heubner (RAH) was first described by Johann Otto Leonhard Heubner in 1872 (19). This artery is the largest of a group of deep perforating arteries known as the lenticulostriate, which supply the basal ganglia as well as the intervening internal capsule and other surrounding white matter. The RAH originates either from the proximal A2 segment of the ACA or from anywhere along the A1 segment. Specifically, the RAH supplies the anterior caudate nucleus, the anterior third of the putamen, the tip of the outer segment of the globus pallidus, and the anterior limb of the internal capsule. Within the dominant hemisphere, the RAH supplies subcortical tissue near Broca's area in the frontal operculum.

Middle Cerebral Artery

The MCA supplies the largest volume of the cerebral hemisphere, including the basal ganglia, the internal capsule, and the visual radiations from the thalamus. The mainstem of the MCA originates from the carotid bifurcation and turns laterally toward the insular cortex. Along this route, it supplies a series of lenticulostriate branches to subcortical structures. Once at the insular cortex, deep in the sylvian fissure, the MCA divides into an upper and lower division. The segment from the carotid bifurcation to the MCA divisions is named M1. The M2 segment constitutes the upper- and lower-division branches within the sylvian fissure. The M3 segment includes the branches to the opercula, and the M4 are the branches overlying the cerebral convexities (Figure 5.3).

The superior division of the MCA supplies the frontal operculum, the lateral convexity of the frontal lobe, and, to a varying extent, the parietal lobe. The inferior division of the MCA supplies the temporal operculum, the lateral convexity of the temporal and occipital lobes, and, to a varying extent, the parietal lobe.

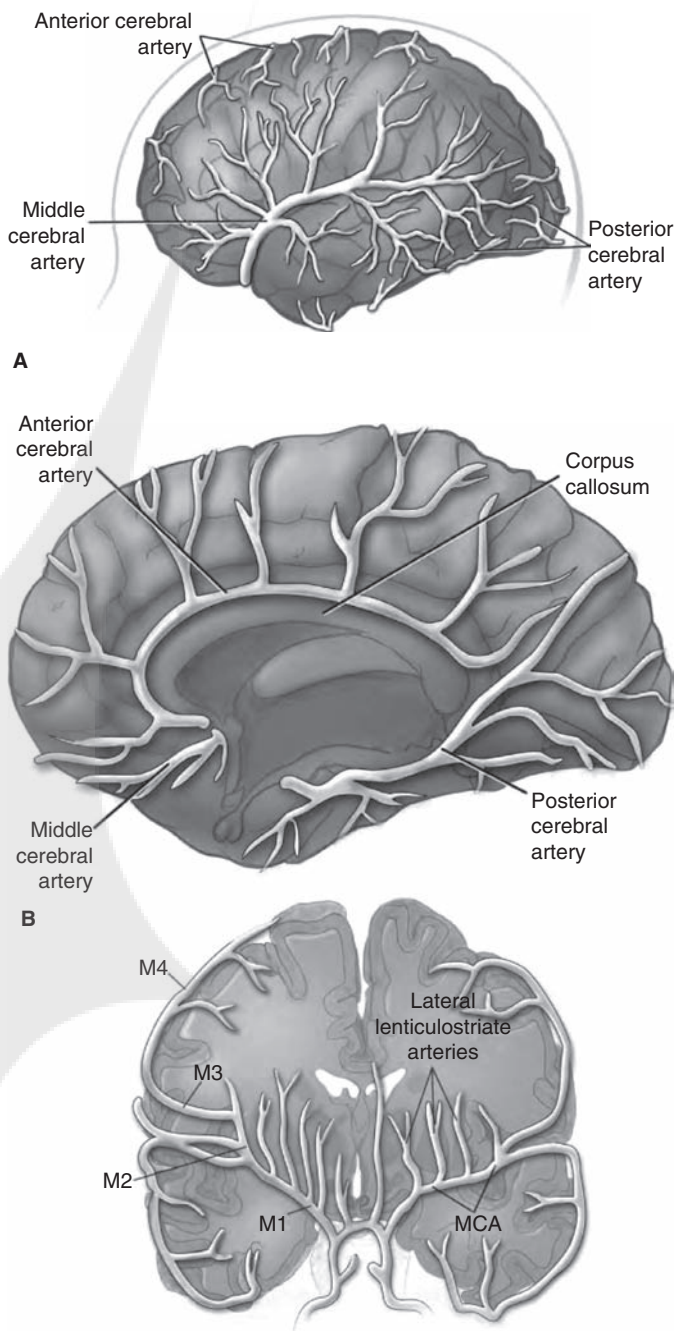

FIGURE 5.3 Vascular supply to cerebral hemisphere of the human brain. (A) Vascular supply to the lateral convexity of the cerebral hemisphere. (B) Vascular supply to the medial portions of the cerebral hemisphere. (C) Distribution of the middle cerebral artery and the subcortical branches of the lenticulostriate arteries.

The Posterior Cerebral Artery

The two PCAs divide at the top of the basilar artery and pass posterolaterally toward the medial temporal lobes. The P1 segment constitutes the section from the basilar artery to the branch of the PComA. The PCA then continues as the P2 segment to supply the medial occipital lobe within the longitudinal fissure, the posterior corpus callosum, and the medial temporal lobes, including portions of the hippocampi. Branch tributaries pass over the convexity of the cerebral

hemisphere and anastomose in a watershed region with MCA tributaries. Other tributaries within the longitudinal fissure anastomose with those of the ACA in the region of the medial parietal lobe (Figure 5.3).

CEREBRAL STROKE SYNDROMES

The stroke-related neurologic syndromes associated with major cerebral artery occlusion are predictable when one understands the neuroanatomy and cerebrovascular anatomy described in the first part of this chapter. In the context of cerebrovascular embolism or thrombosis, ischemic infarct can occur in all or a portion of the vascular bed supplied by the artery, depending on whether occlusion is total or incomplete. Immediate or delayed, intrinsically or extrinsically induced thrombolysis may also influence the extent of damage. The presence of atherosclerotic or small-vessel disease can affect the quality of tissue perfusion in watershed regions of major arteries. Thus, patients may experience all the components of a stroke syndrome, but more often only some of the signs and symptoms. Some of the neurologic impairment may be significant, whereas other impairments may be mild.

The following section includes a description of the most common clinical signs and symptoms associated with major cerebral stroke syndromes. However, it should be understood that individual cases seen in clinical practice may vary somewhat from the classic syndromes. Still, given the history and evidence on imaging of an infarct within a certain vascular distribution, the clinician should look for all signs and symptoms associated with that particular syndrome.

Carotid Artery Syndromes

A thrombus in the common carotid or internal carotid artery is associated with atherosclerotic carotid artery disease. Infarcts can occur from an occlusive carotid thrombus or thromboembolism to distal cerebral arteries (most commonly the MCA). Watershed infarcts in the distal MCA distribution can occur, presenting with partial contralateral hemiplegia and a sensory deficit affecting the shoulder more than the hand and leg. Carotid thrombosis often presents with a transient ischemic attack (TIA), which by definition lasts less than 24 hours and usually lasts only minutes. Amaurosis fugax, which is a transient monocular blindness, is a symptom that is peculiar to carotid TIAs. This phenomenon is typically caused by thromboembolism from the carotid to the ophthalmic artery with immediate thrombolysis. Often described as a "curtain dropping over the eye and rising again," amaurosis fugax more often presents as a visual obscuration, clouding, or fogginess variably affecting the whole, or part, of the visual field in one eye. On rare occasions, a completed stroke from carotid thrombosis will result in ipsilateral monocular blindness and contralateral hemiplegia.

AChA SYNDROME

The AChA syndrome was first described by Foix in 1925 and more thoroughly evaluated by Abbie in 1933 (16,20). Ischemic injury in the territory of the AChA causes a contralateral hemiplegia, because of injury to the posterior limb of the internal capsule. Hemianopsia can also occur, which varies depending on the structures involved. Injury to the optic tract can result in a contralateral hemianopsia and reduced pupillary reaction. A lesion to the geniculocalcarine tract in the medial temporal lobe can also cause a contralateral hemianopsia. If the lateral geniculate nucleus is injured, a contralateral hemianopsia with median horizontal sparing can occur and is diagnostic of an AChA occlusion (21). Visual sparing in the horizontal plane results because a portion of the lateral geniculate is supplied by the lateral choroidal artery. AChA strokes usually cause no language deficit if the infarct is in the dominant hemisphere, but nondominant injuries may cause a left hemineglect syndrome.

ACA Syndrome

The ACA stroke is an uncommon stroke, constituting 3% or fewer of all strokes. Still, patients with ACA stroke present with complex physical and cognitive deficits and usually require comprehensive neurorehabilitation services (22). Patients with a unilateral ACA infarct present with contralateral hemiplegia that is worse in the leg and shoulder than in the arm, hand, and face, because of injury to the medial M1 cortex at the paracentral lobule. If facial weakness is noted, it is likely that the RAH is occluded as well (19). Sensory loss is minimal, usually impaired two-point discrimination if present, and in the same distribution as the motor impairment.

Patients with ACA infarcts, whether in the right or left cerebral cortex, often have limb apraxia that is limited to the left side. This is because the ACA supplies the anterior corpus callosum, which is a main pathway of transcortical interconnectivity between the frontal lobes. Infarcts in either the right or left ACA disconnect the right premotor and M1 cortex from the left language network. This disconnection results in apraxic errors of the left upper limb when the patient is given a command (4,14). However, because the left motor cortex is adjacent to Broca's area, ACA strokes do not affect motor performance on command in the right upper limb. These patients usually perform better with the left upper limb if given visual cues to follow.

In cases of injury to the eye fields of the dorsomedial frontal cortex, head and eye deviation ipsilaterally (away from the hemiplegia) is observed (5). Prefrontal lobe injury is also associated with the grasp reflex of the affected hand as well as some paratonia, which is a kind of limb rigidity that becomes more prominent with an increase in effort by the examiner during muscle stretches (force-dependent rigidity). Other "frontal release" signs such as palmomental or snout reflexes can be seen in some cases.

Medial frontal injury involving the supplementary motor area and cingulate gyrus can also result in reduced initiation and, if severe, in psychomotor bradykinesia. Patients with ACA stroke may be very slow to respond to questions or commands; however, it should be kept in mind that they are often impulsive and may show no impediment in impulsive actions (such as climbing out of bed in an attempt to get to the restroom). Psychomotor bradykinesia can be severe enough to cause reduced verbal expression or even mutism that may be difficult to differentiate from aphasia (3). Executive cognitive functioning that can have a negative impact on independent performance of instrumental activities of daily living is also impaired with injury to the prefrontal cortex.

Patients with ACA strokes can present with aphasia when the infarction includes the vascular supply of the left RAH (19). This usually infarcts subcortical tissue in the region extending between the supplementary motor area and Broca's area, injuring white-matter portions of the language network (23). This most commonly causes a transcortical motor aphasia with reduced fluency, some apraxic errors of speech, and intact repetition (2,3).

MCA Syndromes

Mainstem MCA (M1 segment): Occlusion of the MCA within the M1 segment can cause ischemic injury in the entire MCA distribution, which includes most of the lateral convexity of the cerebral hemisphere. In addition, a substantial injury to subcortical structures—including the internal capsule, visual radiations, and thalamocortical white matter—results from hypoperfusion of the lenticulostriate arterial branches off the M1 segment. Large MCA distribution infarcts can produce significant edema and increased intracranial pressure, which can cause contralateral cerebral injury, uncal herniation, and death. Those who survive a large mainstem MCA stroke will have significant neurologic impairment.

A patient with a mainstem MCA infarct has complete contralateral hemiplegia from injury to the M1 cortex and the entire internal capsule. Contralateral hemisensory loss or even hemianesthesia can result from substantial injury to the subcortical sensory tracts and the S1 cortex, although the thalamus itself may be spared. Infarct of the ipsilateral frontal eye fields in the lateral prefrontal area causes head and eye deviation toward the lesion (away from the hemiplegia) (5). Deep infarction to the geniculocalcarine tract causes homonymous hemianopsia in the contralateral visual field.

If the infarct is in the dominant MCA distribution, there is damage to the language network, including Broca's area, Wernicke's area, the angular gyrus, and the arcuate fasciculus. The patient will have a global aphasia, with reduced fluency, severely impaired comprehension, and an inability to repeat, read, or write.

A nondominant MCA stroke causes severe visual and perceptual deficits, with disrupted spatial body orientation, dressing apraxia, and constructional apraxia. Survivors of nondominant MCA strokes also have a severe left hemineglect syndrome, contributed in part by reduced left attention (from parietal injury) and reduced exploration (from frontal injury) of the left hemispace. There is severe inattention to the left body as well, such that patients may even deny they have a stroke or stroke-related impairments (anosognosia).

Superior-Division MCA

Occlusion of the MCA at the origin of the superior division results primarily in a cortical infarct of the frontal lobe convexity, sparing the medial frontal lobe and subcortical tissue. Symptoms include a contralateral hemiplegia affecting the arm and hand more than the leg. Sensory deficits are mild, usually loss of two-point discrimination, in the same distribution as the weakness. These patients may have transient head and eye deviation toward the lesion (away from the hemiplegia). Visual fields are usually spared.

When the dominant hemisphere is affected, the patient has Broca's aphasia with decreased fluency of speech, apraxic errors, inability to repeat, and minimally impaired comprehension (2,3). These patients have bilateral limb apraxia from injury of the frontal-lobe language network (necessary for carrying out motor commands in either upper limb) (4). Patients often struggle to follow motor commands even with visual cues.

Patients with superior-division MCA strokes in the nondominant (usually right) hemisphere have a hemineglect syndrome, with reduced exploration of left hemispace and mildly reduced attention to left-sided stimuli (11). They often have deficits in visual spatial perception. Oral expression is altered in that patients may have less prosody in their speech, lacking the normal inflections that emphasize the meaning, importance, or emotional content of a sentence. Aprosodia is seen with nondominant frontal-lobe injuries (24,25).

Inferior-Division MCA

Occlusion in the inferior division of the MCA results in a primarily cortical infarct of the lateral convexity of the parietal, occipital, and temporal lobes. Patients with infarction in this region have no motor or somatosensory deficits. They may have a partial contralateral hemianopsia because of partial injury to the visual radiations in the temporal lobe.

Injury to the dominant hemisphere from an inferior division MCA stroke causes a Wernicke's aphasia, with fluent speech that is filled with paraphasic errors and poor comprehension of spoken and written language. Patients with nondominant injuries have a hemineglect syndrome, with reduced attention to the left hemispace and perceptual deficits (12). They may also have a *sensory aprosodia*, also known as an affective agnosia, in which the individual has difficulty in comprehending the prosody in another's speech (24–26).

Posterior Cerebral Artery Syndromes

If an occlusion occurs in the proximal PCA (P1) segment, hypoperfusion occurs in the distal PCA and the thalamoperforant arteries supplying the thalamus. This infarct results in

a contralateral sensory syndrome, with hypoesthesia, a feeling of heaviness in the limbs, and, in some cases, dysesthesia (called Déjerine–Roussy syndrome) (27). The PCA distribution stroke also causes a contralateral homonymous hemianopsia from direct injury to the primary visual cortex in the medial occipital lobe. Injury to the medial temporal lobe and structures of the hippocampus following PCA occlusion have been reported to cause an amnestic disorder in a few cases, but this is not commonly seen with unilateral infarct.

On rare occasions, a PCA infarct in the left occipital lobe can result in *alexia without agraphia* (3,14). These patients are not able to read, but can write. The infarct includes the left primary visual cortex, causing a right homonymous hemianopsia. It also includes the posterior corpus callosum, which disconnects the right primary visual cortex from the language network. Thus the patient can see words in the left hemispace but cannot transfer visual images to the language centers. Writing is not affected because there is no disconnection between the language network and motor cortex (14). Patients with this lesion may have some left neglect syndrome as well (28).

Thromboembolism to both PCAs is uncommon, but is the most common cause of cortical blindness. Other causes include hypertensive encephalopathy, hypoperfusion injury, or trauma. If the infarct includes the primary visual cortices and adjacent visual association areas, the patient may present with blindness and visual anosagnosia, or Anton's syndrome. This syndrome was named after Gabriel Anton, who described a series of such patients in 1899. Anton's syndrome is characterized by denial of visual loss associated with confabulation in the setting of severe loss of vision. These patients will fervently deny that they are blind, but will walk into walls if not guided to avoid them (29). The prognosis for recovery of visual loss is good when the syndrome is caused by hypertensive encephalopathy and the condition is treated, but poor when it is caused by spontaneous stroke. Patients with severe cognitive deficits in association with Anton's syndrome also have a poor prognosis (30).

Lacunar Stroke Syndromes

The term *lacune* means "little lake" and was coined to describe the pathological appearance of small cavities within brain parenchyma. These cavities are produced by small-branch occlusions of deep perforating vessels such as the lenticulostriate or thalamoperforant arteries. By definition, lacunar infarcts are 1.5 cm or less in the largest diameter, which corresponds to the tissue volume supplied by a deep perforating branch (located in subcortical structures such as the internal capsule, putamen, caudate, thalamus, cerebral white matter, and pons). Lacunar strokes are associated with hypertension and are caused by small-vessel occlusion from lipohylinosis of the vascular intima. Miller Fischer reintroduced the term "lacunar stroke" into clinical stroke neurology when he described the lacunar syndromes (31). Although as many as 100 lacunar syndromes have been described, 5 stand out as the most commonly seen in clinical practice.

One of the most common lacunar syndromes is the *pure sensory stroke,* with symptoms of numbness in the face, arm, and leg on one side of the body. There are no associated motor or cognitive deficits. The infarct is usually located in the thalamus. Patients with sensory strokes can develop late or chronic pain syndromes as a result of disruptions of normal sensory tracts. Lesions in other regions of the CNS along sensory pathways may also cause central poststroke pain syndrome (see Chapter 17).

Pure motor hemiparesis is also common and often results in some functional limitations that require rehabilitation. The patient has symptoms of motor loss in the face, arm, and leg, with or without spastic dystonia on one side of the body without associated sensory or cognitive changes. The stroke is located in the posterior limb of the internal capsule or cerebral peduncle, but may also occur in the base of the pons. Prognosis for functional recovery is good because patients lack other symptoms, such as language and visual deficits, and do not have apraxia. Spastic dystonia may complicate the rehabilitation process.

Dysarthria–clumsy hand syndrome, along with *ataxic hemiparesis,* are lacunar syndromes that most commonly occur from lesions in the base of the pons caused by occlusions of the paramedian pontine perforating vessels from the basilar artery. However, dysarthria–clumsy hand syndrome can also present following an infarct at the genu of the internal capsule in the somatotopic regions for face and hand, as well as in other areas of subcortical white matter. These patients have dysarthria and unilateral facial weakness without language deficits, and a mild hemiparesis of the upper limb on one side of the body. The prognosis for recovery is very good, and the patient will benefit from a course of speech therapy and motor retraining of the upper limb. Patients with ataxic hemiparesis often face a considerable challenge in regaining independent gait function because of problems with dynamic balance. But the prognosis is still very good, because the ataxic component often recovers more rapidly than the hemiparesis.

The lesion location for the *sensorimotor stroke* is most likely at the junction of the ventrolateral thalamus and the internal capsule, resulting in sensory loss and motor hemiparesis on one side of the body. Because the vascular supply to thalamus and internal capsule are distinct, the likely explanation is that edema from a thalamic stroke compresses adjacent fibers in the internal capsule, resulting in a mild hemiparesis. This has been described in one pathological case study (32).

RESEARCH FRONTIERS

Historically, our understanding of stroke syndromes came from the careful examination of pathological specimens. Today neuroimaging, especially with magnetic resonance imaging (MRI) and newer digital imaging software, has found a useful role in better defining the anatomical extent of cortical lesions caused by stroke. Techniques such as functional MRI (fMRI) (33) provide the opportunity to study the neuroanatomy following stroke and may further enhance

our understanding of the complex relations between clinical behavior, lesion location, and altered cortical activity in vivo (see Chapter 8).

Large digital-image databases are now being built, providing the opportunity to correlate neuroanatomy with genetic and phenotypic variations in normal adult humans (34). No such database currently exists for cases of cerebrovascular lesions, but such an image library would be invaluable. Several small studies have attempted to further characterize the neuroanatomy of language using fMRI and voxel-based lesion-symptom imaging techniques (35,36). The use of diffusion tensor tractography is helping to increase understanding of the association between white-matter tract lesions and stroke-related behavior (37–39). Such studies will certainly improve our understanding of stroke-related behavior and the corresponding neuroanatomical lesions. Even more important, however, are the prospects for better prediction of functional outcome and the targeting of candidates for rehabilitation interventions that can improve recovery.

CONCLUSION

Understanding the cerebrovascular and neurologic anatomy of stroke lesions can help the neurorehabilitation clinician perform an efficient neurologic examination and identify clinically meaningful impairments that will affect functional performance. Thus, a clear knowledge of common stroke syndromes becomes a valuable tool for assessing functional limitations and setting realistic rehabilitation goals for the patient with stroke. Future research with modern neuroimaging holds promise for better predicting functional recovery and for targeting rehabilitation interventions to achieve optimal outcomes.

Stroke Syndromes: Infratentorial

Richard D. Zorowitz

The infratentorial region, comprising the brainstem and cerebellum, spans the diencephalon and the spinal cord. Despite its size, the brainstem has the potential to cause neurological devastation if damaged. It carries fibers that affect motor and sensory function, as well as arousal and survival; many of these fibers have important modulatory effects on both the cerebral cortex and the spinal cord. Although the cerebellum does not carry direct pathways from the cerebrum to the spinal cord, it too has the potential to cause neurological devastation because it also modulates movement and tone.

This chapter describes the development of the brainstem and cerebellum. Following this, the neuroanatomy of the brainstem and cerebellum and their organization into columns of afferent and efferent neurons is discussed. Understanding the organization of the brainstem and cerebellum is essential to understanding their functional correlates. It is these functional correlates that explain the syndromes discussed in the remainder of the chapter.

DEVELOPMENT OF THE BRAINSTEM

During development of the nervous system, the *neural tube* gives rise to all of the neurons and glial cells of the central nervous system. The caudal portion of the neural tube develops into the spinal cord, while the rostral portion becomes the brain. The rostral neural tube divides into three vesicles, called the *forebrain*, *midbrain*, and *hindbrain* (Figure 6.1). The forebrain, or *prosencephalon*, ultimately matures to form the *telencephalon* (cerebral hemispheres and lateral ventricles) and the *diencephalon* (thalamus and third ventricle).

Three layers form within the wall of the neural tube. The *neuroepithelial*, or *ventricular*, layer contains the innermost cells that ultimately will line the central canal of the spinal column and the ventricles of the brain. The *mantle*, or *intermediate*, layer consists of neurons and glial cells that will form the gray matter of the spinal cord. This layer contains the *alar plate*, which gives rise to sensory neuroblasts of the dorsal horn of the spinal cord; and the *basal plate*, which gives rise to motor neuroblasts of the ventral horn of the spinal cord.

The midbrain and hindbrain form the basis of the brainstem. The midbrain, or *mesencephalon*, does not divide, but evolves into the midbrain, cerebral aqueduct, and rostral cerebellum. The *alar plate sensory neuroblasts* form the cell layers of the superior colliculi and the nuclei of the inferior colliculi (1). The *basal plate motor neuroblasts* form the oculomotor (cranial nerve [CN] III) and trochlear (cranial nerve IV) nuclei, as well as the Edinger-Westphal (cranial nerve III) nucleus, which gives rise to preganglionic parasympathetic fibers. The red nucleus and substantia nigra also originate from the basal plate.

The hindbrain, or *rhombencephalon*, subdivides into two regions: the rostral *metencephalon* and caudal *myelencephalon*. The metencephalon matures into the caudal cerebellum, pons, and rostral fourth ventricle. In the pons, the alar plate sensory neuroblasts give rise to the spinal and principal sensory trigeminal (cranial nerve V) nuclei, and cochlear and vestibular (cranial nerve VIII) nuclei. They also form the solitary nucleus, which carries and receives visceral sensation and taste from the facial (cranial nerve VII), glossopharyngeal (cranial nerve IX), and vagus (cranial nerve X), and the cranial portion of the accessory (cranial nerve XI) nerves. This portion also relays information to the cerebellum through the pontine nuclei. The *basal plate motor neuroblasts* form the trigeminal (cranial nerve V), abducens (cranial nerve VI), facial (cranial nerve VII), and superior salivary (cranial nerve VII) nuclei.

The *myelencephalon* ultimately forms the medulla oblongata and caudal fourth ventricle. The alar plate sensory neuroblasts of the caudal portion of the medulla oblongata form the nuclei gracilis and cuneatus, inferior olivary (cerebellar relay) nuclei, solitary nucleus, spinal trigeminal (cranial nerve V) nucleus, and cochlear and vestibular (cranial nerve VIII) nuclei. The basal plate motor neuroblasts of the medulla oblongata give rise to the hypoglossal (cranial nerve XII) nuclei, nucleus ambiguus (cranial nerves IX, X, and XI), the dorsal motor nucleus of the vagus (cranial nerve X), and the inferior salivatory nucleus of the glossopharyngeal (cranial nerve IX) nerve.

DEVELOPMENT OF THE CEREBELLUM

As described earlier, the caudal portion of the cerebellum develops from the metencephalon, and the rostral portion arises from the caudal mesencephalon (2). It is formed by the thickened alar plates of the mantle layer of the neural tube known as *rhombic lips*. Four regions develop from the

cerebellar primordium. The *vermis* develops through midline growth. The *cerebellar hemispheres* develop by lateral growth. The *cerebellar cortex* migrates from the ventricles into the marginal zone, and forms three layers (molecular, Purkinje cell, and internal granular cell) and four pairs of cerebellar nuclei. The *external granular cell* layer is a germinal cell layer that exists on the surface of the cerebellum between the eighth week of development and the end of the second postnatal year. As the cerebellum grows, *folia* and *fissures* form.

ANATOMY OF THE BRAINSTEM (FIGURE 6.2)

The brainstem is the lower extension of the brain where it connects to the spinal cord. Neurological functions located in the brainstem include those necessary for survival (breathing, gastrointestinal function, heart rate, blood pressure) and for arousal and wakefulness. The brainstem also surrounds a narrow passage for the circulation of cerebrospinal fluid. The occlusion of this passage, the *aqueduct of Sylvius*, is often accompanied by the neurological complications of hydrocephalus.

To better understand how lesions of the brainstem cause specific neurological symptoms, it is important to understand the architecture of the brainstem. As the brainstem develops, neuroblasts develop columns that classify the functions of the body into discrete modalities. *General* fibers are found in most spinal nerves, whereas *special* fibers are found only in specific senses. *Somatic* fibers are found in organs of voluntary movement and sensation; *visceral* refers to internal organs. *Afferent* fibers travel from the periphery to the central nervous system, while *efferent* fibers travel from the central nervous system to the periphery. The modalities of nerve fibers are classified in Table 6.1. The functional divisions of the cranial nerves are listed by modality in Table 6.2.

As the brainstem develops, the alar plate becomes the sensory (afferent) nerves, and the basal plate becomes the motor (efferent) nerves. The motor nerves are positioned medially, and the sensory nerves are positioned laterally (Figure 6.3). By the time the brainstem is fully developed, the cranial nerve nuclei are organized into seven longitudinal columns (Figure 6.4). The cell columns run roughly parallel to the longitudinal axis of the brainstem, but are not always continuous. The organization of the cranial nerves into columns is significant for two reasons. First, neurons are organized with similar functions. For example, neurons mediating taste are located in the same position with respect to the midline. Second, different functions are affected when ischemia or hemorrhage damages areas of the brainstem, depending upon whether they are lateral or medial. As a result, one classification scheme of brainstem stroke syndromes is described by its lateral or medial location with respect to the midline.

Structures of the Brainstem

Midbrain (Figure 6.5)

The midbrain is a short, constricted structure that connects the pons and cerebellum with the thalamus and cerebral hemispheres. It consists of several portions: the *cerebral peduncles*, a pair of cylindrical bodies located ventrolaterally; the *corpora quadrigemina*, consisting of four rounded eminences; and the *cerebral aqueduct*, a passage representing

TABLE 6.1 Modalities of the Cranial Nerves

MODALITY	DEFINITION
General somatic afferent (GSA)	Arise from cells in spinal ganglia and conduct pain, touch, and temperature from the surface of the body and muscle/tendon/joint sense from deeper structures through posterior roots of the spinal cord
General visceral afferent (GVA)	Arise from viscera through the rami communicantes and posterior roots to spinal cord
General somatic efferent (GSE)	Arise from motor neuron cell bodies in ventral horns of spinal cord gray matter to skeletal muscle (i.e., alpha motor neurons, gamma motor neurons)
General visceral efferent (GVE)	Arise from cells in lateral column or base of the anterior column through anterior roots and white rami communicantes to sympathetic ganglia that conduct motor impulses to smooth muscles of the viscera and vessels and secretory impulses to the glands
Special somatic afferent (SSA)	Arise from nerves of special senses to the central nervous system (e.g., optic nerve, acoustic nerve)
Special visceral afferent (SVA)	Arise from nerves associated with gastrointestinal tract to the central nervous system (e.g., olfactory nerve, facial nerve, glossopharyngeal nerve, vagus nerve)
Special visceral efferent (SVE)	Arise from central nervous system to muscles of pharygeal arches (e.g., trigeminal nerve, facial nerve, glossopharyngeal nerve, vagus nerve, accessory nerve)

the original cavity of the midbrain that connects the third and fourth ventricles. Each cerebral peduncle is divided into a dorsal and ventral part, separated by the *substantia nigra*. The dorsal part is known as the *tegmentum*, and the ventral part is known as the *base* or *crusta*. The major gray-matter structures of the tegmentum are the *red nucleus* and the *interpeduncular ganglion*. The major tracts include the *superior cerebellar peduncle*, the *medial longitudinal fasciculus* (MLF), and the *medial lemniscus*.

The *red nucleus* is located in the anterior aspect of the tegmentum and the posterior aspect of the subthalamic region. It appears circular in shape, and receives fibers from the superior cerebellar peduncle and medial lemniscus. Axons cross the midline and project into the lateral funiculus of the

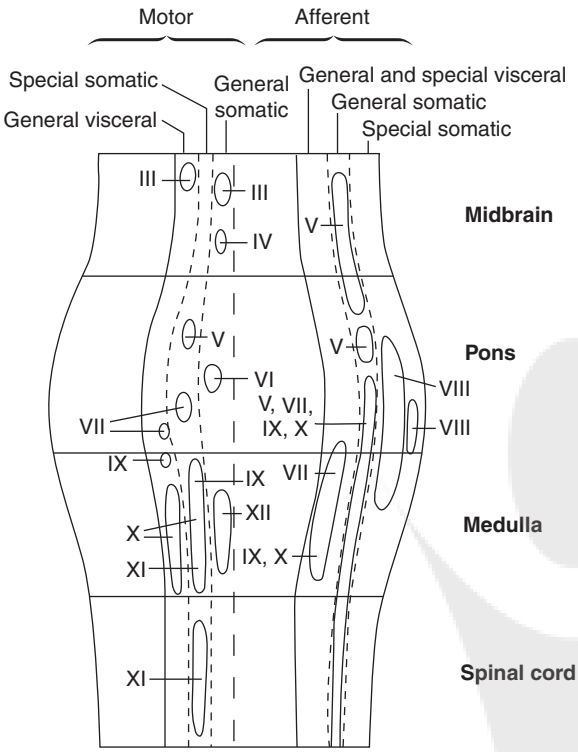

FIGURE 6.4 Columnar organization of the motor and sensory nuclei in the brainstem.

spinal cord as the *rubrospinal tract*, an important part of the pathway from the cerebellum to the lower motor centers.

The *superior cerebellar peduncles* (*brachia conjunctiva*) are two axonal tracts that arise from the dentate nucleus of the cerebellum. The fiber bundles pass rostrally through the dorsal pons to the level of the inferior colliculus. At this point, the fibers decussate, ascend further, and terminate either in the red nucleus or within the motor, ventral lateral, or ventral anterior nuclei of the thalamus. The majority of fibers that convey signals out of the cerebellum to the brainstem are located in these tracts.

The MLF carries information about the direction that the eyes should move as well as head movement (from cranial nerve VIII). The MLF arises from the vestibular nucleus and is thought to mediate the maintenance of gaze. This is achieved by inputs from several structures: the acoustic (cranial nerve VIII) nerve that mediates head movements; the flocculus of the cerebellum that adjusts gain; and head and neck propioceptors and foot and ankle muscle spindles, through the fastigial nucleus. It mediates conjugate gaze by carrying electrical signals from the abducens (cranial nerve VI) nuclei, across the midline, then ascending to the oculomotor (cranial nerve III) and trochlear (cranial nerve IV) nuclei. The MLF also descends into the cervical spinal cord, where it innervates some muscles of the neck.

The vertical gaze center is located in the rostral interstitial nucleus of the MLF that lies just posterior to the red nucleus. From each vertical gaze center, signals are conducted to the subnuclei of the ocular muscles that control vertical gaze in both eyes. Cells mediating downward eye movements are intermingled in the vertical gaze center, but ischemia of this region may result in selective paralysis of upgaze.

The *medial lemniscus* originates in the nucleus gracilis and cuneatus of the medulla oblongata, and crosses to the opposite side in the sensory decussation. It then ascends through the medulla oblongata into the pons and lower portion of the midbrain, where it receives fibers from sensory nuclei of the contralateral cranial nerves. The majority of the fibers, however, enter the ventral lateral nucleus of the thalamus, give off collaterals, and then terminate in the principal sensory nucleus of the thalamus.

The *corpora quadrigemina* are four rounded structures that form the dorsal aspect of the midbrain. The corpora quadrigemina are arranged in pairs, as the *superior* and *inferior colliculi*. The superior colliculi are associated with the sense of sight, the inferior with that of hearing.

The afferent fibers of the superior colliculi largely originate in the retina and are conveyed to it through the superior brachium and lateral geniculate body. Some of the efferent fibers cross the midline to the opposite colliculus, while many ascend through the superior brachium and terminate in the cortex of the occipital lobe.

Pons (Figure 6.6)

The pons is a bridge-like structure that links different parts of the brain and relays information from the medulla oblongata to the higher cortical structures of the cerebrum. It contains the ventilatory and horizontal gaze centers. The pons sits in front of the cerebellum, and is connected to the cerebellum through the *middle cerebellar peduncle*. The pons consists of two aspects: the ventral surface (pars basilaris pontis), and the dorsal surface (pars dorsalis pontis). The ventral surface of the pons consists of superficial and deep transverse fibers, longitudinal fasciculi, and some small nuclei of gray substance (termed *nuclei pontis*) that give rise to transverse fibers. It is in the nuclei pontis that the cortical axons that travel through the internal capsule and cerebral peduncle form synapses with transverse fibers that decussate and pass through the middle peduncle into the cerebellum. The dorsal surface of the pons consists largely of ascending projections of the reticular formation and gray substance from the medulla oblongata. Other significant structures in the pons include the *superior olivary nucleus* and the *paramedian pontine reticular formation* (PPRF).

The PPRF is located anterolateral to the MLF. It receives input from the superior colliculus and from the frontal eye fields. The rostral aspect of the PPRF (rostral interstitial nucleus of the MLF) probably coordinates vertical saccades, while the caudal aspect of the PPRF may generate horizontal saccades. In particular, excitatory burst neurons (EBNs) in the PPRF generate "pulse" movements that initiate a saccade. With respect to horizontal saccades, the "pulse"

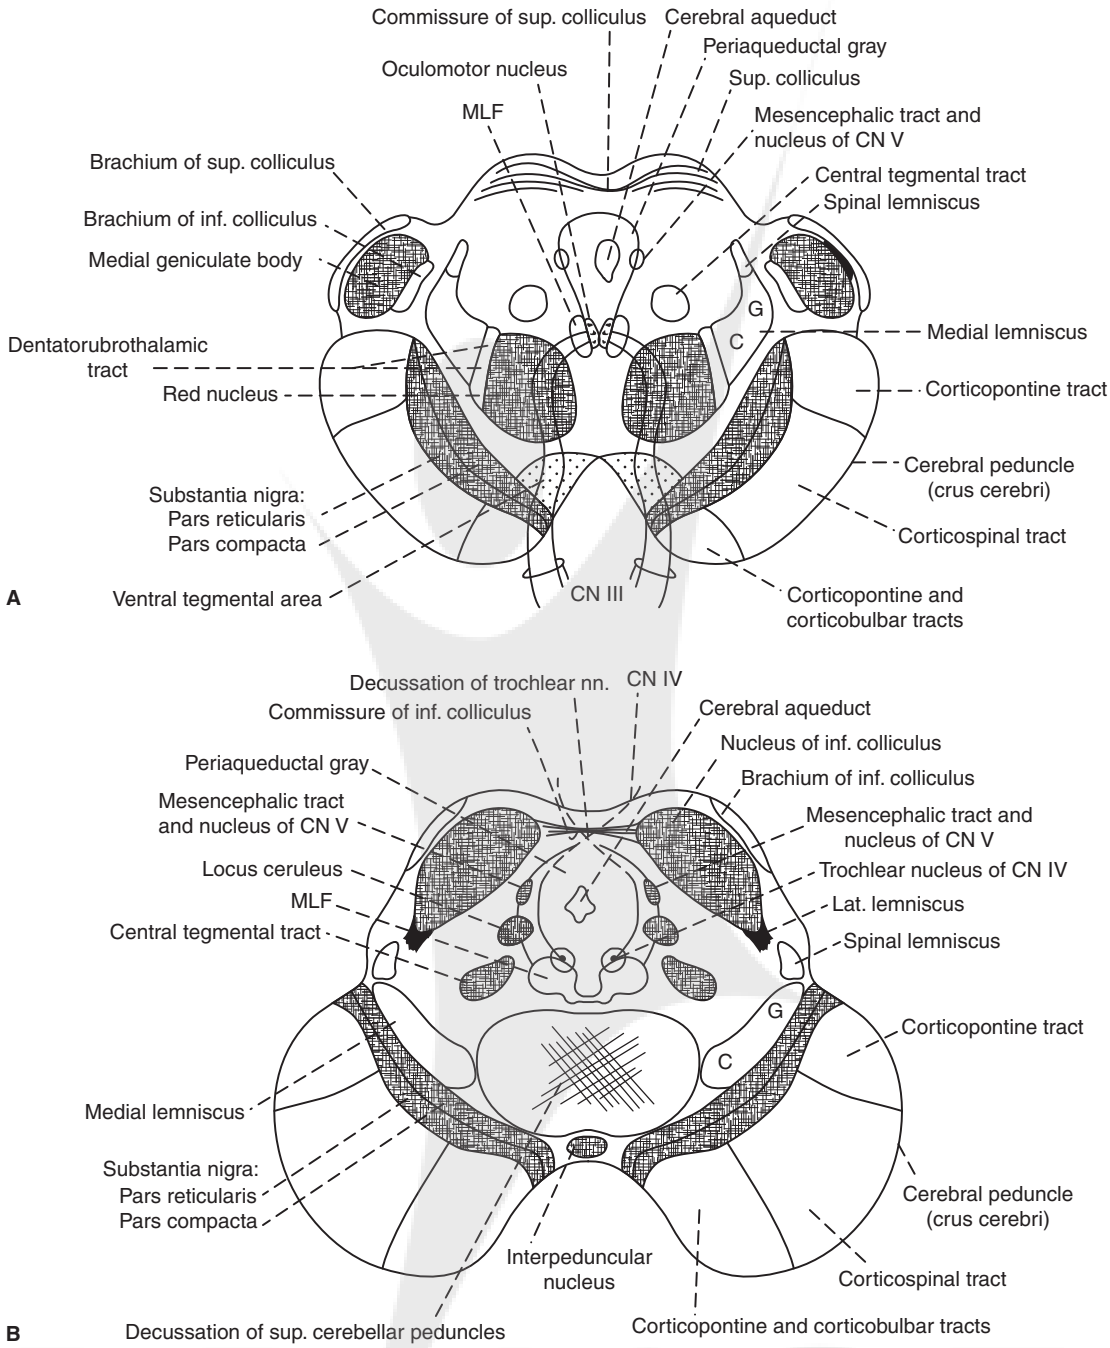

FIGURE 6.5 Clinical neuroanatomy of the midbrain. (A) Midbrain at the level of the superior colliculus. (B) Midbrain at the level of the inferior colliculus.

Source: Reprinted with permission from Fix JD. *Neuroanatomy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.

information is conveyed via axonal fibers to the abducens (cranial nerve VI) nucleus, subsequently initiating horizontal eye movements. Two types of neurons in the abducens nucleus complete horizontal movement: a lower motor neuron that innervates the ipsilateral lateral rectus muscle and an internuclear neuron that sends axons across the midline, up the MLF, and into lower motor neurons of the contralateral oculomotor nucleus that innervate the medial rectus muscle.

Medulla Oblongata (Figure 6.7)

The medulla oblongata extends from the inferior border of the pons to a plane passing transversely between the pyramidal decussation and the first pair of cervical nerves. This plane corresponds with the upper border of the atlas and basilar part of the occipital bone behind, and the middle of the odontoid process of the axis in front. The medulla oblongata functions primarily as a relay station for the crossing of

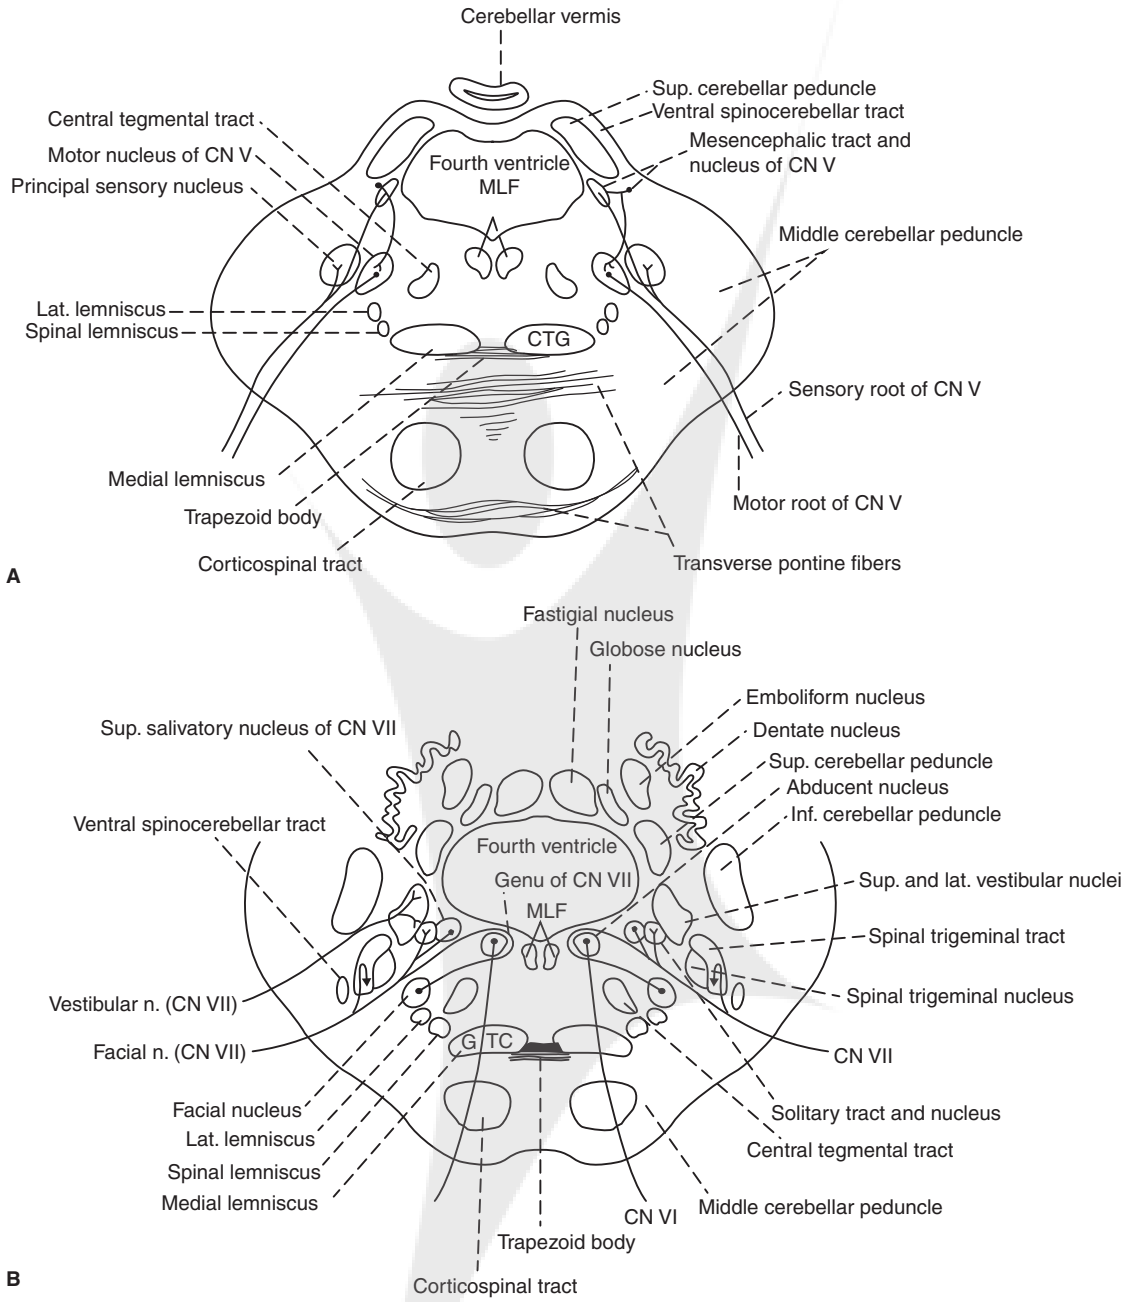

FIGURE 6.6 Clinical neuroanatomy of the pons. (A) Midpontine region. (B) Caudal aspect of the pons.

Source: Reprinted with permission from Fix JD. *Neuroanatomy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.

motor tracts between the spinal cord and the brain. It also contains the respiratory, vasomotor, and cardiac centers, as well as many mechanisms for controlling some involuntary actions such as coughing, gagging, swallowing, and vomiting. Significant structures in the medulla oblongata include the *olive* and the *inferior cerebellar peduncle*. The *olive* is located lateral to the pyramidal tracts.

The *inferior cerebellar peduncle* is located in the superoposterior portion of the medulla oblongata. It is a thick rope-like strand that sits between the inferior portion of the fourth ventricle and the glossopharyngeal (cranial nerve IX) and vagus (cranial nerve X) nerve roots.

The inferior cerebellar peduncles connect the spinal cord and medulla oblongata with the cerebellum. The inferior cerebellar peduncle carries many types of input and output fibers that mainly integrate proprioceptive sensory input with motor vestibular functions, such as balance and posture maintenance. Proprioceptive information from the

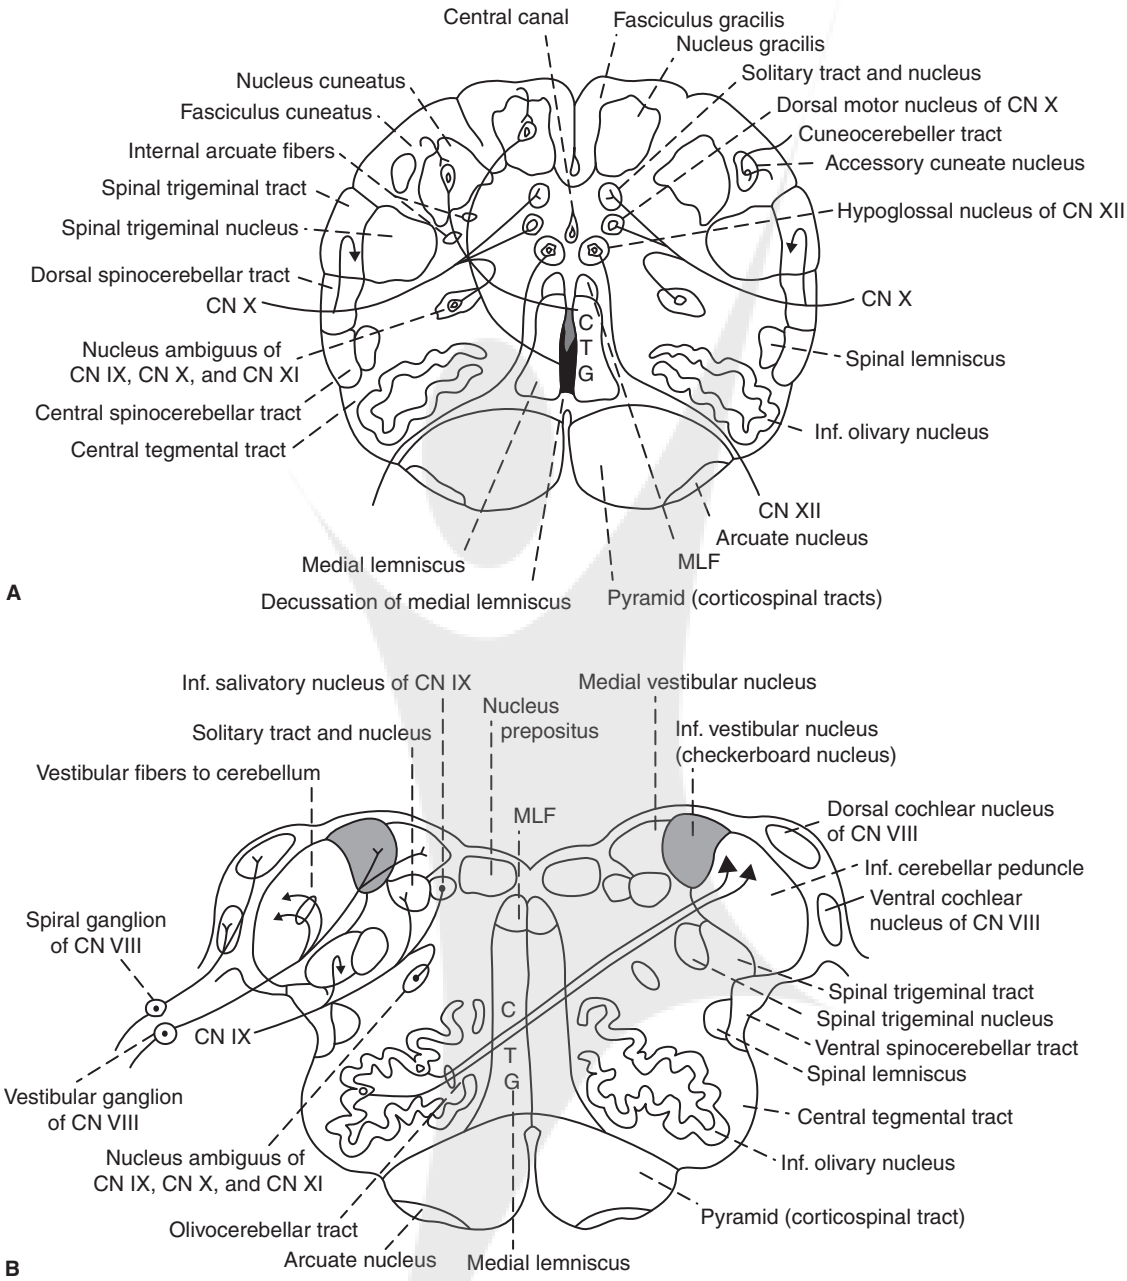

FIGURE 6.7 Clinical neuroanatomy of the medulla oblongata. (A) Rostral aspect of the medulla oblongata. (B) Caudal aspect of the medulla oblongata.

body is conveyed to the cerebellum through the posterior spinocerebellar tract. The inferior cerebellar peduncle also carries information directly from Purkinje cells to the vestibular (cranial nerve VIII) nuclei at the junction of the pons and medulla oblongata.

Nuclei

A cranial nerve nucleus is a collection of neurons (gray matter) in the brainstem associated with one or more cranial nerves. Axons carrying information to and from the cranial nerves synapse at these nuclei. Ischemic or hemorrhagic lesions of these nuclei usually lead to neurological deficits resembling those seen when the nerves with which they are associated are severed. All cranial nerve nuclei, except for the trochlear (cranial nerve IV) nerve, supply nerves of the same side of the body.

The *olfactory nerve* (cranial nerve I) arises from spindle-shaped bipolar cells in the surface epithelium of the olfactory region of the nasal cavity. The nonmyelinated axons ascend through the cribriform plate to the olfactory bulb. At this point, several fibers, each ending in a tuft of terminal filaments, come into contact with the brush-like

end of a single dendrite from a mitral cell, giving rise to the olfactory glomeruli of the bulb. The termination of a number of olfactory fibers in a single glomerulus accounts (in part at least) for the detection by the olfactory organs of very dilute solutions. The olfactory fibers form synapses with dendrites of one or two mitral cells, providing for the summation of stimuli in the mitral cells. The majority of the axons that arise from the mitral cells of the olfactory bulb and course in the olfactory tract travel through the lateral olfactory stria to the uncus and hippocampal gyrus, and terminate in the cortex. Other fibers may pass to the uncus and hippocampal gyrus from the primary olfactory centers in the trigonum and anterior perforated substance. The branches and axons that pass backward terminate partly in the dentate gyrus and hippocampal gyrus. Shorter association fibers connect various sections of the gyrus fornicatus (cingulate gyrus, isthmus, and hippocampal gyrus) and these with other regions of the cortex. These gyri constitute the cortical center for smell.

The *optic nerve* (cranial nerve II) consists chiefly of coarse fibers that arise from the ganglionic layer of the retina. They constitute the third neuron in the series composing the visual path and are supposed to convey only visual impressions. A number of fine fibers also pass in the optic nerve from the retina to the primary centers and are supposed to be concerned with pupillary reflexes. In addition, there are a few fibers that pass from the brain to the retina. They reportedly control chemical changes in the retina and the movements of the pigment cells and cones.

In the optic chiasm, the nerves from the medial half of each retina cross to the opposite optic tract, and the nerves from the lateral half of each retina continue in the optic tract of the same side. The crossed fibers occupy the medial side of each optic nerve, but are more intermingled in the chiasm and in the optic tract. Most of the fibers of the optic tract terminate in the lateral geniculate body, but some may pass through the superior brachium to the superior colliculus, or through the lateral geniculate body to the pulvinar of the thalamus. The superior colliculus receives fibers from the visual sensory cortex in the occipital lobe that pass through the optic radiations.

The *oculomotor nerve* (cranial nerve III) contains somatic motor fibers to the inferior oblique, inferior rectus, superior rectus, levator palpebræ superioris, and medial rectus muscles. In addition, preganglionic sympathetic efferent fibers are carried to the ciliary ganglion. The postganglionic fibers from the ciliary ganglion supply the ciliary muscle and the sphincter of the iris. The axons arise from the nucleus of the oculomotor nerve, and traverse the posterior longitudinal bundle, tegmentum, red nucleus, and the medial margin of the substantia nigra to emerge from the oculomotor sulcus on the medial side of the cerebral peduncle.

The nucleus of the oculomotor nerve contains several distinct groups of cells that vary in size and appearance from each other and terminates its axons at separate muscles. It is uncertain which group supplies which muscle. There are seven of these nuclei on either side of the midline and one medial nucleus. The cells of the anterior nuclei are smaller and may give off sympathetic efferent axons. The majority of fibers arise from the nucleus of the same side. However, some may cross to the opposite side and supply the contralateral medial rectus muscle. Because the oculomotor and abducens nuclei are connected by the MLF, this decussation of fibers to the medial rectus may facilitate the conjugate movements of the eyes in which the medial and lateral recti muscles are involved.

The *trochlear nerve* (cranial nerve IV) contains only somatic motor fibers. It supplies the superior oblique muscle of the eye. Its nucleus is a small, oval mass located in the ventral part of the central gray matter of the cerebral aqueduct at the level of the superior aspect of the inferior colliculus. The axons from the nucleus descend in the tegmentum toward the pons, but abruptly turn dorsally before reaching it, cross horizontally, and decussate with the nerve of the opposite side. The nerve emerges immediately behind the inferior colliculus. There are no branches from the fibers of the pyramidal tracts to these nuclei. It is thought that the volitional pathway must be an indirect one.

The *trigeminal nerve* (cranial nerve V) contains somatic motor and sensory fibers. The motor fibers arise in the trigeminal motor nucleus, and travel ventrolaterally through the pons to supply the muscles of mastication. The sensory fibers arise from the semilunar ganglion, and are distributed to the face and anterior two-thirds of the head. The central fibers pass into the pons with the motor root, and bifurcate into ascending and descending branches that terminate in the sensory nuclei of the trigeminal.

The sensory nucleus consists of an enlarged upper end, the main sensory nucleus, and a long, more slender portion that descends through the pons and medulla oblongata to become continuous with the dorsal part of the posterior column of the gray matter of the spinal cord. This descending portion consists mainly of substantia gelatinosa and is called the *nucleus of the spinal tract of the trigeminal nerve*. Most of the fibers cross to the trigeminothalamic tract of the opposite side, ascend dorsal to the medial lemniscus, and terminate in a distinct part of the thalamus. The somatic sensory fibers of the vagus, glossopharyngeal, and facial nerves probably end in the nucleus of the descending tract of the trigeminal nerve. Their cortical impulses are probably carried up in the central sensory path of the trigeminal nerve.

The *abducens nerve* (cranial nerve VI) contains only somatic motor fibers that supply the lateral rectus muscle of the eye. The fibers arise from the abducens nucleus, pass ventrally through the pons, and exit from the transverse groove between the caudal edge of the pons and the pyramid. These fibers probably terminate in relation with the MLF, which controls conjugate gaze. The fibers of the MLF originate in the terminal nuclei of the vestibular nerve, and give off collateral and terminal neurons to the abducens, trochlear, and oculomotor nuclei. The abducens nucleus also receives collateral and terminal neurons from the tectospinal fasciculus, the reflex auditory center in the inferior colliculus, and other sensory nuclei of the brainstem.

The *facial nerve* (cranial nerve VII) consists of somatic and visceral afferent and efferent fibers. The afferent fibers arise from cells in the geniculate ganglion, and pass through what is often known as the *nervus intermedius*. There are few somatic afferent fibers. Their purpose is to convey impulses from the middle ear, but their existence and central termination have not been confirmed fully. There also are few visceral afferent fibers, and their terminations are likewise unknown. Taste fibers carry impulses from the anterior two-thirds of the tongue via the *chorda tympani* to the solitary tract and nucleus.

Somatic efferent fibers supply muscles derived from the hyoid arch, and originate from the facial nucleus. The facial nucleus consists of a dorsal and a ventral region. The dorsal region innervates muscles of the upper face, and the ventral region innervates muscles of the lower face. Impulses are carried from the cerebral cortex through the corticobulbar tract. Interestingly, the dorsal region of the facial nucleus receives bilateral cortical input, while the ventral region receives only contralateral input. The facial nucleus also receives fibers from the superior colliculus and ventral longitudinal bundle for optic reflexes; the inferior colliculus through the auditory reflex path; and indirectly from sensory nuclei of the brainstem.

Visceral efferent fibers arise from either the small cells of the facial nucleus or cells in the reticular formation, located dorsomedial to the facial nucleus, known as the *superior salivary nucleus*. These preganglionic fibers synapse at the submaxillary ganglion with postganglionic fibers that innervate the submaxillary and sublingual glands. Other preganglionic fibers travel by way of the great superficial petrosal nerve to the sphenopalatine ganglion.

The *acoustic nerve* (cranial nerve VIII) consists of the *cochlear nerve* and the *vestibular nerve*. The cochlear nerve, the nerve of hearing, terminates at the *cochlear nucleus*. The cochlear nucleus consists of a larger dorsal nucleus on the dorsolateral aspect of the inferior peduncle, and a ventral nucleus more ventral to the inferior peduncle and medial geniculate body. Most of the axons continue to ascend beneath the optic tract into the corona radiata and subsequently to the cortex of the superior temporal gyrus.

The *vestibular nerve* mediates the maintenance of bodily equilibrium. Once within the medulla oblongata, it bifurcates into ascending and descending branches. The descending branch terminates in the medial vestibular nucleus, the principal nucleus of the vestibular nerve. The ascending branch passes through the inferior cerebellar peduncle to the contralateral nucleus tecti.

The *glossopharyngeal nerve* (cranial nerve IX) contains somatic and sympathetic afferent, taste, somatic motor, and sympathetic efferent fibers. The afferent fibers arise from the superior ganglion and in the petrosal ganglion. There are few somatic afferent fibers that carry sensory impulses from the external ear, pharynx, and faucial arches. The visceral afferent fibers from the pharynx and middle ear assist in chewing and swallowing. Taste fibers from the tongue combine with fibers from the *nervus intermedius* and terminate in the solitary nucleus. Somatic efferent fibers originate in the nucleus ambiguus and innervate the stylopharyngeus muscle. Visceral efferent fibers originate in the nucleus dorsalis or the inferior salivary nucleus, and synapse through the otic ganglion to their termination in the parotid gland.

The *vagus nerve* (cranial nerve X) contains somatic and visceral afferent and efferent fibers, as well as taste fibers. There are few somatic afferent fibers that carry impulses from a small area of the skin on the back of the ear and posterior part of the external auditory meatus. The visceral afferent fibers carry impulses from the heart and pancreas, and probably the stomach, esophagus, and respiratory tract, to the *dorsal nucleus of the vagus* and glossopharyngeal nerves. The dorsal nucleus comes into relation with neurons that may carry impulses to the muscles of ventilation, such as the phrenic nerve and the nerves to the intercostal and levatores costarum muscles. Taste fibers conduct impulses from the epiglottis and larynx through the vagus nerve and join the *solitary tract*, subsequently terminating in the *solitary nucleus*. The solitary nucleus connects with motor centers of the pons, medulla oblongata, and spinal cord to mediate mastication and swallowing. Somatic efferent fibers from the *nucleus ambiguus* innervate voluntary muscles of the pharynx and larynx, and receive impulses from the opposite pyramidal tract. Visceral efferent fibers arise from the dorsal nucleus and synapse through sympathetic ganglia to fibers that facilitate the function of the esophagus, stomach, small intestine, gallbladder, and lungs; inhibit the function of the heart; and cause secretion within the stomach and pancreas.

The *accessory nerve* (cranial nerve XI) contains only somatic efferent fibers, and consists of spinal and cranial portions. The spinal portion arises from lateral cells in the anterior column of the upper five or six segments of the cervical spinal cord, and innervates the trapezius and sternocleidomastoid muscles. The cranial portion originates in the nucleus ambiguus. The fibers travel through the vagus nerve to the laryngeal nerves, and supply the muscles of the larynx. The spinal portion receives impulses from the ipsilateral pyramidal tracts, while the cranial portion receives impulses from the opposite pyramidal tract and forms the terminal sensory nuclei of the cranial nerves.

The *hypoglossal nerve* (cranial nerve XII) contains only somatic efferent fibers and innervates the muscles of the tongue. Its axons originate in the hypoglossal nucleus and exit the medulla oblongata at the anterolateral sulcus. The hypoglossal nuclei are connected by commissural fibers and dendrites of motor cells that connect the two nuclei. The hypoglossal nucleus receives impulses from the contralateral pyramidal tract.

Tracts (Figure 6.8)

The brainstem is the "superhighway" among the cerebrum, cerebellum, and spinal cord. Motor impulses travel from the cerebral cortex to the extremities, while sensory impulses travel in the opposite direction. Motor and sensory signals also are relayed to and from cranial structures through

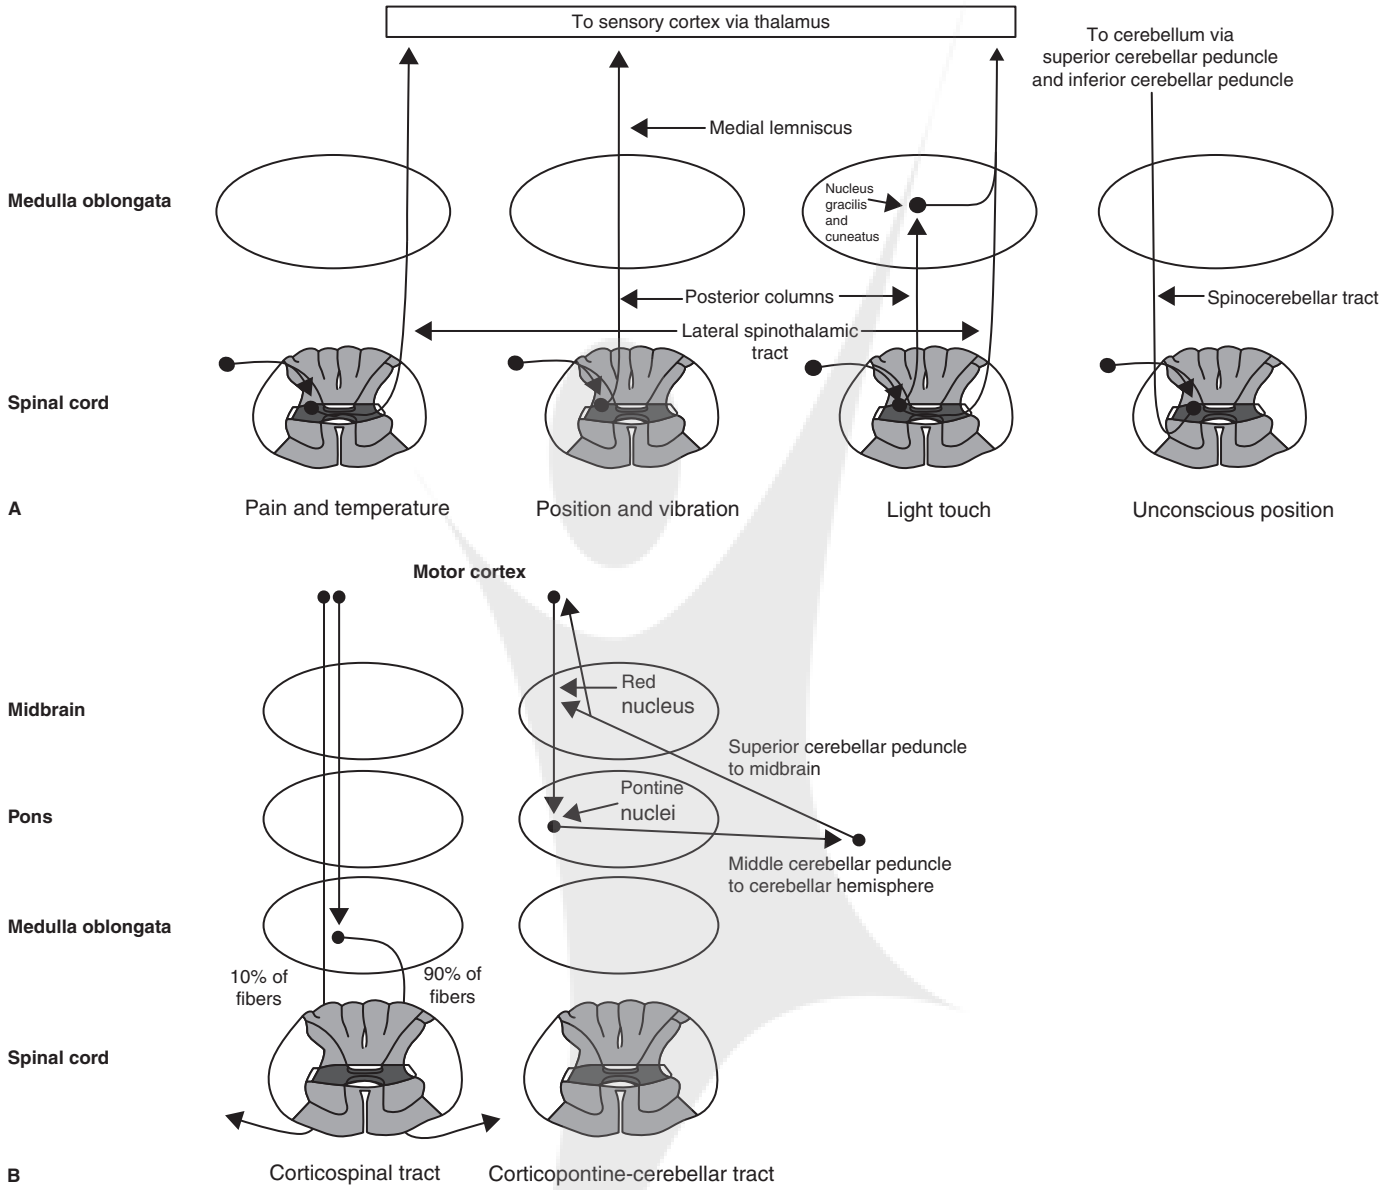

FIGURE 6.8 Schematic diagrams of the brainstem tracts. (A) Brainstem sensory tracts. (B) Brainstem motor tracts.

bulbar pathways. Signals to the cerebellum modulate movement and tone. Impulses to and from the autonomic nervous system mediate the function of visceral structures. Overall, three major types of tracts provide the connections among all of these structures: motor, sensory, and extrapyramidal.

Corticospinal (pyramidal) tract. The *corticospinal* tract is also called the *pyramidal* tract because the bundle of corticospinal axons looks like two column-like structures ("pyramids") on the ventral surface of the medulla oblongata. The corticospinal tract contains a massive number of motor axons that travel between the cerebral cortex of the brain and the spinal cord. The axons originate in the motor cortex and move closer together as they travel caudally through the cerebral white matter and form part of the posterior limb of the internal capsule. The fibers continue into the brainstem, and remain uncrossed until they reach the spinomedullary junction.

At this point, approximately 90% of the corticospinal fibers cross over to the contralateral side in the medulla oblongata (pyramidal decussation), forming the *lateral corticospinal tract* of the spinal cord. The remaining 10% of fibers remain ipsilateral, forming the *anterior corticospinal tract*. These fibers cross at the level where they exit the spinal cord, thereby combining with the lateral corticospinal tract axons at the ventral horn of a given spinal cord level to synapse with the second-order neuron. It is not difficult to understand why one side of the brain controls the opposite side of the body.

The *corticobulbar tract* is considered to be a pyramidal tract. The corticobulbar tract carries signals that control motor neurons located in the cranial nerve brain nuclei. The neurons in the motor cortex send axons contralateral to the cranial nuclei of the midbrain (cortico-mesencephalic tract), pons (cortico-pontine tract), and medulla oblongata (cortico-bulbar tract), and decussate when they reach each cranial nucleus.

Spinothalamic tract. The *spinothalamic tract* is a sensory pathway originating in the spinal cord. It consists of two parts: the *lateral spinothalamic tract*, which transmits information about pain and temperature; and the *anterior spinothalamic tract*, which transmits information about pressure and crude touch. The pathway decussates through the anterior white commissure one to two spinal nerve segments above the point of entry, and travels up the spinal cord into the rostral ventromedial medulla. The neurons ultimately synapse with third-order neurons in the medial dorsal, ventral posterior lateral, and ventral medial posterior nuclei of the thalamus. The cell bodies of neurons that comprise the spinothalamic tract originate primarily in the dorsal horn of the spinal cord. The axons of cells that mediate pain and temperature decussate through the anterior white commissure just above their level of entrance to the spinal cord and travel rostrally in the contralateral spinothalamic tract. The axons of cells that mediate proprioception and vibration travel in the ipsilateral dorsal columns to the nucleus gracilis and nucleus cuneatus within the medulla oblongata, at which time they decussate to the contralateral medial lemniscus. After they enter the brainstem, the sensory axons are positioned more dorsally, and ultimately synapse with third-order neurons in the medial dorsal, ventral posterior lateral, and ventral medial posterior nuclei of the thalamus.

Cerebellar tracts. (See also "Internal Structures of the Cerebellum" subsection in the "Structures of the Cerebellum" section later in this chapter). The cerebellum is connected to the brainstem through three pathways known as *cerebellar peduncles*. The *superior cerebellar peduncle* connects the cerebellum to the pons and midbrain, and contains the *dentorubrothalamic* and *ventral spinocerebellar* tracts. The *middle cerebellar peduncle* contains contralateral pontocerebellar fibers. The *inferior cerebellar peduncle* connects the medulla oblongata to the cerebellum, and contains the ipsilateral *dorsal spinocerebellar* tract.

The cerebellum receives significant input from and gives feedback to the cerebral hemispheres through the *corticopontocerebellar* and *cerebellothalamocortical* tracts. The corticopontocerebellar tracts arise from all lobes of the cerebral hemispheres, most notably the prefrontal area, sensorimotor cortex, and occipital lobes. First-order neurons travel caudally to the ipsilateral pons and synapse with second-order neurons that cross to the contralateral cerebellar hemisphere via the middle cerebellar peduncle. The *cerebellothalamocortical* tract originates largely from the contralateral dentate nucleus and nucleus interpositus of the cerebellum. The fibers travel through the superior cerebellar peduncle into the contralateral ventral lateral nucleus of the thalamus. They synapse with fibers that ultimately terminate in the contralateral premotor and primary motor cortices (although some fibers may terminate ipsilaterally as well).

Vasculature of the Brainstem (Figure 6.9)

Vertebral Artery

The main blood supply of the brainstem comes from the vertebral arteries, the first branch of each subclavian artery. The vertebral artery ascends through the foramina in the transverse processes of the upper six cervical vertebrae, winds behind the superior articular process of the atlas, enters the skull through the foramen magnum, and unites at the inferior aspect of the pons with the opposite vertebral artery to form the basilar artery. Dissection of the vertebral artery may occur when sudden torque forces are applied to the vertebrae.

The branches of the vertebral artery are classified by those given off in the neck, and those given off within the cranium. Spinal branches enter the vertebral canal through the intervertebral foramina, and each divides into two branches: one supplies the spinal cord and its membranes; the other divides into an ascending and a descending branch, which forms an anastomotic chain with arteries from above and below to supply the periosteum and bodies of the vertebrae. Muscular branches supply the deep muscles of the neck along with the occipital and deep cervical arteries. The meningeal branch originates opposite the foramen magnum, and supplies the falx cerebelli. Medullary branches, known as *bulbar arteries*, are minute vessels that supply blood to the medulla oblongata.

The *posterior spinal arteries* arise at the level of the medulla oblongata, and enter the vertebral canal through the intervertebral foramina. Branches from the posterior spinal arteries anastomose around the posterior roots of the spinal nerves and communicate with vessels from the opposite side. An ascending branch near the origin of each posterior spinal artery ends at the side of the fourth ventricle.

The *anterior spinal artery* arises near the union of the vertebral arteries, descends anteriorly to the medulla oblongata, and unites with the opposite artery at the level of the foramen magnum. The single trunk descends anterior to the spinal cord, and is reinforced by many small branches which enter through intervertebral foramina throughout the vertebral canal.

The *posterior inferior cerebellar artery* (PICA) is the largest branch of the vertebral artery. In the brainstem, it supplies the medial and inferior vestibular nuclei, inferior cerebellar penduncle, nucleus ambiguus, intra-axial fibers of the glossopharyngeal and vagus nerves, and portions of the spinothalamic tract and spinal trigeminal nucleus and tract. Disruption of the PICA may cause Horner's syndrome because it also supplies a portion of the hypothalamospinal tract (descending sympathetic tract) to the ciliospinal center of Budge at T1–T2.

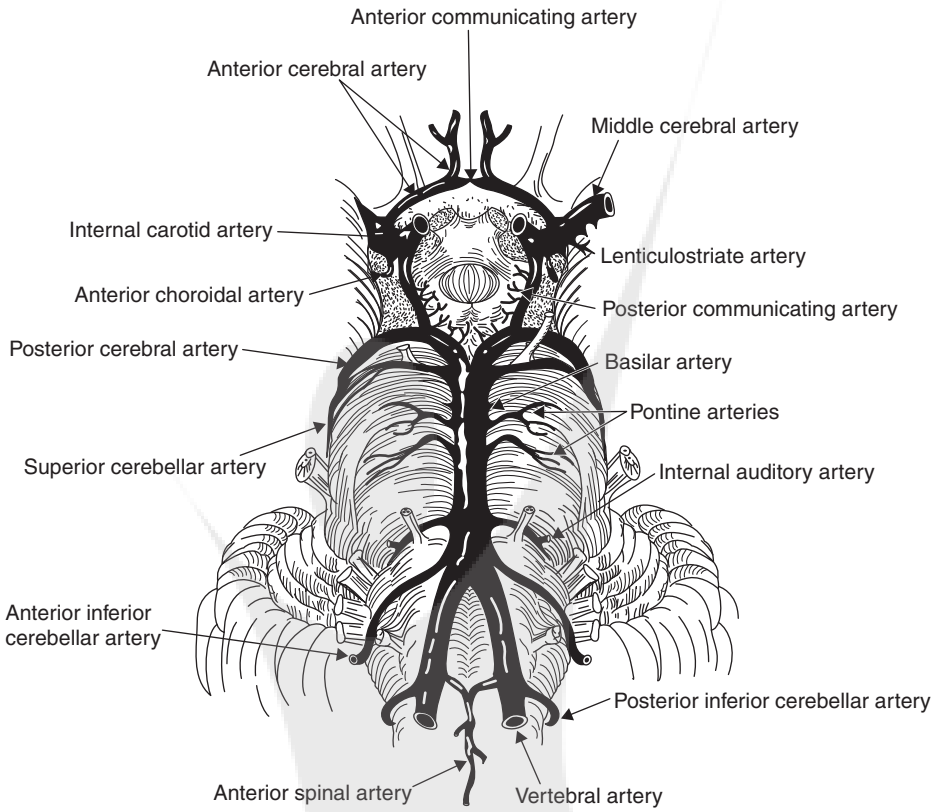

FIGURE 6.9 Vasculature of the brainstem and cerebellum.

Source: Reprinted with permission from Chusid JG. C*orrelative Neuroanatomy and Functional Neurology*. 17th ed. Los Altos, CA: Lange Medical Publications; 1979:47.

Basilar Artery

The basilar artery is named because of its position at the base of the skull. It ascends from its union of the vertebral arteries in the inferior aspect of the pons to the superior border of the pons. At this level, it divides into the two posterior cerebral arteries.

The *pontine branches* come off at right angles from both sides of the basilar artery and supply the pons and adjacent parts of the brain.

The *internal auditory artery* arises near the middle of the artery, and accompanies the acoustic nerve through the internal acoustic meatus, where it supplies blood to the internal ear.

The *anterior inferior cerebellar artery* (AICA) supplies the facial nucleus and intra-axial fibers, the spinal trigeminal nucleus and tract, vestibular nuclei, cochlear nuclei, intra-axial fibers of the acoustic nerve, spinothalamic tract, and inferior and middle cerebellar peduncles. In most people, the AICA gives rise to the labyrinthine artery. Disruption of the AICA may also cause Horner's syndrome because it supplies a portion of the hypothalamospinal tract.

The *superior cerebellar artery* (SCA) originates just below the division of the basilar artery, and passes laterally below cranial nerve III. It supplies the rostral and lateral pons, as well as the superior cerebellar peduncle and spinothalamic tract. Pressure from the artery on the trigeminal nerve is the usual cause of trigeminal neuralgia.

ANATOMY OF THE CEREBELLUM (FIGURE 6.10)

The cerebellum comprises the largest part of the hindbrain. It is positioned posterior to the pons and medulla oblongata. The cerebellum is characterized by a laminar appearance, with deep, curved fissures that divide it into a number of layers or leaves. Between the central portion of the cerebellum and the brainstem is the cavity of the fourth ventricle. It is not convoluted like the cerebrum, but contains many sulci that vary in depth. The proportional size of the cerebellum to the cerebrum increases from approximately 1:20 in the infant to 1:8 in the adult.

The function of the cerebellum is the coordination of movement necessary in equilibration, locomotion, and prehension. The cerebellum processes impulses that mediate muscle and tendon sense, joint sense, and equilibratory disturbances. The exact functions of its different parts are still not well understood.

Structures of the Cerebellum

Lobes of the Cerebellum

The cerebellum has three sections, a median and two lateral, that are contiguous and similar in structure. The median section is the *vermis*, named for its ringlike bands that form ridges and furrows. The lateral sections are the *hemispheres*.

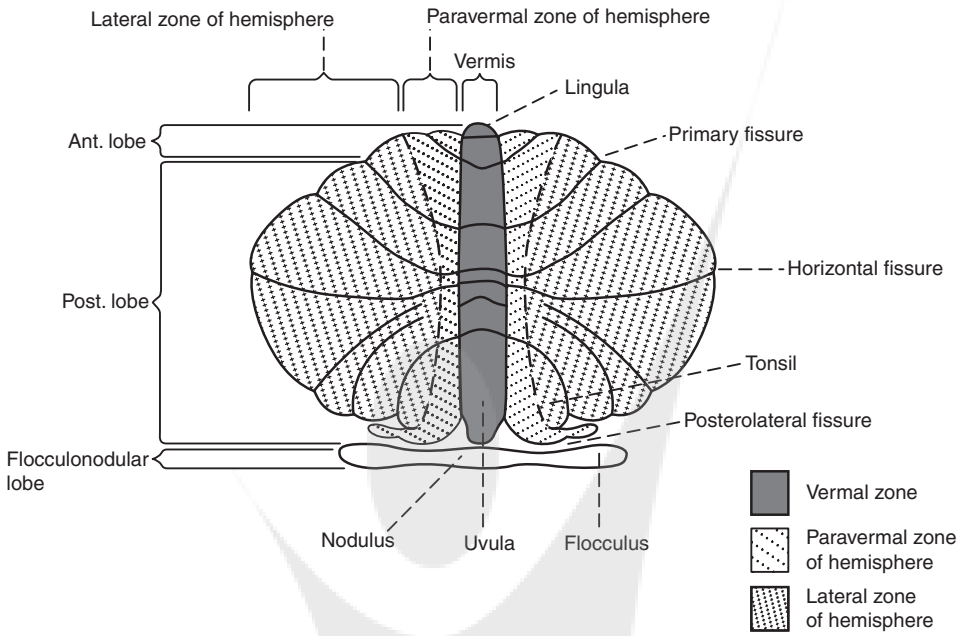

FIGURE 6.10 Schematic neuroanatomy of the cerebellum.

Source: Reprinted with permission from Fix JD. *Neuroanatomy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001:232.

The superior aspect of the vermis is subdivided from anterior to posterior into the *lingula*, the *lobulus centralis*, the *monticulus*, and the *folium vermis*. With the exception of the lingula, each division is contiguous with the corresponding portion of the hemispheres: the *alae*, the *quadrangular lobules*, and the *superior semilunar lobules*.

The inferior aspect of the cerebellum also is divided into the midline *inferior vermis*, and the *hemispheres* on either side. The inferior vermis is subdivided from anterior to posterior into the *nodule*, the *uvula*, the *pyramid*, and the *tuber vermis*. The corresponding subdivisions of the hemispheres consist of the *flocculus*, the *tonsilla cerebelli*, the *biventral lobule*, and the *inferior semilunar lobule*.

Internal Structure of the Cerebellum

The cerebellum consists of white and gray matter. In the sagittal plane, the interior consists of a gray mass, the *dentate nucleus*, which sits in the middle of a central stem of white matter. The white matter contains two sets of nerve fibers: the *projection fibers* and the *fibrae propriae*. The projection fibers consist of the three cerebellar peduncles (Figure 6.11; see also the "Cerebellar Tracts" subsection of the "Structures of the Brainstem" section).

The *dentate nucleus* lies slightly medial to the center of the stem of white matter of the hemisphere. It consists of an irregularly folded grayish-yellow lamina that contains white matter. Most of the fibers of the superior peduncle emerge from the anteromedial aspect of the dentate nucleus, where an opening, the *hilus*, is found. The superior peduncle is responsible for the planning, initiation, and control of volitional movement.

The *superior cerebellar peduncles* are largely derived from cells of the dentate nucleus of the cerebellum. They travel rostrally beneath the corpora quadrigemina, decussate ventral to the Sylvian aqueduct, and divide into ascending and descending tracts. The ascending tract terminates in the red nucleus, thalamus, and oculomotor nucleus, while the descending tract appears to terminate in the dorsal aspect of the pons.

The *middle cerebellar peduncles* are comprised entirely of cells that originate in the contralateral pontine nuclei and terminate in the cerebellar cortex. The tracts have three fasciculi. The superior fasciculus distributes nerve fibers to the inferior lobules of the cerebellar hemisphere and to posterolateral margins of the superior surface. The inferior fasciculus distributes nerve fibers to the folia close to the inferior vermis. The deep fasciculus distributes nerve fibers to the upper anterior cerebellar folia and inferior cerebellar peduncles.

The *inferior cerebellar peduncles* consist of a variety of nerve fibers: the *dorsal spinocerebellar tract* that terminates in the superior vermis; the ipsilateral and contralateral nucleus gracilis and nucleus cuneatus; the contralateral olivary nuclei; the ipsilateral and contralateral medullary reticular formation; the vestibular nucleus and tract that terminate partly in the contralateral roof nucleus; the contralateral cerebellobulbar tracts from the contralateral roof nucleus and dentate nucleus; and some nerve fibers from the ventral spinocerebellar tract that combine with dorsal spinocerebellar tract.

The *fibrae propriae* of the cerebellum are of two kinds: (a) *commissural* fibers, which connect the two halves of the

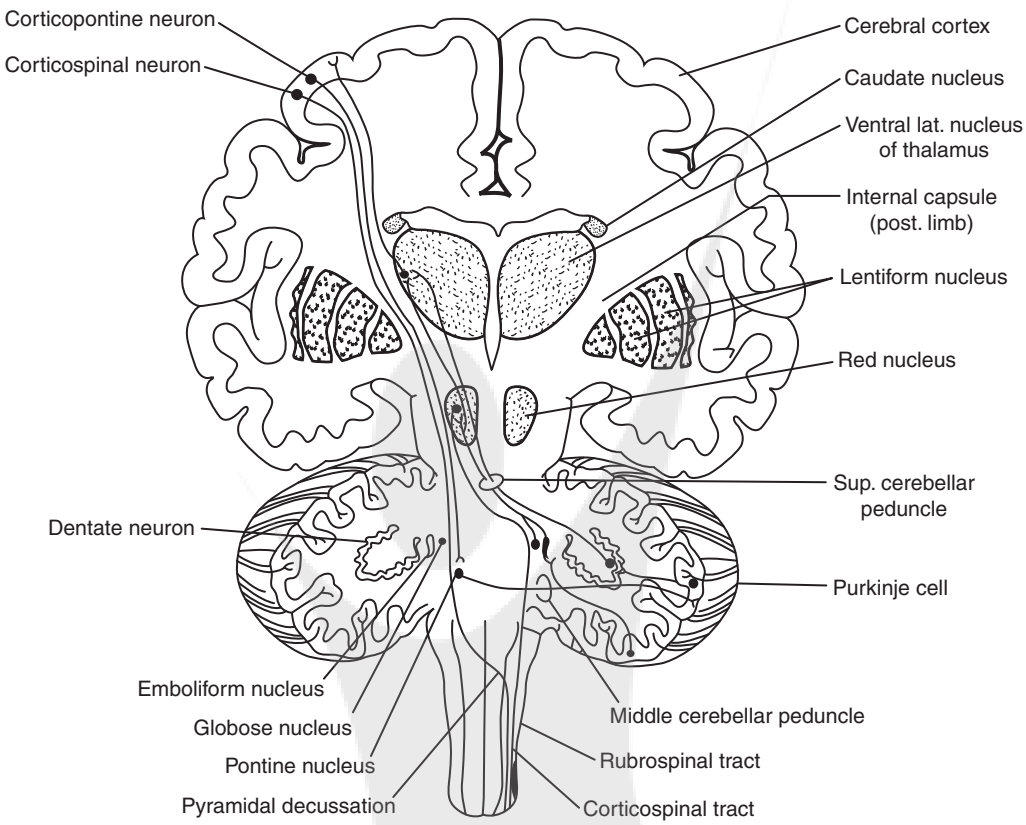

FIGURE 6.11 Connections to the cerebellum.

Source: Reprinted with permission from Fix JD. *Neuroanatomy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001:236.

cerebellum by a decussation at the anterior and posterior aspects of the vermis; and (b) *arcuate* or *association* fibers, which connect adjacent laminae.

Vasculature of the Cerebellum (see Figure 6.9)

The cerebellum receives its vascular supply from branches of the vertebral and basilar arteries. When any of the arteries is disrupted, there is potential for collateral flow from the other cerebellar arteries. In patients with acute basilar artery thrombosis, neurologic outcome improves after intra-arterial thrombolysis if the basilar artery demonstrated collateral filling and thrombosis of the basilar artery was not proximal (3). Patients with collateral filling of the basilar artery also tolerated their symptoms longer.

The PICA traverses the superior portion of the medulla oblongata over the inferior peduncle to the undersurface of the cerebellum. Here it divides into two branches: medial and lateral. The medial branch continues posteriorly to the notch between the two hemispheres of the cerebellum. The lateral branch supplies the undersurface of the cerebellum to its lateral border, where it anastomoses with the anterior inferior cerebellar and superior cerebellar arteries.

The AICA travels posteriorly to the anterior portion of the undersurface of the cerebellum. It anastomoses with the PICA.

The SCA travels laterally around the cerebral peduncle to the upper surface of the cerebellum and dentate nucleus. It then divides into branches that supply the pia mater and anastomose with the anterior and posterior inferior cerebellar arteries.

MIDBRAIN SYNDROMES (TABLE 6.3)

The clinical anatomy of the midbrain is not as complicated as that of the pons or medulla oblongata. However, symptoms of midbrain lesions may be quite varied due to the multiplicity of functions for which the midbrain is responsible (Figure 6.12). In addition to facial and limb sensory-motor deficits, cranial nerve III and IV lesions may cause oculomotor deficits and Horner's syndrome. Infarcts of the tegmentum may result in upgaze paralysis. Classic lacunar infarcts, such as pure motor stroke and ataxic hemiparesis, can be related to infarcts of the dorsolateral midbrain. Subthalamic infarcts may be associated with unilateral or bilateral ballismus or asterixis. Involvement of the red nucleus causes the typical resting tremor that worsens with movement. Coma or changes in consciousness may occur with bilateral midbrain infarcts, but neuropsychological changes should be suspected due to involvement of the posterior cerebral arteries downstream of the midbrain lesions (4).

TABLE 6.3 Midbrain Syndromes

SYNDROME	STRUCTURE	SYMPTOM(S)
Weber	III	Ipsilateral ptosis, external strabismus, dilated pupil
	Corticospinal/corticobulbar tracts	Contralateral paresis of lower face, tongue, arm, leg
Benedikt	III	Ipsilateral ptosis, external strabismus, dilated pupil
	Red nucleus	Contralateral coordination deficit (ataxia, dysmetria, dysdiadochokinesia, rubral tremor [coarse resting tremor that increases with movement]), psuedo-Parkinson tremor
	Corticospinal tract Medial lemniscus (sometimes) Spinothalamic tract (sometimes)	Contralateral paresis of lower face, tongue, arm, leg Contralateral touch, proprioception (contralateral pain, temperature)
Claude	III	Ipsilateral ptosis, external strabismus, dilated pupil
	Red nucleus	Contralateral coordination deficit (ataxia, dysmetria, dysdiadochokinesia, rubral tremor [coarse resting tremor that increases with movement]), psuedo-Parkinson tremor
Parinaud (dorsal rostral midbrain)	Pretectal nuclei (high midbrain tegmentum ventral to superior colliculus)	Bilateral upward gaze paralysis
	Corticotectal fibers (supranuclear fibers to III)	Convergence paralysis, pupillary areflexia
Koerber–Salus–Elschnig (Sylvian aqueduct)	III	Ipsilateral ptosis, external strabismus, dilated pupil Altered mental status Abnormal respiration
Chiray–Foix–Nicolesco (midbrain tegmentum)	Upper red nucleus	Contralateral coordination deficit (ataxia, dysmetria, dysdiadochokinesia, rubral tremor [coarse resting tremor that increases with movement]), psuedo-Parkinson tremor
	Corticospinal/corticobulbar tracts	Contralateral paresis of lower face, tongue, arm, leg
	Spinothalamic tract	Contralateral hemisensory deficit
Nothnagel (dorsal midbrain)	III	Ipsilateral ptosis, external strabismus, dilated pupil
	Brachium conjunctivum	Vertical gaze paralysis
	Medial longitudinal fasciculus (MLF)	Ipsilateral adduction paresis on attempted horizontal gaze, contralateral monocular nystagmus of abducting eye on attempted horizontal gaze
Akinetic mutism (upper segment of basilar artery)	Reticular activating system	Absolute mutism tetraplegia with bulbar paralysis except for eyes

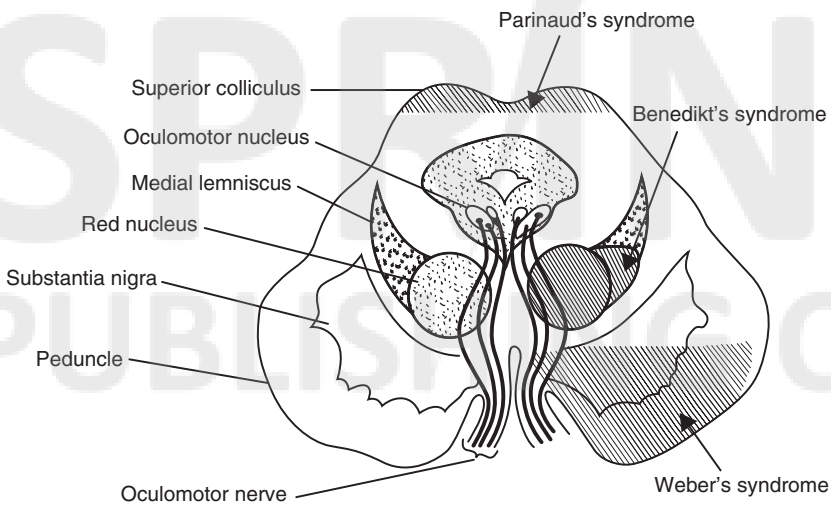

FIGURE 6.12 Midbrain syndromes.

Source: Reprinted with permission from Chusid JG. *Correlative Neuroanatomy and Functional Neurology*. 17th ed. Los Altos, CA: Lange Medical Publications; 1979:29.

Weber Syndrome

Marotte (1853) (5) first described a patient who presented with a cranial nerve III palsy and contralateral hemiplegia. However, Weber (1863) (6) provided the first detailed clinical description of this syndrome. He also attempted to relate the clinical signs and symptoms of the syndrome with vivisection of the human brain in order to answer the question of localization of the lesion. Notably, Weber described clonus of the ankle and flexor spasms of the leg, but did not recognize their significance in cerebral infarction. In this article, he also accurately described the clinical findings of the Babinski sign nearly 30 years before Babinski reported them.

Benedikt Syndrome

The lesion of Benedikt syndrome causes ipsilateral oculomotor paralysis with contralateral tremor and hemiparesis. Patients with this syndrome often have ipsilateral sensory loss. Because the major outflow of the cerebellum traverses the superior cerebellar peduncle (brachium conjunctivum) and red nucleus on its way to the ventral lateral nucleus of the thalamus, patients have a "rubral" tremor, present at rest but amplified with movement. Benedikt (1889) (7) first described the syndrome in a cursory manner in 1874, but spoke of it in more detail during a lecture in Paris. He developed the concept of a primary motor system, and coined the term "parallel motor system" for the afferent and efferent pathways of the cerebellum.

Parinaud Syndrome

The lesion of Parinaud syndrome causes paralysis of conjugate upward gaze and convergence. It is often accompanied by paralysis of the conjugate downward gaze and pupillary areflexia. Parinaud (1883) (8) concluded that the lesion should be located in the tegmentum of the midbrain. It was many years after his death in 1905 that the actual structure—the superior colliculi—and its connections were identified.

Koerber–Salus–Elschnig Syndrome

This lesion of the periaqueductal gray of the midbrain causes rhythmic retraction of the eyes into the orbit, independent of eye movement. Voluntary eye movements usually amplify the abnormality. Salus (1910) (9) found a cysticercus cyst that localized the lesion very specifically to this region. While Koerber (1903) (10) and Elschnig (1913) (11) share the name of the syndrome, Koerber did not identify any brain tissue for neuroanatomic correlation, but termed the syndrome "nystagmus retractorius." Elschnig, who was Salus's teacher, encouraged him to write the case study and found another case of the syndrome the following year.

PONTINE SYNDROMES (TABLES 6.4 AND 6.5)

The pons is supplied by three groups of arteries (12). Branches from the basilar artery form the anteromedial and anterolateral groups. Branches from the AICA form the lateral group. Branches from the SCA form the posterior group.

Infarcts of the pons may result in a range of symptoms (Figure 6.13). Cranial nerve VI and MLF lesions may cause oculomotor deficits. Infarcts of the PPRF may result in conjugate horizontal gaze paralysis. Classic lacunar infarcts, such as pure motor stroke and ataxic hemiparesis, can be related to infarcts of the basis pontis. Involuntary limb spasm also has been described (13).

Pontine syndromes are classified into two types. Table 6.4 uses an anatomic scheme, categorizing lesions as superior, midpontine, and inferior; and as medial or lateral. Medial pontine lesions usually affect the corticospinal tract and medial lemniscus, resulting in contralateral hemiparesis and reduced proprioception and vibration sensation. Lateral pontine lesions usually affect the trigeminal sensory nucleus or tract, autonomic fibers, and spinothalamic tract, resulting in ipsilateral loss of facial sensation, ipsilateral Horner's syndrome, and contralateral loss of pain and temperature. Table 6.5 lists pontine syndromes by eponym.

Millard–Gubler Syndrome

Millard–Gubler syndrome affects cranial nerve VII and the corticospinal tract, resulting in ipsilateral facial weakness and contralateral hemiparesis. Gubler (1856) (14) described the lesion as invading the medial pons, but missing cranial nerve VI because of its slightly anterior course within the pons. He also demonstrated the clinical evidence of the decussation of the facial nerve, thereby differentiating between the "central" lower facial droop and the "peripheral" total facial weakness. In contrast, Millard (1856) (15) made no attempt to localize the anatomy of the lesion. His name is attached to Gubler's probably because the manuscripts were published one after the other.

Foville Syndrome

Foville syndrome consists of conjugate horizontal gaze paralysis in the ipsilateral direction. Cranial nerve VII paralysis results in ipsilateral facial weakness, but hemiparesis is contralateral. Foville (1858) (16) was the first to document the presence of a lateral gaze center in the pons. Although the hemiparesis usually resolves, the gaze paralysis and facial weakness persist indefinitely.

Raymond Syndrome

Raymond syndrome consists of ipsilateral cranial nerve VI paralysis with contralateral hemiparesis. Raymond (1896) (17) described a patient with right hemiplegia, but with aphasia and difficulty recognizing her husband's face

TABLE 6.4 Pontine Syndromes by Location

SYNDROME	STRUCTURE	SYMPTOM(S)
Medial inferior	VI	Ipsilateral horizontal diplopia with nystagmus
	Corticospinal tract	Contralateral face/arm/leg hemiplegia
	Medial lemniscus	Contralateral touch/proprioception hemideficit
	Paramedian pontine reticular formation (PPRF)	Ipsilateral conjugate gaze paralysis
Lateral inferior	Vestibular nuclei (VIII)	Ipsilateral horizontal/vertical nystagmus, vertigo, nausea, vomiting, oscillopsia
	VII	Ipsilateral peripheral facial palsy
	PPRF	Ipsilateral conjugate gaze paralysis
	VIII	Tinnitus, deafness
	Middle cerebellar peduncle	Ataxia
	V sensory	Ipsilateral impaired facial sensation
	Spinothalamic tract	Contralateral arm/leg pain/temperature deficit
Medial midpontine	Middle cerebellar peduncle	Ipsilateral ataxia arm/leg and gait
	Corticospinal/corticobulbar tracts	Contralateral face/arm/leg hemiplegia, eye deviation
	Variable medial meniscus	Contralateral touch/proprioception deficit
Lateral midpontine	Middle cerebral peduncle	Ipsilateral limb ataxia
	V motor	Ipsilateral mastication muscle paralysis
	V sensory	Ipsilateral hemisensory deficit (including corneal reflex)
Medial superior	Superior/middle cerebellar peduncle	Ipsilateral cerebellar ataxia
	MLF	Internuclear ophthalmoplegia
	Central tegmental bundle	Palate/pharynx/vocal cord/ventilatory apparatus/face/oculomotor apparatus myoclonus
	Corticospinal/corticobulbar tracts	Contralateral face/arm/leg hemiplegia
	Rare medial lemniscus	Contralateral touch/proprioception face/arm/leg hemideficit
Lateral superior	Superior/middle cerebellar peduncle	Ipsilateral arm/leg/gait ataxia
	Vestibular nuclei (VIII)	Dizziness, nausea, vomiting, horizontal nystagmus
	Spinothalamic tract	Contralateral face/arm/leg pain/temperature loss
	Lateral medial lemniscus	Touch/proprioception leg > arm hemideficit
	Unknown	Conjugate gaze paresis to side of lesion, loss of optokinetic nystagmus, skew deviation, Horner syndrome

(prosopagnosia). The cranial nerve VI paralysis did not occur for another three months. Raymond described this condition as a "special hemiplegia" that was treated with "mercurial packs and high doses of potassium iodide" for "intensive antisyphilitic treatment." With this treatment, the visual disturbances and cognitive impairments resolved, but the hemiplegia resolved only partially.

Locked-In Syndrome

Locked-in syndrome occurs when an occlusion of the basilar artery causes an infarction of the basis pontis bilaterally. The corticospinal and corticobulbar tracts are interrupted, resulting in tetraplegia and paralysis of all cranial nerve muscles except for those controlling eye movements. It is not unusual for the PPRF to be affected, such that horizontal eye movements are affected and only vertical eye movements are preserved. Because the reticular formation above the caudal pons is spared, patients remain awake and aware. Their only means of communication is systematic eye movements that can be utilized manually to respond to questions, or with augmentative communication devices.

MEDULLARY SYNDROMES (TABLE 6.6)

The medulla oblongata receives its blood supply from a number of penetrating arteries located in the distal vertebral artery. There may also be variable blood supplies from small branches of the PICA, AICA, or the basilar artery. Typically, a lateral medullary infarct occurs because of occlusion of one or more of these penetrating arteries, or more often by occlusion of the vertebral artery (18). The dorsal medulla oblongata receives its blood supply exclusively from the PICA, and is usually accompanied by cerebellar infarction (19). The medial medulla oblongata receives its blood supply caudally from penetrating arteries of the anterior spinal artery, and rostrally from branches of the vertebral artery (20). Medial infarcts usually affect the corticospinal tracts,

TABLE 6.5 Pontine Syndromes by Eponym

SYNDROME	STRUCTURE	SYMPTOM(S)
Millard–Gubler	VII tract	Ipsilateral facial palsy
	Corticospinal tract	Contralateral arm/leg hemiparesis
Foville	PPRF	Ipsilateral horizontal gaze palsy
	VII	Ipsilateral facial palsy
	Corticospinal tract	Contralateral arm/leg hemiparesis
Raymond	VI tract	Ipsilateral lateral rectus paresis
	Corticospinal tract	Contralateral arm/leg hemiparesis
Pontocerebellar Angle	VIII	Early ipsilateral tinnitus, deafness, head tilt/rotation; late hyperacusis
	Inferior/middle cerebellar peduncles	Ipsilatreal intention tremor, dysmetria, ataxic gait, adiadochokinesis
	V spinal tract	Ipsilateral facial pain/temperature hemisensory deficit
	VII	Ipsilateral facial palsy, taste loss anterior 2/3 tongue
	Spinothalamic tract	Contralateral arm/leg pain/temperature hemisensory deficit
	Occasional XI, XII	Ipsilateral trapezius, tongue
Brissaud	VII	Ipsilateral facial spasm
	Corticospinal tract	Contralateral arm/leg hemiparesis
One-and-a-Half	PPRF	Ipsilateral horizontal gaze palsy
	MLF	Contralateral internuclear ophthalmoplegia
Locked-In	Bilateral corticospinal/corticobulbar tract	Tetraplegia with facial palsy (except blinking eyes)
	Bilateral paramedian pontine reticular formation	Bilateral horizontal gaze palsy

TABLE 6.6 Medullary Syndromes

SYNDROME	STRUCTURE	SYMPTOM(S)
Paramedian Bulbar ("Hypoglossal Hemiplegia Alternans")	XII	Ipsilateral paralysis of tongue, contralateral hemiplegia (arm > leg)
	Corticospinal tract	
	Medial lemniscus	Contralateral touch/proprioception arm/leg hemideficit
Lateral Bulbar (Wallenberg)	Lower vestibular nuclei	Vertigo, dizziness, nausea, vomiting
	Nucleus ambiguus (IX, X motor)	Dysphagia, hiccups, dysphonia, uvula deviates to normal side
	V spinal tract	Ipsilateral face pain/temperature hemideficit
	Spinothalamic tract	Contralateral arm/leg pain/temperature hemideficit
	Spinocerebellar/olivocerebellar tracts	Ipsilateral hypotonia, ataxia of limbs (UE > LE)
	Pupillodilator (sympathetic) fibers	Ipsilateral Horner's sign (ptosis, miosis, anhydrosis)
Avellis	Nucleus ambiguus (X, bulbar XI)	Ipsilateral soft palate, pharynx, larynx paralysis; dysarthria; dysphagia
	Solitary tract (sensory X)	Ipsilateral pharynx, larynx hemisensory deficit
	Spinothalamic tract	Contralateral UE/LE pain/temperature hemisensory deficit
Schmidt	X	Ipsilateral soft palate, pharynx, larynx paralysis; dysarthria; dysphagia
	Spinal XI	Ipsilateral sternocleidomastoid paralysis, sometimes trapezius paralysis
Jackson	X	Ipsilateral soft palate, pharynx, larynx paralysis
	XI	Ipsilateral sternocleidomastoid, trapezius paralysis
	XII	Ipsilateral tongue paralysis, atrophy
Tapia	X	Ipsilateral soft palate, pharynx, larynx paralysis
	XII	Ipsilateral tongue paralysis, atrophy
Bonnier	VIII	Paroxysmal vertigo
	IX	Loss of taste on posterior third of tongue
	X	Ipsilateral soft palate, pharynx, larynx paralysis
	Corticospinal tract	Contralateral hemiplegia (arm > leg)
	Other	Somnolence at times Apprehension, tachycardia
Babinski-Nageotte bulbar (similar to Wallenberg syndrome with addition of hemiplegia)	IX	Loss of taste on posterior third of tongue
	X/bulbar XI	Ipsilateral soft palate, pharynx, larynx paralysis
	XII	Ipsilateral tongue paralysis, atrophy
	V spinal tract	Ipsilateral face pain/temperature hemideficit
	Spinocerebellar tract	Ipsilateral hypotonia, ataxia of limbs (UE > LE)
	Corticospinal tract	contralateral hemiplegia (arm > leg)
	Spinothalamic tract	Contralateral arm/leg pain/temperature hemideficit
	Pupillodilator (sympathetic) fibers	Ipsilateral Horner's sign (ptosis, miosis, anhydrosis)

causing contralateral hemiparesis. Lateral infarcts usually involve the spinothalamic tracts, resulting in contralateral loss of pain and temperature sensation. Other infarcts may occur as well, but are less common (Figure 6.14).

Wallenberg (Lateral Medullary) Syndrome

Wallenberg syndrome is probably one of the best-known brainstem syndromes, comprising approximately 2% of all admissions for acute stroke (21). Wallenberg (1895) (22) described this "acute disease of the medulla" with the onset of intense vertigo associated with vomiting. He also listed the presence of dysphonia and dyphagia; ipsilateral facial hemisensory deficit, limb ataxia, and palate and vocal cord paralysis; and contralateral arm and leg hemisensory deficit. Although an ipsilateral Horner's syndrome is present, Wallenberg did not document its presence because his patient had a congenital disease of the eyes. Because of its lateral location, the syndrome does not cause paralysis, as the corticospinal tract is a medial structure.

Jackson Syndrome

Jackson syndrome consists of cranial nerve X, spinal XI, and XII paralysis resulting in ipsilateral weakness of the trapezius, sternocleidomastoid, soft palate, and tongue, as well as dysphagia and dysphonia. Jackson (1865) (23) described this syndrome in a patient with tuberculosis throughout

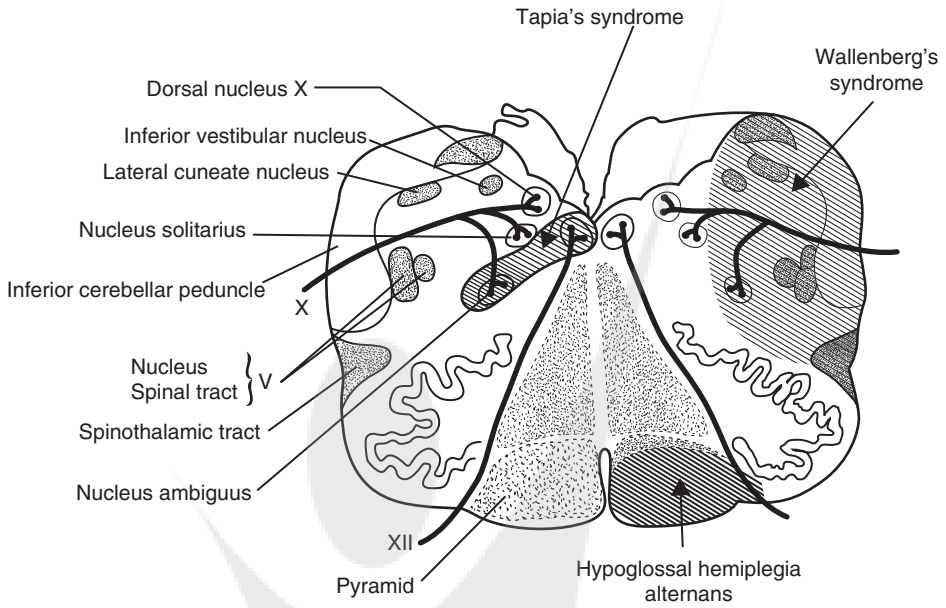

FIGURE 6.14 Medullary syndromes.

Source: Reprinted with permission from Chusid JG. *Correlative Neuroanatomy and Functional Neurology*. 17th ed. Los Altos, CA: Lange Medical Publications; 1979:33.

the brainstem. The correlative neuroanatomy is not well described, but the eponym remains attributed to him.

CEREBELLAR SYNDROMES (TABLE 6.7)

Cerebellar infarcts typically present with the cardinal signs of vertigo, headache, emesis, and gait ataxia (24). However, it was not until the advent of MRI that clinicians could accurately diagnose cerebellar infarcts and correlate them with vascular territories. There is now a better understanding of how to characterize cerebellar infarcts based upon the vascular territories they supply. Table 6.7 reflects one of these classification schema (25).

RESEARCH FRONTIERS

As the preceding descriptions of the syndromes demonstrate, the understanding of brainstem and cerebellar syndromes largely came from the vivisection of autopsy specimens. With the advent of MRI, the neuroanatomy of these lesions could be defined better and earlier (26). Techniques such as functional MRI have provided vital information for better understanding the functional anatomy of the auditory system (27), visual system, (28), and the cerebellum (29). Diffusion-weighted images (DWI) with direction-selective gradients have been used to identify both nuclei and white-matter tracts within the brainstem (30). An evaluation

TABLE 6.7 Cerebellar Syndromes

SYNDROME	STRUCTURE	SYMPTOM(S)
Rostral (superior cerebellar)	Subthalamic area, thalamus, Occipitotemporal lobes	Coma ± tetraplegia Ipsilateral dysmetria, Horner's syndrome; contralateral pain/temperature hemisensory deficit, IV palsy
	Laterotegmental area of upper pons	Dysarthria; headache; dizziness; emesis; delayed coma (pseudotumor form)
Medial (anterior inferior cerebellar)	Lateral area of lower pons	Ipsilateral V, VII, VIII, Horner's syndrome, dysmetria Contralateral pain/temperature Hemisensory deficit
Caudal (posterior inferior cerebellar)	Dorsolateromedullary area	Vertigo, headache, emesis, ataxia, delayed coma (pseudotumor form)
Caudal and medial	Lateral area lower pons and/or lateromedullary area	Vertigo, headache, emesis, ataxia, delayed coma (pseudotumor form)
Rostrocaudal	Brainstem, thalamus, occipitotemporal lobe	Coma ± tetraplegia

of 22 regions of the brainstem has led to the development of a lesion score that potentially may be an independent marker of outcome in basilar artery occlusion (31). Newer high-resolution MRI technology may lead to spatially unbiased localization of lesions, that is, the location of structures on an MRI image equals the expected anatomic location of that structure (32). Three-dimensional MRI velocity mapping may identify substantial diastolic retrograde flow originating from complex plaques in the descending aorta that results in infarcts of the brainstem and cerebellum (33).

Diffusion tensor imaging (DTI) currently is used noninvasively to study the three-dimensional structure of white-matter tracts of the brainstem (34) and cerebellum (35). Specific imaging studies include those of the medial lemniscus (36). Wallerian degeneration in the corticospinal tract imaged by DTI correlates with motor deficit at 7 days (37), 30 days (38), and more than 6 months (39) after a middle cerebral artery infarct; thus, it could potentially be used as a surrogate marker in clinical trials.

In better understanding the neuroanatomical correlates of behavior and activity, clinicians can predict more accurately the types of deficits that occur with brainstem and cerebellar strokes. Using this information, more research is needed to explore physical and pharmacological interventions that can improve recovery from stroke. Ultimately, clinicians can gain a better understanding of functional outcomes when specific infarcts or hemorrhages occur in these regions.

CONCLUSION

Recognition of signs and symptoms of infratentorial stroke syndromes is essential in the diagnosis and treatment of stroke. Infratentorial strokes affect a wide variety of body systems, and knowledge of the combinations of neurological signs is vital if one is to suspect the presence of a brainstem or cerebellar infarct or hemorrhage. Although imaging modalities have vastly improved to visualize previously unvisualizable lesions, the diagnosis of a stroke still begins with a detailed physical examination and knowledge of neuroanatomic correlates. However, more research is needed to better understand the interactions between nuclei and tracts that form the foundation of activity and behavior. With a more detailed knowledge base, clinicians may be able to more effectively diagnose and treat infratentorial strokes with appropriate physical and pharmacological modalities. With more effective and varied treatments, clinicians may be able to improve functional outcomes and quality of life in the future.

NEUROPHYSIOLOGY OF STROKE RECOVERY

7

The Mechanisms and Neurophysiology of Recovery From Stroke

Randolph J. Nudo and Scott Barbay

More than three decades have passed since the groundbreaking studies of Michael Merzenich, Jon Kaas, and others, who demonstrated that the neural representations of the hand in the somatosensory cortex are altered by peripheral injury. A once-tenuous notion that functions of the cerebral cortex are alterable in adult mammals has developed into a neuroscientific tenet. The phenomenology of cortical plasticity and the study of its underlying mechanisms have rapidly migrated from the laboratory to the clinic, as new interventional strategies are now conceptualized in relation to their ability to encourage adaptive plasticity.

After injury to the cerebral cortex, as often occurs in stroke, a large portion of the sensory–motor apparatus in the frontal and parietal cortex is often damaged, resulting in deficits in motor function in the contralateral musculature. However, substantial spontaneous recovery occurs in the weeks to months following injury. Understanding how the remaining sensory–motor apparatus can support the recovery of such functions has been a primary goal of much of the recent research in this area. Thus, this chapter will review the basic organization of the sensorimotor cortex, the current theoretical models for functional recovery, and our understanding of the ability of spared tissue to be functionally and structurally altered. This review relies most heavily on recent neurophysiological and neuroanatomical data from nonhuman primate and rodent models and neuroimaging studies in humans.

ORGANIZATION OF MOTOR CORTEX IN PRIMATES

Since middle cerebral artery strokes often affect the motor cortex, we provide a brief review of the structure and function of cortical areas involved in the motor control of skeletal musculature. The motor cortex, defined as the part of the cerebral cortex that requires the least amount of electrical stimulation to evoke movement, is subdivided into several distinct areas (Figure 7.1).

Though each area has been reported to play a somewhat different role in the control of movement, there is considerable overlap in function (1,2). Further, it is now clear that the motor cortex does not execute motor tasks in isolation. A broad network minimally involving the primary and secondary motor areas, the dorsolateral prefrontal cortex, the parietal cortex, the striatum, and the cerebellum is involved in motor skill acquisition, planning, and execution. Thus, motor behavior is controlled by a distributed network, and it may be overly simplistic to think in terms of compartmentalized units that have mutually exclusive functions (3).

Primary Motor Cortex

The primary motor cortex (M1) is thought to mediate skilled voluntary movements, especially of the distal musculature, since M1 lesions result in disruption of skilled limb use in the contralateral musculature (4–7). The global topography of motor representations in M1 follows an orderly progression from hindlimb medially to forelimb and face laterally (Figure 7.1). M1 is subdivided into a caudal component (M1c), receiving predominantly cutaneous somatosensory information, and a rostral component (M1r), receiving predominantly proprioceptive input (8,9). Consistent with this parcellation, in nonhuman primates, differential motor deficits result from small lesions in either M1r or M1c (10). Cortical areas that are reciprocally connected with M1 include primary somatosensory areas 3a, 1, 2, the second somatosensory area (S2), the ventral premotor cortex (PMv), the dorsal premotor cortex (PMd), the supplementary motor area (SMA), cingulate motor areas (CMA), and, to a lesser extent, primary somatosensory area 3b, posterior parietal cortex (PP), and the parietal ventral area PV (11–14).

The corticospinal (CS) neurons provide the cerebral cortex with direct access to the spinal cord motoneurons and have been the subject of intense investigation since the mid-1800s. CS neurons can be found throughout much of the frontal and parietal cortex, although the concentration is greatest in M1 (15). A subset of CS neurons, found predominantly in M1, project monosynaptically to motoneurons of the spinal cord and are thus called corticomotoneuronal (CM) cells. Spike-triggered averaging techniques in awake nonhuman primates reveal that individual CM cells can facilitate up to four or five motoneuron pools (16). This provides further evidence for the divergence in the anatomical projections from cortex to spinal cord and challenges the notion that functional organization in the motor cortex is

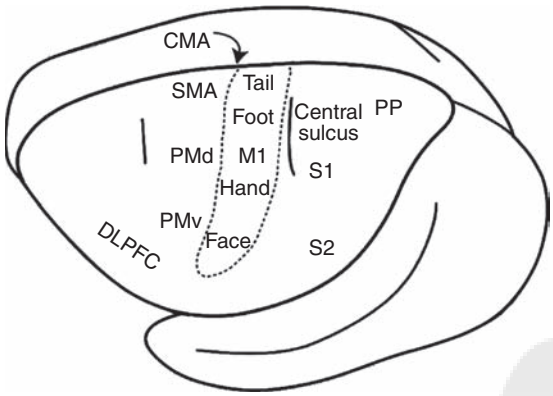

FIGURE 7.1 Motor areas in the frontal cortex of a nonhuman primate (squirrel monkey). At least five separate motor areas can be identified. These include M1, SMA, PMd, PMv, and CMA. This basic arrangement is similar in all primates, though these areas have been divided further in some species. Also, in some primates, the sulci are much deeper (e.g., humans, macaques), and thus, these motor areas are not as accessible. Each motor area contains a separate representation of the forelimb, and some areas contain a complete representation of the skeletal motor apparatus. It has been suggested that each of these motor areas plays a somewhat different role in motor control; though considerable overlap exists. Thus, it is more accurate to consider the cortical motor apparatus as part of a distributed network for control of movement.

Abbreviations: CMA, cingulate motor areas; DLPFC, dorsolateral prefrontal cortex; M1, primary motor cortex; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; PP, posterior parietal cortex; S1, primary somatosensory cortex; S2, second somatosensory area; SMA, supplementary motor area.

based on muscle-specific domains. Direct evidence refuting muscle-specific domains in the motor cortex has been provided from neuronanatomical studies. Rabies viruses can be used as transneuronal retrograde markers. Injecting the virus into a single muscle results in retrograde transport of the virus to the cell bodies in the spinal cord motoneuron pool. There, the virus replicates and is picked up by terminal arbors that innervate the motoneurons. In turn, the virus is retrogradely transported back to second-order neurons in the cerebral cortex, red nucleus, and other locations. At the appropriate survival time, post-mortem analysis reveals the location of CS neurons that contain the virus. Thus, these neurons represent CM cells that project to the specific motoneuron pool of interest. Combining results of injections into various forelimb muscles of different animals reveals that the cortical neurons that influence the various forelimb muscles are completely interspersed and overlapping (17). Thus, the motor cortex can be viewed as containing a shared neural substrate for motor control of the hand. The highly overlapping and divergent architecture provides an ideal substrate for flexibility in outputs to the spinal cord that can be rearranged based on behavioral demands.

One of the more common methods for demonstrating the functional spatial topography of M1 is via electrical or magnetic stimulation and the observation of evoked movements or electromyographic activity. Current thresholds for evoking movement via either invasive or noninvasive stimulation methods are lowest in M1, coinciding with the location of large numbers of CM cells. Owing to these neuroanatomical and neurophysiological differences, M1 is thought to be the cortical motor area most related to movement execution. However, discrete movements of specific joints can also be evoked by stimulation of other motor areas of the frontal cortex, though at somewhat higher current levels. At least seven nonprimary motor areas involved in controlling arm movements have been identified in the frontal cortex of primates (18). Many of these premotor areas have also been identified in humans based on functional neuroimaging data, though homologies are in some instances not completely clear (14,15,19–21).

Dorsal Premotor Cortex

The premotor areas are located anterior to the M1 motor strip in Brodmann's area 6. Based on separate hand representations, different anatomical connectivity, and somewhat different functional attributes, the premotor cortex has been subdivided into a dorsal portion or PMd and a ventral portion or PMv. PMd is located immediately anterior to the M1 representation. The histologically defined boundary between M1 and PMd is not well defined. For example, using the density of large CS neurons as a guide to the identification of the M1-PMd border yields a gradient, rather than a sharp boundary, with more large CS neurons located in M1. PMd contains separate representations of the forelimb, hindlimb, and trunk, and is thought to be involved in visually guided tasks since PMd neurons are active during a preparatory motor-set (22) and in relation to visuomotor-association tasks (23). Compared with M1, the activity of PMd neurons (and PMv, SMA neurons) is less related to the kinematics of the movement but more related to aspects of the goal (24) and to movement selection (25). PMd inactivation affects the ability of macaque monkeys to select movements without affecting the spatial organization of the movements selected (26). Neuroimaging studies in humans confirm the role of PMd in visually guided motor tasks (27). PMd has topographically organized, intracortical connections with other frontal motor regions (11,28,29) and with the posterior parietal cortex (PP).

Ventral Premotor Cortex

In nonhuman primates, the PMv is located anterior and lateral to the M1 hand representation. In primate species with lissencephalic brains (e.g., prosimian primates, squirrel monkeys, marmoset monkeys) PMv is exposed on a flat sector of cortex, whereas in other primate species (e.g., macaque monkeys, Cebus monkeys) PMv is largely buried in the arcuate sulcus. In general, PMv is thought to be involved in visual–motor and somatosensory–motor integration for motor control of the upper extremity (30–37). PMv provides prominent inputs to M1, exerting a powerful facilitatory effect, especially during visually guided movements of the hand (38,39).

PMv also has reciprocal, topographically organized connections with other motor areas of the frontal cortex (M1, SMA, PMd, CMA) (11,19,28,29) and with the parietal cortex, much like PMd. However, there are substantial differences between PMd and PMv in their connections with the parietal cortex. PMd is not strongly connected with the somatosensory areas of the anterior parietal lobe but, rather, with medial parietal areas that are more related to visual and visuomotor function (29,30,40–42). Most of the parietal inputs to PMv (15% of all inputs) (11) arise from more lateral areas, such as the second somatosensory area (S2) and the parietal ventral area (PV). Relatively few inputs (1.5%) arise from the more medial PP areas that are thought to be most involved in visually guided motor behaviors (11,43). Human neuroimaging studies have shown somatotopic maps of face and fingers in PMv (44). In addition, activation is increased in PMv of humans during a working memory task requiring a vibrotactile discrimination (45). Thus, although PMv appears to receive polymodal information, its primary inputs are from parietal somatosensory areas. Inactivation of PMv in macaque monkeys has little effect on the ability to reach out and grasp food morsels (37), in contrast to M1 inactivation (6).

Supplementary Motor Area

The SMA, sometimes called M2, is located in the medial aspect of Brodmann's area 6, largely extending onto the medial wall. Evidence from neuroanatomical and neurophysiological studies in monkeys and from neuroimaging studies in humans suggest a direct (though not exclusive) involvement of SMA in motor planning, especially in motor sequences and in bimanual motor control (46–48). Like other cortical motor areas, movements of the skeletal musculature can be evoked by stimulation of SMA (49–51) and constituent neurons project directly to the spinal cord (15,51–53). Several human neuroimaging studies and monkey neurophysiological studies have implicated SMA in movement planning, especially of learned movement sequences (48,54,55). Lesions of SMA in macaque monkeys result in deficits in bimanual coordination (56) and mild impairment in errors made during motor sequence tasks (57). SMA shares connections with PMd, PMv, M1, CMA, areas rostral to SMA, and PP cortex medial to the intraparietal sulcus (41,58–62). Thus, SMA connections are similar to PMd connections, in that parietal connections are primarily with more medial areas. One exception is that connections between SMA and S2 have been reported in some primate species (58,59).

Two SMA representations can be differentiated in primate species based on distinct cytoarchitecture, intracortical microstimulation, neuronal response properties, and connection patterns. These two areas, located on the medial surface of the cerebral hemispheres, are referred to as SMA-proper (or simply SMA; also called F3) and the pre-SMA (also called F6), situated more rostrally (63). In general, SMA proper is thought to be involved primarily in simple tasks, whereas pre-SMA is activated during relatively complex tasks (2). SMA and pre-SMA can also be differentiated in human neuroimaging studies; though until recently, reliable distinctions among the motor areas of the medial wall (SMA, pre-SMA, and CMA) were rarely possible. New approaches using diffusion tensor imaging may provide significant improvements in differentiating these areas (64–67).

DIFFERENTIAL PROCESSING STREAMS BETWEEN PARIETAL AND PREMOTOR CORTEX

To summarize, PMv, PMd, and SMA are strongly connected to parietal areas, though they receive differential input from separate sensorimotor-processing streams (Figure 7.2) (32,42). PMv is strongly interconnected with unimodal somatosensory areas of the anterior parietal lobe and with visual and polymodal areas in the lateral portions of the parietal cortex (7b, not shown). In contrast, PMd and SMA receive input primarily from visual and polymodal PP areas medial to the IP sulcus. Thus, except for the possible exception of S2 projections to both PMv and SMA, these premotor areas, PMv, and PMd/SMA appear to be involved in different aspects of motor control of the hand.

Cingulate Motor Areas

At least three cingulate motor areas—CMAd, CMAv, and CMAr—located on the medial wall, project directly to M1,

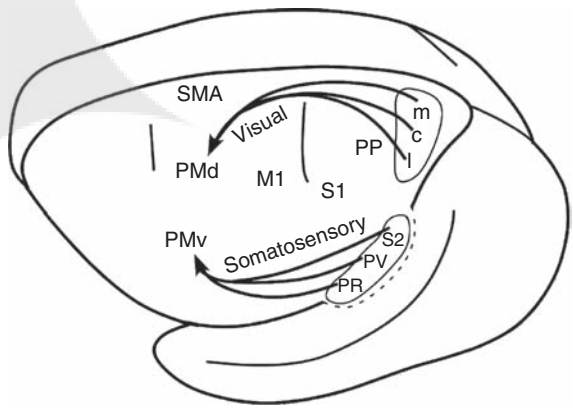

FIGURE 7.2 Sensory streams between parietal cortex and premotor areas of the frontal cortex. Recent tract-tracing results have revealed two distinct processing streams from parietal to premotor areas (*Source*: From Refs. (11,29)). PMv receives substantial inputs from somatosensory fields conveying cutaneous and proprioceptive information relayed from S1. These include PR, PV, and S2. In contrast, PMd and SMA receive substantial input from rostral, medial, and lateral aspects of PP cortex, conveying visual and polymodal information. These PP areas are probably homologous to areas 5, 7a, 7ip, 7m, and possibly MIP and PO of macaques (*Source*: From Ref. (29)). Thus, it appears that PMv and PMd/SMA process different sets of sensorimotor information and, thus, may have separate roles in motor control of the hand. Not shown in the figure are SMA connections with S2.

Abbreviations: m, c, l, medial, caudal, and lateral aspects of PP cortex; MIP, medial intraparietal area; PO, parietal occipital area; PR, parietal rostral area; PV, parietal ventral area.

other premotor areas, and directly to the spinal cord. It is thought that many of the functions originally associated with SMA may be mediated by CMA (47). Because it is less accessible for neurophysiological mapping studies and associated focal lesions, it is not a specific focus of this chapter.

Primary Somatosensory Cortex

Although not strictly a motor structure, the somatosensory cortex must be considered in the cortical control of movement, especially with respect to potential plasticity mechanisms involved in recovery after M1 lesions. Both primary (S1) and secondary (S2) somatosensory areas contain a large proportion of CS neurons; though most terminate in superficial and intermediate laminae of the spinal cord. Thus, CS neurons originating in the somatosensory cortex are thought to be involved primarily in modulating somatosensory inputs to the cord (68). Whereas stimulus-evoked motor output can be elicited by ICMS in S1, the effects are much weaker in magnitude and require higher currents (69). However, focal lesions in the S1 hand area result in deficits in motor skill, similar to those produced by M1 lesions (70). Further, neuroimaging studies in humans have demonstrated structural and functional plasticity in S1 after M1 injury (71–73). Thus, S1 should be included in any comprehensive study of cortical areas contributing to the recovery of motor function after M1 injury.

EXPERIENCE-DEPENDENT PLASTICITY IN CEREBRAL CORTEX

Over two decades of experimentation in the cerebral cortex have demonstrated many physiological and anatomical examples of cortical plasticity. Although these phenomena are triggered by many endogenous and exogenous events, one of the most potent modulators of cortical structure and function is behavioral experience (74–79). Emergent properties of each cortical area are shaped by behavioral demands, driven largely by repetition and temporal coincidence. For example, skilled motor activities requiring precise temporal coordination of muscles and joints must be practiced repeatedly. Such repetition is thought to drive the formation of discrete modules where the conjoint activity is represented as a unit (78).

One possible mechanism for mediating functional changes in the motor cortex is the modification of synaptic strength of horizontal connections (80). In slice preparations after motor learning, rats have larger amplitude field potentials in the motor cortex contralateral to the trained forelimb (81). Thus, the synaptic strength of horizontal connections in the motor cortex is modifiable and may provide a substrate for altering the topography of motor maps during the acquisition of motor skills. Structural alterations also occur in adult animals as a consequence of experience (82). Dendritic and synaptic morphologies of motor cortex neurons are altered by specific motor-learning tasks (83–87). Plasticity in the motor cortex is probably skill or learning-dependent, rather than strictly use-dependent. Tasks that require the acquisition of new motor skills induce neurophysiologic and neuroanatomic changes in the motor cortex, but simple repetitive motion or strength training tasks do not (85,88,89). New technological advances in microscopy such as transcranial two-photon microscopy allow the visualization of learning-dependent synaptic plasticity within the living brain by acquiring active images of axons and dendrites. For example, mice engaged in varying motor skill-acquisition procedures show task-specific clustering of dendritic spines as it occurs during skill acquisition. Only repetitive training on the same motor skill task resulted in task-specific clustering of new dendritic formations associated with motor memory (90,91).

Although the majority of our understanding of the relationship between behavior and motor cortex organization at the cellular and synaptic levels of analysis comes from rodent studies, the use of nonhuman primates has provided invaluable knowledge. Primates possess several unique advantages over rodents, including differentiated motor and sensory cortices, which can be subdivided into smaller regions similar to human sensorimotor cortical organization (11). This allows for the study of the differential contribution of various subregions to motor learning and allows for a more direct comparison to human studies. Furthermore, it allows for an understanding of how these subregions are functionally integrated through their extensive network of intracortical connections. In addition, primates possess the ability to perform complex behavioral tasks, especially those that require the use of fine digit manipulation. This digital dexterity is, with few exceptions, unrivaled in the animal kingdom (92) and is ideal for studying the acquisition of motor skills, as well as allowing for a large degree of control and detail in the design of behavioral training and testing paradigms.

The term "motor learning" is not rigidly defined in most experimental models, but instead thought of as a form of procedural learning that encompasses such elements as skill acquisition and motor adaptation. More specific is motor skill learning itself, which is often described as the modification of the temporal and spatial organization of muscle synergies, which results in smooth, accurate, and consistent movement sequences (93). Functional magnetic imaging studies in humans have led to the hypothesis that motor learning is a two-stage process (94). The first stage is rapid and results in within-session decreases in neural activity. The second, slower stage results in increases and expansion of activity in M1.

Although it is evident that numerous brain areas are involved in the production of complex motor movements, M1 has long been implicated in the acquisition and performance of skilled motor behaviors. Although originally believed to be involved in the activation of complex motor reflexes (95), the subsequent advancement of electrophysiological techniques revealed that movements could be elicited through electrical stimulation of the precentral gyrus (96). Based on these early findings, John Hughlings Jackson (1884) hypothesized that movement control was somatotopically organized. This hypothesis was later confirmed when

more systematic cortical stimulation studies were used to develop a somatotopic map of the precentral gyrus (97,98).

The development of the more sophisticated intracortical microstimulation (ICMS) technique in the late 1960s by Asanuma and colleagues allowed for the derivation of much higher spatial resolution maps within M1, which, in turn, revealed a more complex and dynamic cortical map organization, including the presence of columnar organization (99). The ICMS technique typically consists of applying a volley of short-duration cathodal pulses at a high frequency while using very weak currents (60 mcA), thus allowing for relatively little spread of cortical excitation. This greater spatial resolution revealed that although M1 is somatotopically organized on a macro scale, discrete cortical areas are comprised of a montage of representations of individual muscles and movements, which are repeated and highly overlapping. Based upon ICMS mapping experiments that define movements evoked by the lowest possible current levels, motor map organization resembles a fractured mosaic of movement representations, overlaid over a gross somatotopic representation.

Since the advent of ICMS, numerous studies have expanded our understanding of the relationship between motor maps and motor skill learning. Several general principles of motor map organization have been demonstrated that are thought to underlie the motor cortex's ability to encode motor skills (100). First, as mentioned above, motor maps are fractionated, in that they contain multiple, overlapping representations of movements. Second, adjacent areas within cortical motor maps are highly interconnected via a dense network of intracortical fibers. Third, these maps are extremely dynamic and can be modulated by a number of intrinsic and extrinsic stimuli. Together, these characteristics provide a framework that facilitates the acquisition of novel muscle synergies, at least in part, through changes in the intracortical connectivity of individual movement representations.

However, the dynamic nature of motor maps belies the issue of stable neural connections that must be maintained to respond to environmental demands and to retain acquired motor skills. Within the cortex, this balance is thought to be achieved through interactions of the excitatory and inhibitory connections of pyramidal cells and local inhibitory networks (101–103). This, in turn, requires an internal mechanism that is capable of shifting this balance toward strengthening relevant synaptic connections. Horizontal fiber connections have been shown to arise from excitatory pyramidal neurons and allow for the co-activation of adjacent and nonadjacent cortical columns. In addition to activating excitatory pyramidal cells, they also generate inhibitory responses via the activation of GABAergic interneurons (104). Furthermore, the activity of these horizontal fibers has been shown to be mediated by both long-term potentiation (LTP) and long-term depression (LTD) between distant motor cortical areas (80,105). LTP and LTD are persistent increases or decreases (respectively) in synaptic strength. These processes are thought to represent the synaptic mechanisms responsible for learning and memory.

Whereas the phenomena of LTP and LTD are now well established from experiments in slice preparations and intact animals, the concept of use-dependent modulation of synaptic strength was postulated much earlier by Hebb in the 1940s. Hebb proposed that synaptic efficacy can be increased by a presynaptic cell's repeated or persistent stimulation of a postsynaptic cell. This concept has taken on many forms and is pervasive in most theories of the synaptic basis of learning and memory. Many contemporary terms still honor Hebb's contribution to this field, such as Hebbian learning, Hebbian cell assemblies, and Hebbian engrams. Hebb's theories are often summarized in the now common phrase "cells that fire together, wire together." Specifically with regard to plasticity in cortical networks, alterations in synaptic strength in horizontal fibers provide a mechanism capable of both facilitating the activation of multiple novel muscle synergies that are required for motor skill acquisition, while likewise providing a mechanism, via inhibitory processes, of motor map stability that is required to maintain stable, neural representations in response to irrelevant (i.e., untrained) environmental events.

Utilizing manual dexterity training in combination with ICMS maps has been crucial in demonstrating the dynamic relationship between motor skill learning and cortical map plasticity. The first study to directly examine this relationship used varying behaviorally demanding tasks to selectively activate specific components of motor maps (78). In these tasks, monkeys were rewarded with small, banana-flavored food pellets for performing skilled movements with the hand. In one task, the pellets were placed one at a time into food wells of different diameters. The monkey simply was required to extract the pellet. Large food wells required minimal manual skill. Small food wells required the insertion of only one or two digits and, thus, maximal manual skill. Retrieval from the smaller wells required practice over the course of about 10 to 12 days for asymptotic performance to be achieved. In a second task, monkeys were required to reach through a narrow tube and rotate a key back and forth, requiring repetitive pronation and supination of the forearm. Posttraining ICMS mapping revealed training-induced changes in motor map topography that directly reflected the demands of the particular behavioral task. That is, the pellet retrieval task resulted in expansion of digit representations, whereas the key-turning task resulted in expansion of wrist and forearm representations.

In addition, an increase in ICMS-evoked multi-joint movements was observed. These movements consisted of simultaneous executions of digit and wrist, or proximal movements at low ICMS thresholds, and were only observed after training on the digit-use intensive manual dexterity task. Both before and after training, thresholds for evoking multi-joint responses were significantly lower than single-joint responses. These results imply that behaviorally relevant, simultaneous or sequential movements may become associated in the motor cortex through repeated activation.

A temporal correlation hypothesis has been proposed to explain these phenomena and derives from similar results

obtained from studies in the somatosensory cortex. For example, digit representations in the somatosensory cortex are typically individuated, with sharp boundaries between adjacent digit areas. If two digits are experimentally joined surgically in a so-called digital syndactyly procedure, then the representations of those digits become fused, with neurons displaying multi-digit receptive fields that cross the suture line. The hypothesis suggests that as inputs from the two separate digits are made temporally coincident by the syndactyly, the new multi-digit representations appear as an emergent property of the plastic somatosensory cortex. It is possible that this hypothesis is generalizable to the motor cortex as well. Thus, muscle and joint synergies used in complex, skilled motor actions may be supported by alterations in local networks within the motor cortex. As skilled tasks become more stereotyped in the timing of sequential joint movements, functional modules emerge in the cortex to link the outputs of different motoneuron pools.

These findings lead to the question of what aspects of motor skill learning drive the observed changes in map representations. It is possible that increased muscle activity alone produced the observed changes in map representations. To address this issue, a group of monkeys were trained exclusively on either the largest or the smallest well in the manual dexterity task described above. The rationale in this design is that the largest well allows for simple multi-digit movements for pellet retrieval, which does not require the subject to develop novel skilled digit movements since simply grasping for food is a normal part of their daily home cage behavior and already part of their behavioral repertoire. Small-well food pellet retrieval, in contrast, requires the monkey to manipulate one or two digits to retrieve the pellet, which is considerably harder, given that squirrel monkeys lack monosynaptic CS projections to motoneurons, which probably limits individuation of digit movements (106). Compared to pretraining maps, monkeys trained on the large-well pellet retrieval did not show an expansion of the digit representation, whereas those trained on the small well did exhibit an expansion of the digit representation (88). These findings strongly suggest that an increase in motor activity in the absence of motor skill acquisition is insufficient to drive neurophysiological changes in the motor cortex. Similar findings have been found in rodents during examinations of pellet retrieval vs. bar pressing. Rats that learned to retrieve pellets from a rotating platform displayed more distal movements in their motor maps. This expansion was associated with significant synaptogenesis (76,85).

PLASTICITY IN ADJACENT TISSUE AFTER FOCAL DAMAGE TO M1

Direct evidence that adjacent regions of the cortex might function in a vicarious manner after injury can be traced to studies by Glees and Cole in the early 1950s (107). Monkeys were subjected to focal injury to the thumb representation. When brains were remapped following behavioral recovery, the thumb area reappeared in the adjacent cortical territory. However, using ICMS techniques, somewhat different findings were observed by Nudo et al. in the 1990s. Small, subtotal lesions were made in a portion of the distal forelimb representation (DFL) in squirrel monkeys, and the animals were allowed to recover spontaneously (i.e., without the benefit of rehabilitative training) for several weeks. In contrast to earlier findings, the remaining DFL was reduced in size, giving way to expanded proximal representations (78). However, in animals that underwent rehabilitative training with the impaired limb, the DFL was preserved or expanded (108). In retrospect, it is quite possible that the re-emergence of thumb representations in the early study may have been driven by postinjury behavioral demands.

Studies in human stroke patients also suggest that the intact, peri-infarct cortex may play a role in neurologic recovery (109–111). Using transcranial magnetic stimulation (TMS) after stroke, it has been shown that the excitability of the motor cortex is reduced near the injury, and the cortical representation of the affected muscles is decreased (112,113). It is likely that this effect occurs from a combination of diaschisis-like phenomena and disuse of the affected limb (114). Further, after several weeks of rehabilitation, motor representations in the injured hemisphere are enlarged relative to the initial postinjury map (113,115). Also, when goal-directed movement with the impaired hand is encouraged, a significant enlargement of the representation of the paretic limb is produced (116), closely paralleling results in nonhuman primates.

Neuroanatomical changes also occur in the peri-infarct cortex. After middle cerebral artery occlusion in rats, Stroemer and colleagues examined immunohistochemical correlates of neuronal sprouting in the spared, peri-infarct tissue. Between 3 and 14 days after infarct, rats demonstrate increased GAP-43 immunoreactivity, suggesting significant neurite outgrowth in the peri-infarct region (117). Then, 14 to 60 days after infarct, synaptophysin staining is elevated, signifying increased synaptogenesis (117). The extent of injury-induced neural plasticity depends upon the extent and type of injury. For example, unlike ischemic brain injury, there is now evidence that synaptic plasticity and axonal sprouting may be constrained after severe to moderate traumatic brain injury (TBI) (118). TBI injuries also produced more persistent deficits than comparable ischemic cortical injuries (119). These differences further exemplify the role of enhanced plasticity in recovery as proposed by these earlier studies.

Although these experiments provided indirect support for neurite outgrowth and synaptogenesis in the peri-infarct zone after an ischemic cortical injury, direct evidence for local axonal sprouting has been obtained in experiments utilizing the so-called rodent cortical barrel field (120). This specialized region of somatosensory cortex in rats and many other species contains a somatosensory representation of the mystacial vibrissae, or simply, whiskers. The advantages of this system are two-fold: First, an individual "barrel" in the rat barrel field represents a single whisker, thus allowing precise experimental manipulation of the inputs to this

isolated region. Second, the barrel field, and individual barrels, can be identified in histological stains, allowing for precise identification of the barrel that has been manipulated. In studies by Carmichael and colleagues, focal ischemic lesions were made in the rodent barrel field cortex. A few weeks later, a neuroanatomical tracttracer was injected into the cortical tissue bordering the infarcted region, and the axonal projections of the labeled neurons were plotted. Rats with small ischemic strokes in barrel cortex had local, axonal projections arising from the peri-infarct cortex that were substantially different in orientation compared with control tissue. This result implies that new intracortical (horizontal) connections are formed in the peri-infarct tissue, at least over short distances of perhaps a millimeter in rats (120). There is also evidence that the rapid changes in the length of dendritic spines may also have neuroprotective effects by isolating excitotoxic events from reaching the neuronal soma (121). Whereas we are just beginning to understand the molecular events that drive local axonal growth after injury, the picture is now emerging of an evolving peri-infarct environment in which growth inhibition is suppressed for about 1 month after infarct. This period is followed by "waves" of growth promotion that may modulate axonal sprouting and, therefore, the brain's self-repair processes (122).

Based on the large number of paradigms demonstrating that the adult somatosensory cortex is plastic, it is not surprising that somatosensory organization is altered by cortical injury, as might occur in stroke. After small, ischemic lesions that destroy single-digit representations in S1 of adult monkeys, the destroyed representation re-emerges in the adjacent cortical territory (70). Neuroimaging studies in human stroke survivors suggest that structural plasticity accompanies somatosensory cortical reorganization. Cortical areas that undergo changes in activation response to tactile stimuli show increased cortical thickness (71).

FUNCTIONAL AND STRUCTURAL PLASTICITY IN REMOTE REGIONS AFTER FOCAL DAMAGE TO M1

Primate brains are endowed with a rich intracortical network that allows reciprocal communication among the various sensory and motor areas. Injury to the motor cortex results in a potent disruption of integrated sensorimotor networks, resulting in loss of fine motor control (77). Thus, even focal injuries produce widespread and persistent changes in areas that are quite remote from the site of injury. For example, injury to M1 in rats and nonhuman primates results in upregulation of NMDA receptors and downregulation of $GABA_A$ receptors throughout the ipsilesional and contralesional hemisphere (123). Therefore, it follows that intact motor areas outside of M1 may also contribute to recovery. As mentioned previously, the frontal cortex contains several areas that contribute to skilled motor behaviors in primates, including PMd, PMv, and SMA. All of these areas possess reciprocal connections with M1, contain numerous CS neurons, and contain complete hand representations. Thus, it is plausible that following an injury to M1, the remaining, intact motor areas play some role in functional recovery, via intracortical connectivity with other cortical regions and/or their direct CS projection pathways.

Experiments by Liu and Rouiller (124) showed in nonhuman primates that inactivation of the premotor cortex with the GABAergic agonist muscimol following an M1 ischemic lesion reinstated behavioral deficits. This reinstatement was not observed with inactivation of the peri-lesional or contralateral cortex. Thus, it follows that if the premotor cortex is capable of compensating for the loss of motor function following an M1 injury, there should exist physiological changes that accompany this recovery. In adult squirrel monkeys, ICMS mapping techniques have characterized representational maps of both M1 and PMv before and after experimental ischemic infarcts that destroyed at least 50% of the M1 hand representation (125). All subjects showed an increased hand representation in PMv, specifically in digit, wrist, and forearm sites. Further, the amount of PMv expansion was correlated with the amount of the M1 hand representation that was destroyed. In other words, the more complete the M1 hand area lesion, the greater was the compensatory reorganization in PMv (Figure 7.3).

Interestingly, when lesions were smaller than 50% of the M1 hand area, the PMv hand representation decreased in size (Figure 7.3). Thus, examining the entire spectrum of M1 infarcts of varying sizes, the linear relationship is maintained. This result occurred despite the fact that some of these subtotal M1 hand area lesions nonetheless destroyed nearly the entire terminal field of PMv-M1 connections. What possible compensatory changes in the neuronal network could account for proportional gains in premotor hand

FIGURE 7.3 Relationship between size of lesion in primary motor cortex (M1) hand representation and subsequent change in hand representation in ventral premotor cortex (PMv). The percentages refer to the proportion of the M1 hand representation that was destroyed by an experimental cortical infarct in squirrel monkeys. Note that as lesion sizes exceed 50% of the M1 hand representation, hand representations in PMv expand in a linear fashion.

Source: From Ref. (125). Frost SB, Barbay S, Friel KM, Plautz EJ, Nudo RJ. Reorganization of remote cortical regions after ischemic brain injury: a potential substrate for stroke recovery. *J Neurophysiol*. 2003;89(6): 3205–3214.

areas but losses with very small lesions? This phenomenon is reminiscent of Lashley's classic description of the relationship between cerebral mass and behavioral change (126,127). According to this hypothesis, lesion size is generally assumed to be associated with the severity of deficits, while lesion location is related to the specificity of deficits. Lashley also proposed the concept of equipotentiality, suggesting that each portion of a given cortical area is able to encode or produce behavior normally controlled by the entire area. In that vein, after smaller lesions, the surviving M1 tissue could potentially subserve the recovery of function. In that case, reorganization in distant, interconnected cortical areas would be a more "passive" process, resulting from the loss of intracortical connections. This reorganization could be compared to a "sustained diaschisis" of PMv. After larger lesions, reorganization of the adjacent tissue may not suffice for normal motor execution. Thus, learning-associated reorganization would need to take place elsewhere, resulting in greater PMv expansion. Accordingly, in rats, the contralesional cortex is thought to be involved in behavioral recovery only after large lesions (128). Lesion size appears to be a major factor involved in the initiation of some of the vicarious processes that purportedly play a role in recovery from CNS lesions.

Yet another form of postinjury sprouting of cortical projection pathways from PMv was discovered in the injured hemisphere of adult nonhuman primates. Five months after an ischemic injury to the M1 hand representation, most intracortical connection patterns of the PMv remain intact (129). This is despite the fact that the major intracortical target of PMv is destroyed by this procedure. However, after M1 lesions, monkeys display a remarkable proliferation of novel PMv terminal projections in primary sensory cortex (S1), when compared to uninjured control monkeys, specifically in the hand representations of areas 1 and 2. Likewise, this somatosensory area had a significant increase in the number of retrogradely labeled cell bodies, indicating an increase in reciprocal projections from S1 to PMv. In addition, intracortical axonal projections from PMv significantly altered their trajectory near the site of the lesion (Figure 7.4).

This finding is particularly interesting, given the direct intracortical connections between M1 and somatosensory cortex as well as the presence of direct CS projections originating from PMv. One hypothesis is that the postinjury sprouting represents a repair strategy of the sensorimotor cortex to re-engage the motor areas with somatosensory areas. In intact brains, M1 receives input from various regions of the parietal lobe that supply cutaneous and proprioceptive information that is largely segregated in the M1 hand area—cutaneous information arriving in the posterior portion of M1 and proprioceptive information arriving in the more anterior portion. The functional importance of this somatosensory input can be appreciated from studies employing discrete lesions in these subregions in M1. Lesions in the posterior M1 hand area lesions result in behavioral deficits akin to those seen after S1 lesions. These deficits appear to be similar to sensory agnosia, in which the animal reaches for food items but does not appear to know whether the item is actually in the hand (130). In contrast, anterior M1 hand area lesions result in deficits in metrics of the reach, perhaps indicating the disruption of proprioceptive information in the motor cortex (10). One lesson from these studies is that the motor cortex cannot be considered solely as a motor structure. Deficits result from sensory–motor disconnection, in addition to disruption of motor output. Thus, after M1 injury, there is a substantial reduction of somatosensory input to motor areas. Perhaps, the novel connection between PMv and S1 is an attempt by the cortical motor systems to reconnect with somatosensory input.

It is likely that this phenomenon of intracortical sprouting of remote pathways, interconnected with the injured zone, is not a unique event. It is more likely that many structures, both cortical and subcortical, that are normally connected with the injured tissue undergo substantial physiological and anatomical alterations. For instance, each of the other cortical motor areas (PMd, SMA, CMA) is likely to change its intracortical connectivity pattern since its targets are destroyed. If so, it follows that the brain with a focal injury is a very different system. It is not simply a normal

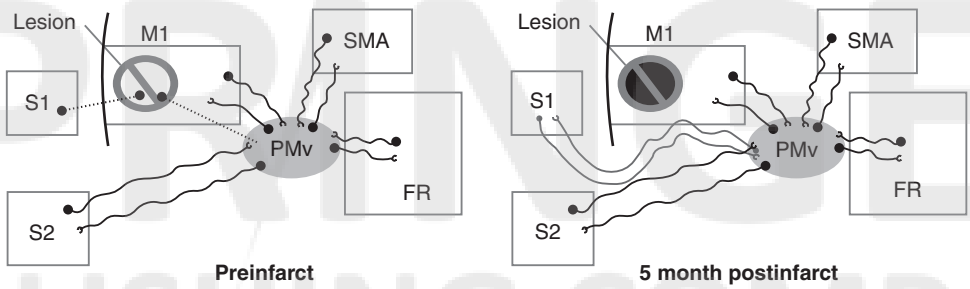

FIGURE 7.4 Rewiring of intracortical connections after M1 infarct. Normally, PMv provides a major input to M1. M1 shares significant connections with S1. Five months after an infarct in M1, novel connections form between PMv and S1. Other intracortical connections of PMv remain unchanged.

system with a missing piece. If intracortical reorganization is a predictable process, as we think it is, then we may be able to begin to develop ways of enhancing adaptive, while suppressing maladaptive, connection patterns.

After stroke in humans, widespread changes occur in activation patterns associated with movement of the paretic limb in both the ipsilesional and contralesional hemispheres (131–133). Whether such bilateral activation is adaptive or maladaptive is still a matter of debate, but it appears that, as recovery proceeds, activation of the various regions in the ipsilesional cortex increases (115,132), possibly representing a restoration of excitatory/inhibitory balance between the two hemispheres (134). Increased ipsilateral activation after stroke is quite widespread, including spared premotor areas (135,136). In one longitudinal study, increased activation of SMA was correlated with better recovery (137). Stroke survivors with middle cerebral artery strokes that included lateral PM areas had poorer recovery (138), whereas increased lateral PM activity was associated with better recovery (139). In an experiment analogous to monkey secondary inactivation studies, the ipsilesional PMd of human stroke survivors was inactivated temporarily with low-frequency repetitive TMS. This procedure resulted in reaction-time delays that were not generated by inactivation of the contralesional PMd or the PMd of healthy subjects (140). From the results to date, it is not possible to determine if any one motor area is more important in the recovery of motor abilities after stroke. A likely hypothesis is that the entire cortical and subcortical motor system spared by the injury participates to varying degrees depending upon the extent and location of the injury and behavioral demands. At least some of the functions of the injured region(s) are thus redistributed across the remaining cortical and subcortical motor network.

An example of this can be seen after unilateral cortical lesions in rats where corticostriatal fibers, which primarily connect cortical motor areas with the striatum on the same side of the brain, sprout from the intact cortex on the opposite side of the brain and cross to the opposite striatum (i.e., on the side of the lesion) (141). In other words, unilateral lesions produce novel crossed corticostriatal pathways that originate in areas completely remote from the injured zone. Although still speculative, such plasticity in crossed fiber systems may provide one mechanism for the remaining intact hemisphere to participate in recovery by gaining access to the deafferented striatum in the injured hemisphere.

The benefit of compensatory axonal sprouting may be limited by the extent of brain damage as seen after a TBI (118). Various pharmacological, physiological, and behavioral interventions are being investigated to facilitate adaptive plasticity associated with recovery. These new innovations in rehabilitative therapy take advantage of the brain's natural ability to form new functionally adapted networks in response to environmental demands. Thus, the success of these new therapies depends on the quality of behavioral experience accompanying their implementation.

ROLE OF BEHAVIOR IN MODULATING POSTINFARCT RECOVERY

Several new approaches to improving functional recovery after stroke have been developed that are based on neuroplasticity mechanisms. Constraint-induced movement therapy encourages the use of the impaired limb, and engages it in functional tasks that purportedly drive adaptive plasticity in the intact portions of the ipsilesional hemisphere. Clinical trials support the efficacy of this approach over standard and usual care (see Chapter 20) (142). D-amphetamine administration, when combined with behavioral experience, appears to enhance recovery in rodent and nonhuman primate models, though clinical results have been mixed (143,144). D-amphetamine is known to induce increased synaptogenesis in the peri-infarct region in rats (see Chapter 12) as well as axonal sprouting from the intact hemisphere after a unilateral infarct to the deafferentated, red nucleus and cervical spinal cord when paired with rehabilitative training (145). Several studies have also found promising results with methylphenidate (146). Recently, new drugs have been developed to enhance cortical plasticity with more specificity than amphetamines. These drugs increase neural excitation by antagonizing heightened, tonic GABAergic inhibition within the peri-infarct zone induced by a stroke, thereby augmenting the beneficial effects of rehabilitation (147). Also, signaling pathways associated with axonal development after an ischemic infarct from the peri-infarct area and the homologous, contralateral cortical area have been identified as potential therapeutic targets to promote recovery (148). Other potential therapeutic targets are being discovered as postischemic expression of growth-promoting genes, associated with axonal sprouting, is revealed (149).

Cortical electrical stimulation, when combined with rehabilitative training, appears to have a positive effect on recovery in rodents and nonhuman primates (150,151). Although the mechanism is not well understood, the approach is thought to enhance excitability of the intact regions of the ipsilesional hemisphere. Noninvasive analogs of this approach are now being examined (152). What these approaches have in common is the importance of repetitive behavioral tasks, especially those that have high skill demands. Thus, although pharmacological and device-oriented approaches to increasing cortical excitability and growth of neuronal processes are clearly beneficial, their effects are modulated and shaped by behavioral experience.

Recent evidence from developmental and injury studies may suggest ways in which behavior may specifically influence neuroanatomical plasticity after injury. First, during development, guidance cues for axonal sprouting are activity-dependent. There are two phases in the maturation of thalamocortical connections. In the first phase, thalamocortical axons are directed to their cortical targets by axonal guidance molecules. This process may involve spontaneous neural activity (153). In the second phase, cortical activity guides axonal sprouting within the cerebral cortex, determining topological connectivity patterns (154). Postnatal axonal

branching patterns within the cerebral cortex have also been shown to involve sensory-related stimulus activity, possibly by initiating molecular retrograde signals such as brain-derived neurotrophic factor (155). After a focal ischemic infarct in rats, synchronous neuronal activity is a signal for postinfarct axonal sprouting to be initiated from the intact cortical hemisphere to periinfarct cortex and the contralateral dorsal striatum (156). Thus, evidence now supports the importance of cortical activity for axonal sprouting within the developing and adult brain.

The significance of neuroplasticity for rehabilitation is that it provides a mechanistic rationale for understanding therapeutic interventions. Thus, it may be possible to develop more effective recovery protocols if we can elucidate the effects of such interventions on physiological and anatomical plasticity in the injured brain. For example, technological advances in micro-electro–mechanical systems are now being utilized to develop "bridging devices" that can reconnect areas within a damaged cortical network to reestablish sensorimotor integration (157). Functional connections as well as behavioral skills are reestablished through activity-dependent stimulation during therapeutically relevant behavioral activity (158).

As demonstrated by the mapping studies after microinfarcts in nonhuman primates noted above, it is clear that behavior is one of the most powerful modulators of postinjury recovery. Behavioral interventions to enhance recovery after stroke have become increasingly popular because of the success of task-oriented functional therapeutic interventions, such as constraint-induced movement therapy (see Chapter 20). Whether such behaviorally driven changes in motor performance are caused by the reestablishment of original motor programs in spared tissue or by the compensatory use of unimpaired body parts remains a controversial subject. Nonetheless, plastic changes must take place in the spared neuronal substrate, whether the improvement is caused by the true restoration of function or compensation. Behavioral use clearly plays a role in the contralesional changes that take place in the uninjured cortex of rats following cortical infarction. Other studies have demonstrated that task-specific rehabilitative training is most effective in driving postinjury neuroanatomical changes (159). Thus, it would appear that CNS injury produces an environment in which the neuronal network is particularly receptive to modulation by specific behavioral manipulations.

Functional Imaging and Stroke Recovery

Erin Burke and Steven C. Cramer

Stroke remains a leading cause of disability in the United States and many other countries, with the rate of survival increasing in recent years. Thrombolytic therapy has been approved for the treatment of acute stroke, but only 5.2% of Americans receive intravenous tissue plasminogen activator (t-PA) (1), and approximately half of those who are treated and survive show long-term disability (2). Stroke can cause deficits in a number of neurological domains, most commonly in the motor system (3,4). In most patients, the time when spontaneous behavioral recovery is seen is the first three months following a stroke (5,6), though this time period might be longer for neglect, aphasia, and other cognitive areas (7–11).

Although many patients show some degree of spontaneous recovery during the months after a stroke, the degree of this recovery is generally incomplete. In addition, the heterogeneous nature of stroke means that not all stroke survivors stand to achieve the same behavioral gains, making recovery highly variable. The best measures with which to establish prognosis and response to treatment are undetermined. The severity of initial deficits has traditionally been the measure most often used to predict the outcome after stroke (12–15). A number of other measures have been found to predict the degree of spontaneous recovery after stroke, including age (16), sensory or motor-evoked potentials (17–20), cognitive impairment and accompanying neurological deficits (21), and many more. That the list is so long is not surprising, however, given the large number of factors that influence brain function after stroke (22) (Table 8.1). However, a large amount of recovery variance remains unexplained using traditional clinical and demographic measures.

Exploring additional anatomical and physiological measurements in the stroke-affected brain is likely to provide greater insight into the likelihood of recovery. Animal studies have elucidated the cellular and molecular mechanisms (23), both near and remote from the lesion, that underlie spontaneous poststroke improvements. Because cellular and molecular measurements are generally inaccessible in human patients, a number of neuroimaging methods have been examined to better understand, predict, and guide poststroke recovery. MRI studies have shown that infarct volume, a global neural measure of neural injury, has value for predicting recovery (24–27), but much variance remains unexplained (28,29). More specific features of stroke-related injury, such as location (30,31) or effect on motor and sensory-evoked potentials (19,20,32), also have predictive value. In line with this, system-specific neural measures are more likely to predict system-specific behavioral outcome. Functional brain imaging is a useful tool that can elucidate the degree of activation and plasticity within the poststroke motor system. How such functional magnetic resonance imaging (fMRI) measurements predict behavioral outcome, as well as response to intervention, is discussed in this chapter.

METHODS FOR EXAMINING SPONTANEOUS BEHAVIORAL RECOVERY FOLLOWING STROKE

Animal Studies

A number of molecular and cellular events underlying spontaneous behavioral recovery after stroke have been identified. Available evidence suggests a range of processes including neurogenesis, axonal sprouting, synaptogenesis, and angiogenesis, many of which might be related to logical therapeutic targets in humans (33–39). Plasticity also occurs in response to treatments such as enriched rehabilitation (40), motor skill training (41–43), and exogenous pharmacologic administration (44–47). Importantly, some of these processes can be measured, directly or indirectly, with neuroimaging (48–51). Therefore, neuroimaging shows great promise in probing poststroke plasticity, both with and without treatment. Neuroimaging studies in human stroke patients are critical to optimal translation of preclinical findings, as they address some of the limitations of animal models. Some of these limitations (52) are ambulation on four legs, lack of comparable heterogeneity of injury and of preinfarct behavioral status, the nonphysiological nature of the injury induced in some models (53,54), limited modeling of stroke risk factors, limited modeling of psychosocial factors, and important differences in brain structure and function (e.g., the average brain weight is 2.5 grams for rats and 1300 grams for humans).

TABLE 8.1 Clinical Variables That Likely Modify Brain Function After Stroke

Stroke topography and sites injured
Time post stroke
Age
Hemispheric dominance
Side of brain affected
Depression and psychiatric comorbidities
Injury to other brain network nodes
Infarct volume

Type and amount of poststroke therapy
Acute stroke interventions
Medications during stroke recovery period
Final clinical status
Stroke mechanism
Genetics

Human Brain Mapping

Insights into the brain events underlying stroke recovery can be obtained from studies of brain systems via human brain mapping. Several functional neuroimaging modalities have been used to probe systems-level neuroplasticity, including fMRI, positron emission tomography (PET), EEG, magnetoencephalography (MEG), transcranial magnetic stimulation (TMS), and near infrared spectroscopy (NIRS). Some of these methods provide useful insights into the topography of injury, data that usefully complement measures of brain function. In other cases, these techniques measure the volume of regional brain activation, the magnitude of this activation, and the balance of activation across hemispheres, often reported as a laterality index, during a task or at rest. Techniques such as fMRI, EEG, and MEG also provide estimates of functional connectivity (FC) and assess lesion effects on neural networks (55). Effective connectivity is a similar technique that evaluates not only changes in the temporal correlation of activation between regions, as with FC, but also the strength and directional influence of one brain region on another. As no single method is sufficient to examine all relevant aspects of neuroplasticity, multiple functional techniques are often used to achieve the most robust understanding of poststroke plasticity (56) and to help develop therapeutic protocols that best target these mechanisms (57).

Brain mapping data have provided insights into changes in brain structure and function arising after stroke, many of which are concordant with repair-related findings in animals. The current review considers these data, with an emphasis on fMRI of the motor system, which has received considerable study. One goal of these studies is to better understand reorganization of brain function to optimize restorative interventions and behavioral recovery, for example, by better predicting outcome, triaging, or defining measures of therapy at the level of the individual patient (58). This perspective is considered in the following text.

CHANGES IN BRAIN FUNCTION IN RELATION TO RECOVERY OF BEHAVIOR AFTER STROKE

Ample data from studies in animals and humans have shown that the brain has the capacity to change its function and structure, in association with behavioral recovery, in the days to weeks following a stroke. Several patterns of altered brain function have been described.

Increased Activation Across a Network

A common pattern described since the first functional imaging study of brain function after stroke (59) is increased activation within multiple nodes that together comprise distributed networks (60–71). This has been reported in numerous brain networks, including those related to motor, language, and attention functions. These studies converge on the conclusion that maintenance of behavioral output after injury to one node of a network is associated with increased activation within surviving network areas, a finding substantiated as studies have considered a broader range of behavioral outcomes (72,73). In healthy subjects, performance of an increasingly complex task is also associated with increased activation of multiple brain areas comprising a network, and so in this regard, brain function after stroke can be thought of as analogous to perpetually performing in a high-complexity/high-demand setting (74–79).

Additional studies have shed light on these overactivations that are distant from the site of stroke-related injury. Increased activation in distal sites is highest in those with the poorest behavioral outcome (72,80). However, studies using virtual lesion (81–87) and neurophysiological (88–91) approaches suggest that this change in brain function is nevertheless important to whatever behavioral recovery does occur spontaneously after stroke. Thus, these network-wide changes in brain function after stroke contribute to behavioral outcome and generally are most pronounced in association with incomplete restoration of function.

Diaschisis

Other changes can arise in injured areas distant from stroke, including diaschisis. *Diaschisis* refers to reduced activity and function, with consequent decreases in blood flow and metabolism, in uninjured brain areas that have rich connections with injured brain areas (92–95). In some studies, behavioral recovery is related to resolution of diaschisis, that is, restitution of brain activity in uninjured areas that are distant from, but connected to, the site of infarct (96,97). However, fMRI is likely not an ideal probe for the presence of diaschisis, as blood oxygenation level dependent (BOLD) activation may appear normal in areas of reduced blood flow (98), whereas PET is sensitive to blood flow and metabolism, depending on the

technique. The exact effect of diaschisis in humans, and the time period post stroke when this process is most relevant, requires further study.

Reduced Activation in the Injured Zone

In contrast to the often increased activation in distant areas after stroke, the injured ipsilesional hemisphere sometimes shows reduced activity, especially if injury is to the elegant/eloquent cortex or its efferents (99). For example, a study of subjects who had reached a plateau in motor recovery after paresis-inducing stroke found that primary sensorimotor cortex activation in the stroke-affected hemisphere during affected hand movement was smallest in those with lesser recovery, moderate in those with full recovery, and largest in healthy controls (100). These results are concordant with TMS studies of motor cortex after stroke (101), which show that, after stroke, motor maps are smaller, and corticospinal tract integrity is reduced in parallel with the severity of clinical deficits. Similar findings have been described with stroke affecting the language system, where aphasia is accompanied by increased activation in secondary cortical regions and decreased activation in the key dominant hemisphere's language regions (69,102–105).

Displacement of Function and Representational Maps

In some cases, depending on the topography of injury, the localization of particular cortical functions can be displaced to neighboring areas (106). A common example of this compensatory event in the motor system is the finding that after a stroke injures the motor system elements related to hand movement, hand representation on the primary motor cortex extends ventrally toward the face area. Weiller and colleagues described a ventral shift in the center of activation during motor task performance in recovered patients whose stroke affected the posterior aspect of the internal capsule (107). Subsequent fMRI studies reported the same finding (73,99,100). A shift of the motor cortex hand representation after stroke in the dorsal (108) or posterior (109–114) direction has also been described, suggesting that topographic shifts in cortical representation site might reflect survival of distinct subsets of corticospinal tract fibers. Some of these shifts might have functional consequences. For example, activation of primary sensory cortex after stroke along with therapy can support motor recovery (115), which may be partly because of increased responsiveness to sensory input (116). Different patterns of injury might thus invoke different forms of cortical map plasticity, a consideration that might explain the mosaic of reorganization patterns reported in some group analyses of stroke recovery (80).

Changes in Peri-Infarct Activity

One topic that requires further study is the evolution of function in surviving tissue that surrounds a cortical infarct. When examined histologically in animals, this zone shows the greatest levels of growth-related molecular change after stroke (33,40,44,45,117–127). Furthermore, in some cases, these specific peri-infarct events can be further amplified by therapeutic intervention, a phenomenon that has been associated with additional behavioral gains (44,120,128,129). Together, these observations suggest that this zone is of particular importance to the return of function after stroke and represents important therapeutic targets—assertions supported by human studies which found that the volume of threatened but surviving peri-infarct tissue is directly related to the final clinical outcome (130,131). Functional assessments of this zone in humans, using a range of functional neuroimaging modalities, have specifically noted activation in the peri-infarct region of patients with chronic stroke (62,104,111,132–139). The significance of these observations can be further clarified, for example, by assessing whether the extent of these events is related to behavioral status. An fMRI study of patients with cortical stroke did not find a significant correlation between the extent of peri-infarct activation and behavioral outcome after stroke (140). However, this correlation was complicated by the additional observation that the T2*-weighted MRI signal used to measure brain activation with fMRI was itself altered in the peri-infarct zone. This observation complicates the interpretation of peri-infarct fMRI data in patients with cortical stroke and suggests that functional neuroimaging methods besides fMRI might be important to best understand the contribution that peri-infarct activity has on the behavioral outcome after stroke.

Changes in Interhemispheric Laterality

Another finding in subjects with stroke is a reduction in the laterality of brain activity (60,68,107,141,142). For example, a right-hand motor task or language task that activates the left hemisphere in healthy controls will activate relevant regions within both the right and the left hemispheres in patients with a left hemisphere stroke. Indeed, a number of cases have been published where the main sites of brain activation are restricted to the nonstroke hemisphere, contralateral to findings in controls (62,68,143–145). This issue has also received considerable attention in the study of normal aging (146) and has also been identified as a pattern of cerebral reorganization in a number of other neurological settings, including epilepsy (147), traumatic brain injury (148), and multiple sclerosis (149). The shift in the balance of activation toward the contralesional hemisphere varies over time, being particularly common in the early days to weeks after a stroke (150). Subsequently, the activation balance shifts back toward the stroke-affected hemisphere, more so in patients with better behavioral outcome (69,71,73,150–154). In contrast to the motor system, recovery from poststroke aphasia may depend on right-hemisphere language areas in addition to preservation of left hemisphere (70,83).

Changes in fMRI laterality have been related to altered interhemispheric interactions, suggesting that improved

function of ipsilesional brain regions might be facilitated by normalizing the pathological interhemispheric interactions that arise after stroke (155,156). A shift in hemispheric lateralization might in part reflect changes in the balance of interhemispheric inhibition (157–161). Recent studies of connectivity have provided insight into the roles of interhemispheric changes in excitation and inhibition. The general consensus from studies of paired-pulse TMS is that the unaffected motor cortex exhibits abnormally high inhibition onto the affected motor cortex during movement after stroke (161,162). Indeed, this has been confirmed using fMRI-derived measures of effective connectivity: Greater inhibition from contralesional primary motor cortex (M1) onto ipsilesional M1 during movement of the paretic hand correlates with poorer motor performance (163). Yet, changes in interhemispheric connectivity might facilitate behavioral improvement in some cases (164). Interestingly, at rest, greater coupling of ipsilesional supplementary motor area (SMA) and M1 correlate with better motor performance of the paretic hand (163). Therefore, the neural correlates of better motor behavior may be different depending on whether a stroke patient is at rest or moving. The neural functional correlates may also be different depending on the stage of recovery (165). Reductions in corticospinal tract integrity and interhemispheric white-matter integrity are also associated with poorer outcome after stroke (166–169) and might underlie some of the observed changes in laterality of fMRI activation (170,171).

A number of factors have been found to modify the extent to which stroke is associated with a reduction in the degree of interhemispheric laterality. Examples include time after stroke, with laterality increasing toward normal as patients recover (69,96,150,152,172,173); hemispheric dominance, with motor task performance with the nondominant hand being less lateralized than with the dominant hand, in both healthy controls and after stroke (62,100,174); topography of injury, with reduced laterality being more common with a cortical, as opposed to subcortical, infarct (134,175); and greater injury and/or deficits, with reduced laterality present with larger infarcts and more severe behavioral deficits (73,152,176,177). Other factors relevant to laterality in normal subjects are also likely important after stroke, with less lateralization present with increasing task complexity (88–93), increasing subject age (146), lower task familiarity (178), and more proximal movement (179–181). One study also found that gender influenced laterality of brain activation (182).

Time is an important factor in the study of brain function after stroke, with many of the processes discussed here evolving rapidly, a finding that is likely to have therapeutic implications. Early after stroke, insulted brain areas show reduced function. Intact areas with strong connections to sites of injury sometimes show reduced function as a consequence of diaschisis. Laterality is shifted toward the nonaffected hemisphere. Over time, the shift of balance points back toward the affected hemisphere, with reduced activation in the nonstroke hemisphere and increased activation in the stroke-affected hemisphere. Some therapies have demonstrated value in increasing this shift back toward the affected hemisphere (78,81,94,106,143,144,146,156,160,169,170). The relationship between the degree of fMRI laterality and motor behavior may not change from the subacute to the chronic phase (183), suggesting that efforts to restore laterality could improve motor function regardless of time post stroke.

One principle apparent from a review of the literature is that changes in brain function after stroke for a given task are partly related to the normal functional anatomy for that task. Thus, swallowing (184), facial movement (73), and gait (185) are normally more bilaterally organized than distal extremity movements, and a shift in hemispheric balance after stroke occurs most often and with greatest clinical gains in these tasks. Similarly, movement of the nondominant hand is more bilaterally organized than the dominant hand normally, and this too remains true after stroke (100). This principle suggests the hypothesis that behaviors that are more bilaterally organized normally might benefit from a more bilateral approach to therapy. However, elegant and eloquent neocortical functions are generally highly lateralized (e.g., to the dominant hemisphere for language and fine motor skills); for these brain regions, the best behavioral outcomes are apparent when this remains true after stroke.

THERAPEUTIC INTERVENTION AND RECOVERY

Although many patients show some degree of spontaneous recovery during the months after a stroke, this recovery is generally incomplete. Restorative therapies aim to improve outcome not by salvaging threatened brain tissue but by promoting plasticity within surviving neural resources (186,187). Examples of such brain repair therapies include growth factors, cell-based therapies, antidepressants, noninvasive brain stimulation, devices such as robotics, and function-oriented physical therapy regimens such as constraint-induced movement therapy (CIMT) (44,45,129,188–201). However, there is currently no approved therapy for enhancing outcome after a CNS injury such as stroke. The maximum value of functional neuroimaging methods such as fMRI will be appreciated when used to improve application of an established restorative intervention.

One case for use of functional neuroimaging to improve application of restorative interventions is made from examining medical practice in nonneural systems. For many body systems, data on the functioning of an organ are used to inform and improve clinical decision making. Hypothyroidism is optimally treated by serial measures of pituitary–thyroid axis via serum TSH. Dosage in treatment of myeloproliferative disease and other hematological syndromes is based on serial measure of the cell population of interest. Other diagnostic approaches examine organ function before versus after a diagnostic stressor. For example, cardiac arrhythmias are sometimes treated by inducing tissue dysfunction in the electrophysiology laboratory and then evaluating the effectiveness of selected

drugs. Coronary artery disease is often assessed by stressing the heart with exercise, or with introduction of the sympathomimetic dobutamine. These practices suggest that some form of functional neuroimaging—possibly during introduction of a diagnostic stressor—might be useful for patient selection, treatment selection, or treatment dosing when introducing a restorative intervention, with the intent of modifying brain function and behavioral status.

Brain Mapping to Guide Poststroke Therapy

Some studies have already made strides in improving therapy with neuroimaging. One series of studies used fMRI to guide details of decision making during therapy (194,202). An fMRI scan was used to identify the centroid of primary motor cortex activation in patients with stroke. This information then guided neurosurgical placement of an investigational epidural cortical stimulation device. Using this approach, patients receiving stimulation plus rehabilitation therapy showed significantly greater arm motor gains than patients receiving rehabilitation therapy alone. A similar approach was used in studies that found repetitive TMS to be useful for improving motor function after stroke (193,203), in treatments that employed TMS to identify the optimal physiological representation site for hand motor function.

Brain Mapping to Predict Treatment Responses and Outcomes

The heterogeneity of stroke makes prediction of treatment responders, as opposed to nonresponders, a great challenge. The ability to predict response to therapy and prospectively separate subgroups could be useful for stratifying patients (58) to appropriate therapies to maximize behavioral gains, efficiently utilize rehabilitation and financial resources, and reduce variance to increase power in clinical trials.

Behavioral measures of motor impairment and function have been used most often to predict outcome after stroke (15), but pretreatment behavior alone is unlikely to sufficiently predict behavioral gains from restorative therapies. Several studies have used an assessment of brain function to predict behavioral response to a restorative intervention. For example, Cramer and colleagues (204) examined the ability of a baseline fMRI to predict behavioral gains. These patients each underwent baseline clinical and functional MRI assessments, received six weeks of rehabilitation therapy with or without investigational motor cortex stimulation, and then had repeat assessments. Across all patients, several baseline measures showed predictive value for trial-related gains in univariate analyses. However, multiple linear regression modeling found that, when controlling for other factors, only two variables remained significant predictors: degree of motor cortex activation on fMRI (lower motor cortex activation predicted larger gains) and arm motor function (greater arm function predicted larger gains). In the language system, fMRI activation within the right contralesional hemisphere is associated with greater behavioral gains from constraint-induced aphasia therapy (205).

In many areas of medicine, the response to a dynamic challenge is more informative than a single cross-sectional measure; the change in serum cortisol after introduction of IV ACTH is far more informative than is a single check of serum cortisol. Some studies suggest that this principle extends to stroke recovery. In two studies, early neurologic response to therapy significantly predicted long-term behavioral gains (206,207).

Recent studies have found that the motor system structure is also important for therapy response. A seminal study by Stinear and colleagues (208) generated a predictive algorithm of response to motor therapy. Although they found no predictive ability of fMRI, the structural and functional integrity of the corticospinal tract using diffusion tensor imaging and TMS, respectively, successfully predicted meaningful gains. The extent of overlap between an infarct and normal white-matter tracts descending from M1 and dorsal premotor cortex (PMd) is also a strong predictor, for example, of motor gains from a course of robotic therapy (209) (Figure 8.1). This study also highlights the importance of using a systems approach to predicting gains, as neither infarct volume (a general measure of neural injury) nor baseline behavior were significant predictors. Similar results have been found with a course of transcranial direct current stimulation plus physical therapy (210). Integrity of transcallosal fibers after stroke, as well as integrity of the corticospinal tract, may also hold predictive value (210).

These studies emphasize that an assessment of brain function or structure can be uniquely informative for clinical decision making in the setting of restorative therapy after stroke.

Functional Imaging of Treatment-Induced Recovery

The principles important to reorganization of brain function during spontaneous recovery from stroke might also operate in the setting of treatment-induced recovery. If true, brain mapping might be a useful tool to guide patient selection or choice of rehabilitation strategies, for example, by measuring the capacity of residual brain networks to respond to therapeutic challenges. In this way, such measures could serve as biomarkers of stroke recovery—one that reflects a brain event related to recovery and also correlates with the behavioral state. A biomarker of restorative therapy effects might be useful by providing a measure related to the treatment's mechanism (see Chapter 9). Differences in patients and their patterns of injury are likely associated with divergent neural responses to rehabilitation therapy. As with spontaneous recovery, functional imaging of therapy-induced recovery might be a unique source of insights. Published studies support this concept for CIMT.

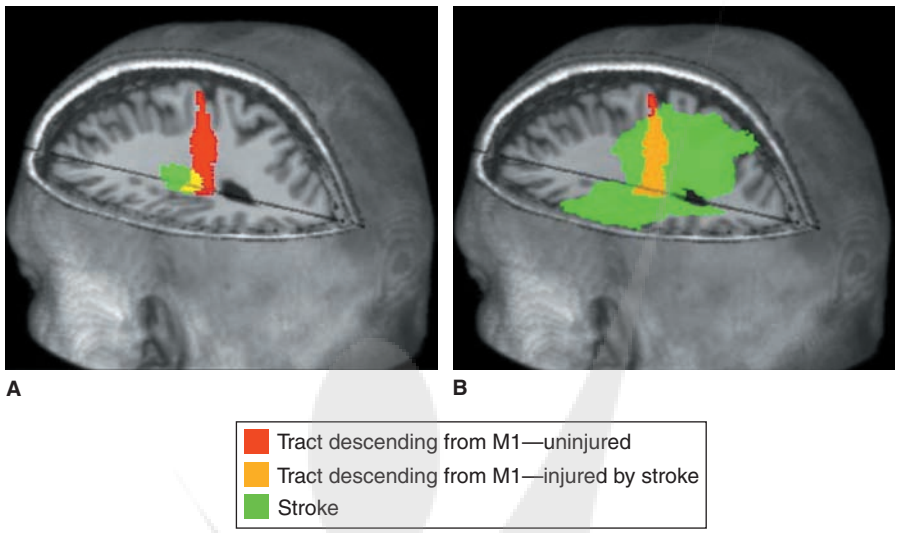

FIGURE 8.1 Examples of stroke injury to the tract descending from M1. (A) This subject had 37.5% of the M1 tract injured by stroke and had a gain of 11 points on the FM scale across the period of therapy. (B) This subject had 93.4% of the M1 tract injured by stroke and had a gain of 1 point on the FM scale across a period of therapy.

CIMT (211) is an approach to improve motor function that is effective in producing enduring motor gains in eligible patients in the setting of chronic (197), subacute (212), or acute (213) stroke. A range of functional neuroimaging methods, including EEG, fMRI, and TMS, have demonstrated changes in brain function that parallel treatment-related motor gains (214–219). Changes in brain function after CIMT include altered motor excitability, a shift in activated brain areas, a change in motor system interhemispheric laterality, and an increase in affected hand motor representation area (220,221). Importantly, cortical changes with therapy are likely to be specific to the training elements of the therapy. For example, a study of robotic therapy found that activation volume increased for a task that was part of the training, whereas activation volume did not increase during a task that was not part of the training (222) (Figure 8.2). In general, studies have typically diverged as to whether increased activation with CIMT is primarily in the ipsilesional or contralesional hemisphere (223).

The divergence in findings likely reflects differences in patient characteristics. For example, in chronic stroke patients, successful CIMT was associated with reduced interhemispheric laterality in a study of weaker patients (215) and increased laterality in a study of less impaired patients (219). A recent study found that patients with poorer baseline motor behavior and the largest behavioral improvements had the largest increases in ipsilesional sensorimotor cortex activation (224). However, whether the effect of a restorative therapy is beneficial or potentially maladaptive may also depend on the patient's baseline level of impairment (225). Greater injury to the corticospinal tract also affects treatment-induced cortical plasticity (224,226). Activation changes with therapy may also depend on intracortical excitability (227). Understanding these differences might be important when using functional imaging as a tool to guide poststroke rehabilitation therapy.

Motor Learning and Plasticity

Application of rehabilitation therapies might be improved if based on models of patterns of brain plasticity seen in healthy subjects. For example, some authors have drawn a parallel between brain events related to learning and those underlying rehabilitation-based motor gains after stroke (228). Motor learning theory is particularly important to the clinical application of poststroke therapies, such as CIMT, given that a goal of these approaches includes improved performance and retention of new motor skills. Studies of motor learning provide insights into the brain events underlying acquisition or refinement of movement skills, for example, with activity shifting from cortical to subcortical (229–232) or cerebellar (233) areas. Such changes can be short term (230,234) or long term (235), with both measures being potentially important to understand how structures of the brain motor system store kinematic details induced by motor training.

Implicit motor learning is an approach that might be particularly valuable for subjects with stroke, given the frequency with which concomitant deficits could impair explicit learning such as CIMT (236–240). It has been suggested that

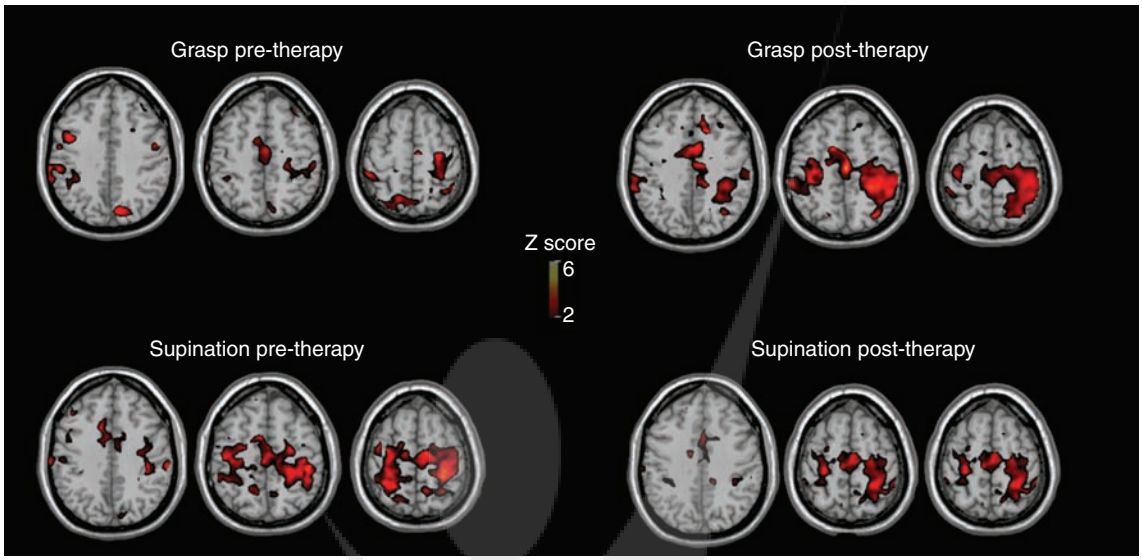

FIGURE 8.2 The grasp task that was central to therapy showed significantly increased activation volume over time within the left (stroke-affected) primary sensorimotor cortex, whereas the nonpractice supination task did not. This change in grasp task activation volume was not accompanied by a change in task-related EMG, suggesting that its basis was altered brain organization rather than altered subject performances.

Source: From Ref. (222). Takahashi CD, Der-Yeghiaian L, Le V, et al. Robot-based hand motor therapy after stroke. *Brain.* 2008;131(pt 2):425–347.

improved implicit learning is associated with decreased PMd activation and greater superior frontal cortex activation, findings not seen with such learning in healthy controls (241). These findings emphasize that the mechanisms of behavioral improvement will likely differ according to the nature of the restorative therapy.

Gray matter changes with learning, and treatment can be structural as well as functional. In healthy subjects, training on a dynamic balancing task increased gray-matter volume that correlated with the degree of behavioral improvement (242). Such studies are limited in stroke, but a study of CIMT administered to chronic stroke patients found a bilateral increase in sensorimotor cortex and hippocampi that was not identified in control subjects (243). Importantly, the volumetric increases correlated with the extent of increased use of the affected arm.

Abundant preclinical research indicates that white-matter structure and integrity are important to achieving behavioral gains with restorative therapies after stroke. However, this issue has been much less examined in human subjects. Studies of motor learning in healthy subjects have also elucidated some of the structural changes that occur in parallel with functional changes. Several examples of changes in white-matter integrity in parallel with training-induced behavioral gains have been described in healthy subjects (244–247). Recently, noninvasive cortical stimulation was found to alter white-matter integrity in chronic stroke patients with aphasia (248).

Considering the spectrum of functional and structural changes that occur in response to restorative therapies, multimodal neuroimaging studies are of high value, for example, because functional and structural changes can co-localize (242,244,249).

EMERGING CONNECTIVITY METHODS TO STUDY CORTICAL FUNCTION DURING STROKE RECOVERY

Newer methods have enabled researchers to move beyond fMRI activation metrics, such as percent signal change and activation volume, to evaluate cortical function as part of a network. Techniques such as resting-state BOLD MRI, EEG, and MEG can be used to provide estimates of FC, which can assess lesion effects on neural coupling across networks near the infarct and remotely (55) in ways that are more limited with traditional fMRI studies. Serial imaging of FC has the potential to unlock how stroke treatments alter functional connections between brain areas and how those changes are related to behavioral gains. Resting-state FC, reflective of neural coupling in the absence of active task performance, is an attractive means to evaluate network changes in clinical populations such as stroke because the patient does not need to perform a task. As such, the effect of task-related motion is minimized, and such motion is common during scanning of subjects with impaired motor control, producing substantial motion artifact in fMRI images. Increases in resting-state FC among several networks have recently been found to positively correlate with gains from both robotic and motor imagery training (250). Another measure, that of effective

connectivity, evaluates not only changes in the temporal correlation of activation between regions after stroke, as is done with FC, but also the strength and directional influence of one brain region on another.

Using connectivity measures to predict gains from restorative therapies has received limited study but is promising. Studies of spontaneous stroke recovery suggest that these connectivity measures will have predictive value. Such relationships may differ, however, when patients are examined in relation to introduction of a restorative therapy. Greater behavioral recovery from stroke is predicted by MEG- and fMRI-derived measures of resting FC within bilateral brain regions (251,252). Reduced effective connectivity from secondary ipsilesional areas onto ipsilesional M1 during a motor task has been found to correlate with recovery (165). Resting-state FC between ipsilesional M1 and several contralesional areas obtained near stroke onset positively correlates with motor improvement six months later (164). Recent findings encourage the use of such additional measures to probe functional changes across the brain during stroke recovery.

FUTURE STUDIES

The use of functional imaging is shifting from being employed primarily to study spontaneous recovery in a cross-sectional manner to longitudinal studies aiming to predict, and to evaluate mechanisms of, therapy-induced behavioral gains in a clinical trial setting. Despite advances, some key limitations still exist. Many of the studies to date have examined patients in the chronic phase. However, the brain is most primed to respond to treatment in the early days after a stroke (190,253,254). Therefore, further studies of predictors and biomarkers in the early days following stroke onset are critically needed. Also, many studies have enrolled patients with relatively mild impairments and those with subcortical infarct (255,256), but studies of the full spectrum of stroke-related deficits are needed to best understand the value of neuroimaging measures in this setting.

Evidence suggests that measuring brain function is useful for defining features of poststroke restorative therapies. A better understanding of the underlying neurobiological principles related to therapy-induced behavioral gains will likely improve this approach, and thus maximize gains derived from restorative interventions that aim to promote brain repair and thereby minimize impairment and reduce disability after stroke. A multimodal approach that incorporates measures of function and structure might provide the richest perspective on these issues.

Anatomical and Physiological Predictors of Recovery

George F. Wittenberg, Crystal L. Massie, and Kelly P. Westlake

GOALS OF BIOMARKER RESEARCH

Research in stroke rehabilitation is now actively testing new and more effective treatments, but is hampered in these endeavors by the complexity of primary outcome measures. It is acknowledged that the most important outcomes are those that affect quality of life and participation in society. However, it is unlikely that an intervention with effects on biological structures will have immediately measureable results at such a high level of analysis. To make this concrete, if we had an intervention that could reliably improve speech intelligibility by 20%, would we also find reliable changes in participation in family interactions? There might be other factors changing during the course of the study that would have an impact on the same high-level measure. But if we had a good measure of intelligibility and a mechanistic explanation for how the intervention improved it, then the intervention should be considered promising even if there were no significant changes at the level of participation.

The concept of a biomarker is, in some ways, a collection of old ideas under one label. The official National Institutes of Health (NIH) definition of a *biomarker* is "a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention" (1). The biomarker is in one sense a substitute (or surrogate) for a clinical outcome that is too difficult or too remote in time to measure, and in another sense an indicator of a biological mechanism relevant to the intervention. The use of a surrogate can be problematic when there are other factors, which are important to the real outcome, that are affected by the treatment but not measured by the biomarker. This has led to actual problems in clinical trials and is an issue well worth considering in the choice of a biomarker in a field such as stroke recovery, which has a wide heterogeneity in the disease expression.

This has posed significant challenges in stroke rehabilitation research because there is no equivalent to the simple biomarkers used in many other fields, such as blood pressure, tumor size, or blood count. The development of biomarkers in stroke recovery is needed before studies can be as streamlined as in other fields of medicine. Work on biomarkers will have an added benefit of exploring the mechanisms underlying stroke recovery. In one sense, the mechanistic work of the past few decades has set the stage for the establishment of biomarkers in this field. This chapter reviews the work that has been done and makes some suggestions for the future use of biomarkers in stroke-related clinical trials.

Idea of Prediction

Although prognosis in stroke is an active area of research, issues of predication are sometimes ignored when new rehabilitation methods are developed. The ability to predict outcome, based on measures during the acute phase, has been recognized as having important implications in decisions regarding discharge planning and beyond (2). In one sense, biomarkers are already used in a practical way to generate discharge dates, although generally in a heuristic manner. That is, the impairment, age, social situation, and other factors collected on admission to inpatient rehabilitation are used to predict a date of discharge when the patient is expected to make a safe return home, or else reach a plateau that will necessitate transfer to a new setting.

Prediction of outcome is also very useful when considering interventions. Therapeutic approaches and techniques vary, and some may be more effective than others for particular patients. Newer rehabilitation approaches consist of focused types of task practice or neuromuscular stimulation, and often represent a significant commitment of time and expense. A set of biomarkers associated with good response to a particular intervention would allow these treatments to be targeted to those with expected outcomes, while saving predicted nonresponders' time and third-party payers' expense.

Correlation With Recovery

If a biomarker were to correlate with function, it would also be useful as a surrogate marker for recovery. That is, if function changed over some time interval, whether or not because of an intervention, then the biomarker would

change and the changes would be correlated with recovery. Conceivably that biomarker would be useful as a measure in clinical trials. It would be less useful in practice, given that it is actually function that we care about; no biomarker, however good, would substitute for real-life function. But during the course of treatment, if the biomarker were easier to obtain than a functional measure, it could help guide treatment, with decisions on therapeutic methods made on the basis of changes in that biomarker. An example would be surface EMG as a measure of specific muscle recruitment. If upper extremity function correlated strongly with specific activation of wrist flexors and extensors, then a metric of voluntary activation (and lack of coactivation) could be constructed as used on a daily basis to measure progress. If a particular rehabilitation treatment began to plateau for this metric, then a rational decision could be made about another intervention.

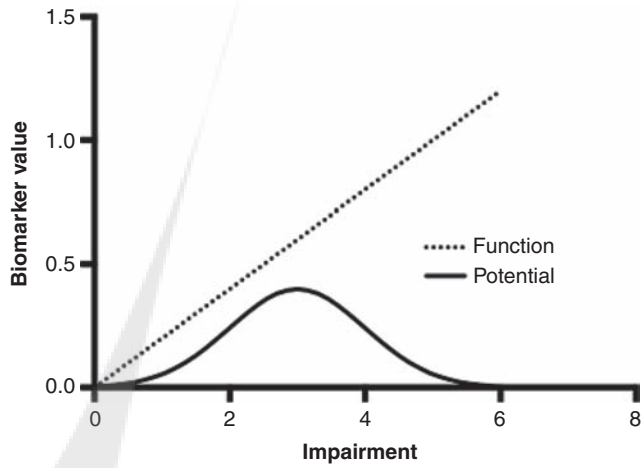

FIGURE 9.1 Two types of biomarkers in stroke recovery.

Motor Focus

This chapter deals mainly with biomarkers useful in rehabilitation of motor function, because this has been the primary focus of research in this field. Motor function has the advantage that it is relatively easy to measure with the cooperation of the patient. Of course, a patient may not understand the instructions in a motor task, may not give full effort, or may have other limitations in movement related to medical condition. In such a case, a biomarker could be useful. Such a biomarker would not have to depend on effort (unlike the preceding example of surface EMG activation) but could include something like white-matter tract integrity as measured by diffusion tensor imaging.

The Ideal Biomarker in Stroke Recovery

Would Help Define Normality. Because normal form and function are the goal of rehabilitation, it is no surprise that the ideal biomarker would have normal values in those patients most likely to recover normal function. Thus, there are two main classes of biomarkers useful in rehabilitation: (a) *functional* and (b) *potential*. The functional biomarkers correlate with function, whereas the potential biomarkers correlate with capacity to improve function.

But Normal Form and Function Are Possible Only in the Smallest Lesion. The functional biomarker would be close to normal values in only the smallest lesion, whereas the potential biomarker would likely have a bell-shaped distribution because of ceiling effects on one side, and substrate effects on the other (Figure 9.1). That is, there is no potential to recover in the undamaged situation, whereas large bilateral lesions would reduce the likelihood of meaningful recovery. So the potential biomarker would provide some insight into the substrate for recovery, namely the spared brain tissue that can participate in restoration of lost function. This situation is likely to be dynamic for the first several weeks or months after stroke (3) and related to functional status, so the potential biomarker will likely have to include input from both time and functional data.

Even if such a biomarker worked for recovery with usual clinical care and experience, it might not predict response to an experimental treatment. This results in a very complex situation in which many potential biomarkers may be associated with different prediction algorithms depending on:

1. Time
2. Functional status
3. Type of functional outcome being sought (e.g., general independence vs. specific impairment)
4. Type of intervention

ANATOMICAL MARKERS

Lesion Volume/Location

One of the most obvious biomarkers in stroke is the characterization of the lesion itself in location and extent. Yet lesion size is less useful than initial functional ability in terms of predicting outcome (4). Lesion location and the disruption of key areas for a function are most important—for example, the corticospinal tract and its impact on motor function or the dominant hemisphere perisylvian regions in language. Although there is likely to be a strong relationship between the amount of damage to these key regions, techniques are not yet available to allow good clinical correlation; however, there is some recent promise in this area (5). This may be because of variations in individual, structural, and functional anatomy. So, though the promise of imaging-based prognosis and prescription of therapy remains, it is a long way from reality.

Focus on the Corticospinal Tract

In the motor system, the corticospinal tract is the final common output from the cortex for movement of the distal extremities. There are other projections from the cortex that can produce movement, including corticorubral and corticoreticular projects. Of course, for movements of the face, it is more accurate to speak of the corticobulbar tract, because the lower motor neurons are in the brainstem. Studies have shown a relationship between number of corticospinal fibers and motor outcome (6). In the field of cerebral palsy, there has been a demonstration that anatomic assessment of the corticospinal tract is related to motor function (7) and that response to an intervention depends on physiological assessment (8).

Fractional Anisotropy as a Measure of White-Matter Integrity

Fractional anisotropy (FA) is a measure derived from diffusion tensor imaging. If water were equally free to diffuse in all directions, it would imply that there is no orientation of barrier (such as myelin sheaths) to diffusion. That would be a situation of complete isotropic diffusion. But when nerve fibers are oriented in a single direction, then water can diffuse most easily only in that single direction, and the anisotropy measure approaches 1. Whereas the relationship of myelination to FA values is baffling, in general FA has become synonymous with white-matter integrity.

FA as a Predictor of Response to Therapy

While FA is correlated with function, it also appears to predict response to treatment, perhaps by indicating that there is sufficient substrate to respond. Despite it being a white-matter measure, it may be more accurate than gray-matter measures because it better shows functional output and connectivity. An increase in FA value (or decrease in mean diffusivity) may occur after rehabilitation, and as such may serve as a potential biomarker for response to therapy (9,10).

Tractography

The data acquired from a diffusion tensor image (DTI) may be used to trace white-matter fiber tracts from one region to another. This technique, with the obvious name of "tractography," relies on the principle that axons tend to bundle when they are headed to the same place. They also tend not to take sharp turns, so a path can be inferred by following the main orientation of axons from one voxel to the next. Needless to say, the assumptions of bundling and smooth pathways can be violated, and automated methods to trace pathways may fail. However, this is an active area of research and continual improvement in methods for probabilistic tracing have overcome some of these limitations. But to have a chance of tracing a tract, the source images must contain precise measures of diffusion in many different directions. These high-quality scans can take up to 30 minutes.

Tractography can generate attractive and clinically useful images, but can also be used for quantitative measures. Therefore, the number of intact fibers in a tract can be estimated and then serve as a biomarker. Although it seems that increases in tract size would be unlikely in the adult human brain, recovery and experience do affect DTI measures. This may be because of a trophic relationship between activity and both myelination and axon size.

Another problem specific to the use of tractography as a biomarker is the effect of brain lesions on DTI data at the site of the lesion. In a very acute stroke, edema, blood, and other structural changes because of damage can reduce or even eliminate the ability to trace a tract through an injured region.

PHYSIOLOGICAL MARKERS IN MOTOR RECOVERY

The field of stroke rehabilitation is ultimately focused on improving quality of life and function, with rehabilitative efforts dependent on a strong understanding of the functional deficits that have underlying biological mechanisms (11). Anatomical markers have appeal because of their potential objectivity, sensitivity, and reliability, but of course they cannot address function directly. Alternatively, understanding the functional deficits, at best, provides speculation as to the biological underpinnings. A number of physiological measures have been tested for their relationship to function and recovery, and this section describes some of them.

Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) is a technique that noninvasively stimulates brain regions and therefore is an excellent complement to methods that measure either anatomy or activity. It can evoke measureable outputs, such as limb movement, or transiently interfere with function in a specific brain region. In this way, it can both test *sufficiency* (ability to be involved in a function) and *necessity* (requirement for activity for that function).

Brief Introduction to Method

TMS uses pulsed magnetic fields to induce electrical fields in excitable tissue. In practice, this is accomplished with electromagnets with discharge of a high voltage into copper coils. The technique has been around for more than a century, but the development of high-voltage, silicon-controlled rectifiers has made possible compact, nonarcing devices that could be used in clinical and nonclinical settings. Some of the earliest uses have included stimulation of the visual cortex with inducement of phosphenes and stimulation of the motor cortex with induction of muscle activity.

MEP Presence and Recovery

One of the most basic measures in TMS is the motor evoked potential (MEP). The MEP is the electrical analog of

TMS-induced muscle activity caused by excitation of muscle fibers. Thus, it is a rather *indirect* measure of the upper motor neuron activity caused by TMS in the motor cortex, but it is more sensitive than measurement of movement, as a small amount of electrical activity may occur in the muscle without visible movement. Almost all normal individuals will have MEPs in distal upper-extremity muscles. The presence or absence of MEPs after stroke in such muscles is therefore a measure of damage to the motor system. Absence of MEPs in the affected upper limb within the first weeks of stroke correlates with poor recovery of arm and hand (12). Return of MEPs in hand muscles was associated with return of hand function, but as these authors noted, there was no such correlation between return of MEPs and return of movement in proximal arm muscles. This may be because of more mixed cortical/subcortical control of proximal upper limb muscles, or to the related fact that MEPs are not as reliably measured in some more proximal muscles. A meta-analysis reported strong evidence that the presence of MEPs is associated with better arm recovery, with at least 15 of 20 studies reporting significant associations (13).

Beyond the absence or presence of MEPs, MEP peak-to-peak amplitude is an objective metric that represents response of the corticospinal tract to stimulation at a particular intensity (Figure 9.2). The amplitude is considered in relation to the relative stimulation intensity or the change in amplitude as a function of increasing the stimulation intensity. This latter approach, known as the *recruitment curve* or *stimulus response curve*, is determined by measuring MEP amplitude with increasing stimulation intensity. Generally, MEP amplitude will increase as stimulation intensity increases to a point where a plateau is reached. Thus, these curves have a sigmoidal shape. The slope is considered to represent changes in synaptic excitability, with a steeper slope occurring as greater changes in MEP amplitude correspond to an increase in stimulator intensity. As a result, this slope can be considered as a measure of the integrity of the motor system and a potential indicator of recovery, with a steeper slope signifying that a greater number of upper motor neurons were recruited with lower stimulation intensity, that is, the motor system was more responsive or excitable to the stimulation. One of the inherent challenges with interpreting the slope of the curve as a potential indicator of recovery arises because the slope can be calculated by various mathematical methods such as a linear slope and a nonlinear, sigmoid function, and these two methods can be quite different (14). In addition, if not enough points on the curve are measurable to calculate a slope, the use of a recruitment curve as a marker for recovery can be limited. This suggests that use of the recruitment curve as a biomarker is limited to those survivors of stroke who have MEPs, and that it is better suited for distal muscles compared to more proximal muscles, similar to the presence or absence of MEPs proximally versus distally (14,15). Quantifying MEP amplitude provides a sensitive measure (16), but is useful only if MEPs are present in survivors of stroke. Thus far, recovery-related changes in recruitment curve have not been examined, and rehabilitation-related changes have not been found (17).

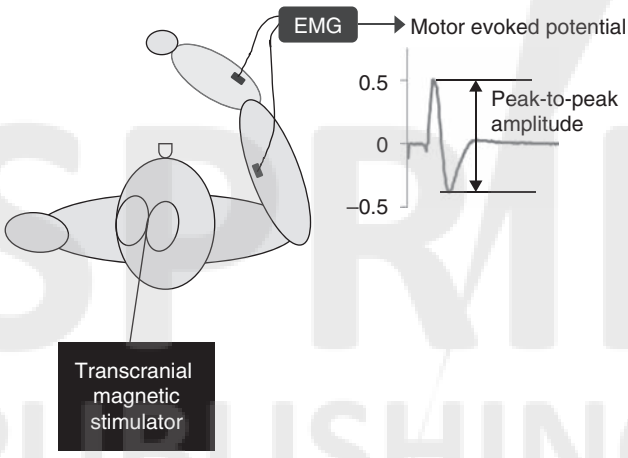

FIGURE 9.2 Schematic of TMS setup. The TMS is applied to the motor cortex with the motor evoked potential recorded by an EMG system. One of the most common metrics recorded is the peak-to-peak amplitude of the motor evoked potential.

Central Motor Conduction Time

Although most TMS studies in the motor system gauge the amplitude of the muscle response, it is possible to estimate the time for conduction within the upper motor neuron. This is done by measuring the difference in latency between TMS of the motor cortex and stimulation of the motor root, generally by magnetic stimulation over the spine. Whereas the latency difference includes somewhat more processes than conduction of the action potential from axon hillock to synapses of the upper motor neuron (UMN), peripheral nerve conduction time is effectively removed, and the resulting central motor conduction time (CMCT) can be used as a measure of central axon action potential velocity. This measure is used clinically in multiple sclerosis and cervical myelopathy to measure local or diffused demyelination and damage.

In stroke, the measure has been used to demonstrate the natural history of motor recovery, with abnormally slow CMCT increasing over time in some individuals (18) and slow CMCT indicating an intermediate progress between those with absent MEP (poor) and CMCT (good) (19). While CMCT has been suggested as a useful prognostic indicator (20), there has been little use over the past decade. This may be because its measurement is limited to patients with MEP, a category that already has a better prognosis, whereas other measures such as MEP size or recruitment curve slope offer an assessment of UMN health similar to that of CMCT.

Silent Periods

The *silent period* is the time during which voluntary lower motor neuron (LMN) activity is suppressed after stimulation of the motor cortex (21,22). Operationally, a silent period is

measured by asking for activation of a muscle at a constant and defined level followed by delivery of suprathreshold stimulation of the motor cortical representation of that muscle. The EMG response will show a MEP followed by absence of activity for several milliseconds, followed by resumption of activity, often with high levels of activity at first. The definition of the silent period, in the simplest form, is the duration in milliseconds from the stimulating pulse to the resumption of activity. But interpretation is complicated by technical issues, such as incompleteness of suppression, and the fact that the earliest part of the silent period is dominated by recurrent spinal inhibition. The first problem is how to handle a single motor unit that appears as an "island" during the silent period. This can be addressed by measures that reflect the loss of activity caused by stimulation, not just the period of complete silence. The second problem (that of recurrent spinal inhibition) does not generally require special consideration, because TMS results in a longer silent period than more direct methods of corticospinal tract stimulation, suggesting that it is more effective at activating cortical inhibitory interneurons. Therefore, the TMS-evoked silent period may be a good measure of the state of intracortical inhibitory networks.

After a stroke, the silent period is usually asymmetric, most often prolonged on the affected side but rarely shortened (23,24). Longitudinal studies have shown a predictive value of the relationship between voluntary activation and silent period duration, so that when the silent period was lost with voluntary activation, poor recovery was more likely (25). Other investigators also showed a gradual shortening of silent period duration over time, correlated with clinical recovery (26). Acute studies have been less positive about the prognostic value of the silent period (27) and silent periods do not appear to be affected after transient ischemic attack (TIA) (28).

In summary, the silent period is a sensitive measure of intracortical inhibition that may be most useful for prognosis in more mildly affected subjects. The general consensus is that the silent period, prolonged after stroke, also suggests that excess inhibition is a direct consequence of ischemia to the corticospinal system, and that reduction in inhibition is part of recovery.

Ipsilateral Silent Period. A different type of silent period is measured with stimulation to the motor cortex ipsilateral to the activated muscle (Figure 9.3). In the case of a stroke

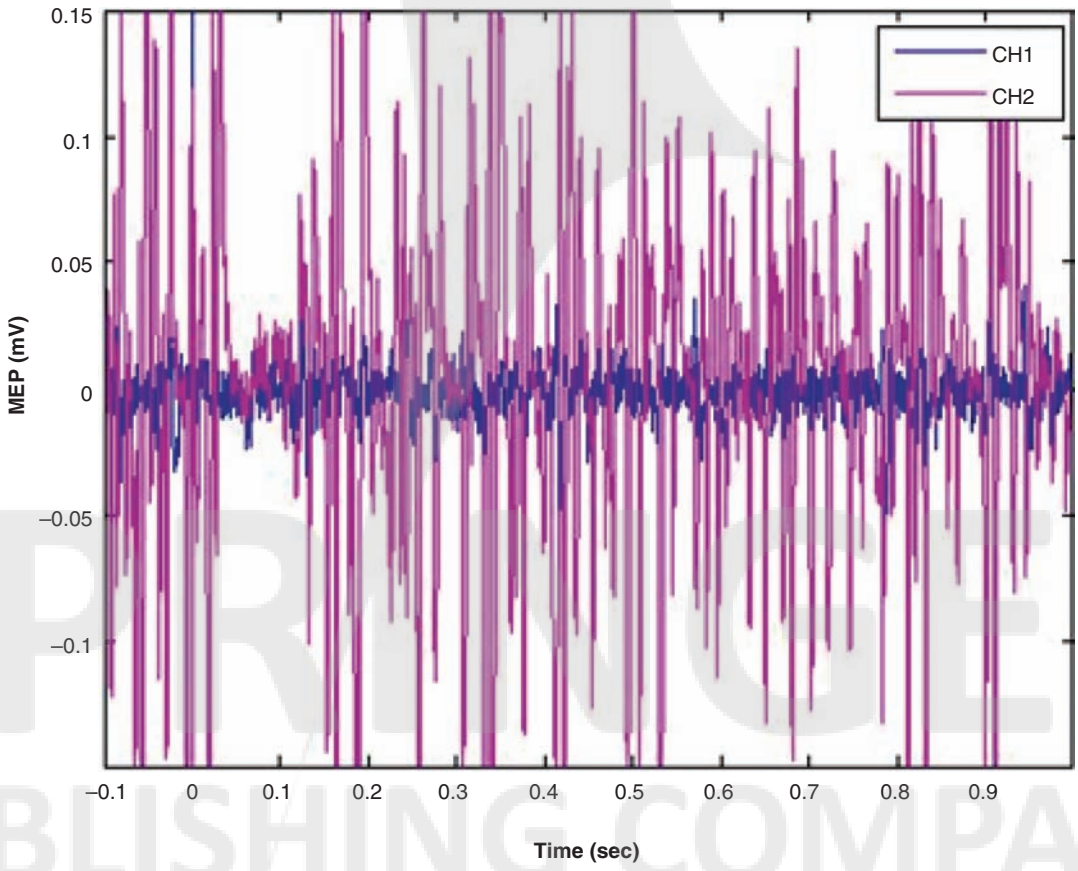

FIGURE 9.3 Ipsilateral silent period in a chronic stroke patient. Voluntary motor activity is present in a finger extensor (channel 1) and biceps muscle (channel 2) in the affected hemisphere prior to stimulation of the unaffected hemisphere, at time = 0. *Note*: reduction in activity for >100 ms after stimulation.

patient, this would mean stimulation of the unaffected cortex with activation of the affected side. Such a silent period is called "ipsilateral" and reflects contralateral interhemispheric inhibition. It has an advantage in that it more directly tests the inhibitory effects of interhemispheric connections (rather than a mix of inhibitory influences that operate intracortically). One disadvantage is that the level of inhibition is often not as complete as with the contralateral silent period. In many cases of stroke, stimulation of the unaffected side will result in an ipsilateral MEP, in which case the silent period no longer represents a purely interhemispheric phenomenon.

The length of the ipsilateral silent period has been shown to be proportionally related to impairment in a moderately affected range; training-related improvements are associated with reduction in duration (29).

Problems With Silent Period Interpretation. Because the silent period depends on voluntary activation, which is often difficult after stroke, the measure may have a very different meaning in severe cases, where voluntary activation through cortical mechanisms is poor. In our experience, ipsilateral silent periods are often absent in severely affected subjects, defined as those with absence of MEP following stimulation of the lesioned hemisphere. This is perhaps not surprising, except that many of these subjects can voluntarily activate the target muscle as part of a synergy pattern. However, synergistic activation may result from subcortical output that is not subject to cortical inhibition. In the right range of subjects, both types of silent period measurement appear to be methods that are related to both impairment and recovery. They have the advantage of requiring only a single TMS stimulator as well as a method to standardize voluntary motor activation. Further work is required to develop the silent period biomarker and evaluate it as a measure independent of impairment.

Paired-Pulse Inhibition and Disinhibition as a Recovery Mechanism

Recurrent inhibition, negative feedback through inhibitory interneurons, is a common theme in neural systems. It may serve several purposes, including preventing runaway excitation, such as might lead to seizures; and sharpening responses in time and space. While recurrent inhibition is a feature of systems that are functioning normally, it presents an opportunity for plasticity in that disinhibition can enhance function of intact areas to compensate for damaged ones. This is analogous to removing a car's muffler when the engine has lost a cylinder. Although you may get back some power, it will have other undesirable effects.

Disinhibition following injury to the brain can be studied using TMS. Stimulation of the motor cortex induces inhibition to further stimulation with a particular time course. Although most studies have examined the phenomenology of such *paired-pulse* stimulation, a variety of evidence demonstrates that short-interval (2–5 ms) effects are because of cortical GABA-B interneurons, and the phenomenon is thus termed SICI, for short-interval cortical inhibition. SICI is affected by pharmacological interventions and is strongly affected by stroke, with a dynamic course after the initial insult (30) eventually resulting in less inhibition in the affected hemisphere (31).

Though inhibition appears to be an important factor that is affected by both stroke and stroke recovery, it has several features that lessen its attractiveness as a biomarker. Measurement of paired-pulse inhibition requires more equipment and adjustment of parameters, making it more difficult, time consuming, and operator dependent. Furthermore, in severe stroke MEPs cannot be elicited with paired-pulse stimulation, making measurement of inhibition impossible.

Response to Stimulation of Nonprimary Areas, Unaffected Hemisphere

The primary motor cortex, M1, is not the only source of input to the contralateral lower motor neurons. Other, predominantly frontal, cortical areas project to the spinal cord, although many of these projections are on spinal interneurons that then synapse with spinal motor neurons. The potential role in motor recovery for the nonprimary motor areas, such as the premotor area and supplementary motor area, has long been recognized (32). Elegant studies have shown that these areas have a key role in voluntary movements after stroke.

Although TMS can be used to stimulate nonprimary cortical areas and the cerebellum, the measures do not have characteristics of good biomarkers. Often the effects are in the context of voluntary or TMS-evoked motor output, and require precise coil placement and timing. However, this work is an active area that promises to elucidate mechanisms of recovery.

There are also spinal projections of brainstem areas, including the pontine reticular formation. The role of these areas in recovery of function is being actively investigated. While once thought to be related mainly to posture and proximal movement, they appear to play a role even in finger movement (33), as well as in reaching (34,35). It is a familiar finding after stroke that voluntary movement of the upper limb is limited to a flexion synergy pattern, and these muscle synergies may be modulated by postural interventions (36) that likely originate from reticulospinal neurons. One method for studying the output of the reticulospinal system noninvasively is the acoustic startle. However, it cannot be assumed that all motor output from a startle comes directly from reticulospinal pathways, as there are reticulocortical connections as well (37,38). Thus far, the acoustic startle response has not been developed as a biomarker for recovery.

EEG/MEG

Electroencephalography (EEG) is one of the oldest techniques for measuring brain activity noninvasively. The principle is simple: electrical currents in the brain cause electrical potentials in the scalp, although the size of these potentials is reduced by the resistance of the head and the filtering properties of the brain, CSF, and other cranial contents.

FIGURE 9.4 275-channel biomagnetometer (MEG) that measures the magnetic fields generated by neuronal activity of the brain. The magnetic fields are then analyzed to determine the neural sources in the brain and are then superimposed on an MRI image. Brain recordings can be obtained while an individual is seated or supine.

Photo courtesy of MEG International Services, Ltd, Coquitlam, BC, Canada.

This leads to problems with localization in space, and brain activity is not recorded equally by surface electrodes. Magnetoencephalography (MEG; Figure 9.4) is another way to record electrical activity. Because MEG is sensitive to the magnetic fields generated by electrical currents in the head, the skull does not present much of a barrier. However, it still has limitations in that electrical currents in the brain are not represented equally in the magnetic fields at the scalp surface, and some currents may not produce measurable potentials at all.

EEG

The late Joseph Green was a pioneer in the use of high-resolution EEG to study changes in the motor system after stroke and spinal cord injury (39,40). However, these studies were not conclusive with respect to changes in timing of motor-related potentials, but they did show changes in localization consistent with functional imaging. Later studies also showed a correlation between NIH Stroke Scale and an index of resting EEG activity called the delta-change index (41). The advantage of this method is that it does not require high-resolution electrode arrays and does not depend on motor performance. These findings have, so far, led to little work on a practical EEG biomarker for impairment or responsiveness to rehabilitation. In aphasia, a correlation has been noted between slow wave activity and function (42), and recovery has been related to changes in alpha location (43).

The promising aspect of EEG is its applicability to almost any patient and setting. Although spatial localization is inherently limited, as mentioned earlier, the potential to use time and frequency domain information does offer something different from other functional imaging methods.

MEG

Given the spatial limitations of EEG, alternate neurophysiological techniques are surfacing as potentially more precise measurements of the millisecond temporal coherence between brain regions. Such insights into the spatiotemporal propagation of neural signals can broaden the understanding of restorative mechanisms. MEG is a tool used to evaluate the timing and, in turn, the hierarchical role of brain regions with respect to the onset of movement. In addition, MEG can be used to produce a spectral profile of rhythmic neural activity and more accurately describe modulations in resting-state networks. For example, functional connectivity is greatest in somatosensory, visual, and language cortex within the alpha frequency band in healthy subjects (44). Within the sensorimotor network, activity in a combination of primarily low-frequency bands has been found (45,46). Therefore, assessing shifts in bandwidth representations may provide an additional important biomarker for the pathophysiological mechanisms of recovery after neurological insult.

Resting-state functional connectivity has also been proposed as a useful biomarker of sensorimotor impaired brain states, such as in Parkinson's disease (47,48), amyotrophic lateral sclerosis (49), multiple sclerosis (50,51), and brain tumors (44). Evaluating the dynamics of neural networks in a task-free model provides valuable information about the intrinsic function of the brain and can account for variation in motor performance. MEG studies provide hints of a disrupted local resting neural network after stroke, with abnormally increased activity in the delta and alpha frequency bands of acute perilesional areas (52,53). The value of functional connectivity within a widely distributed network, both local and remote to the stroke lesion, has also been identified. In particular, motor recovery was found to be predicted by increased connectivity in the ipsilesional somatosensory area, supplementary motor area, and cerebellum, contrasted with reduced connectivity of contralesional motor regions, after controlling for age, stroke onset time, and lesion size (Figure 9.5). These findings define brain regions in which the extent of network participation may become an important surrogate marker to identify poststroke recovery potential (54).

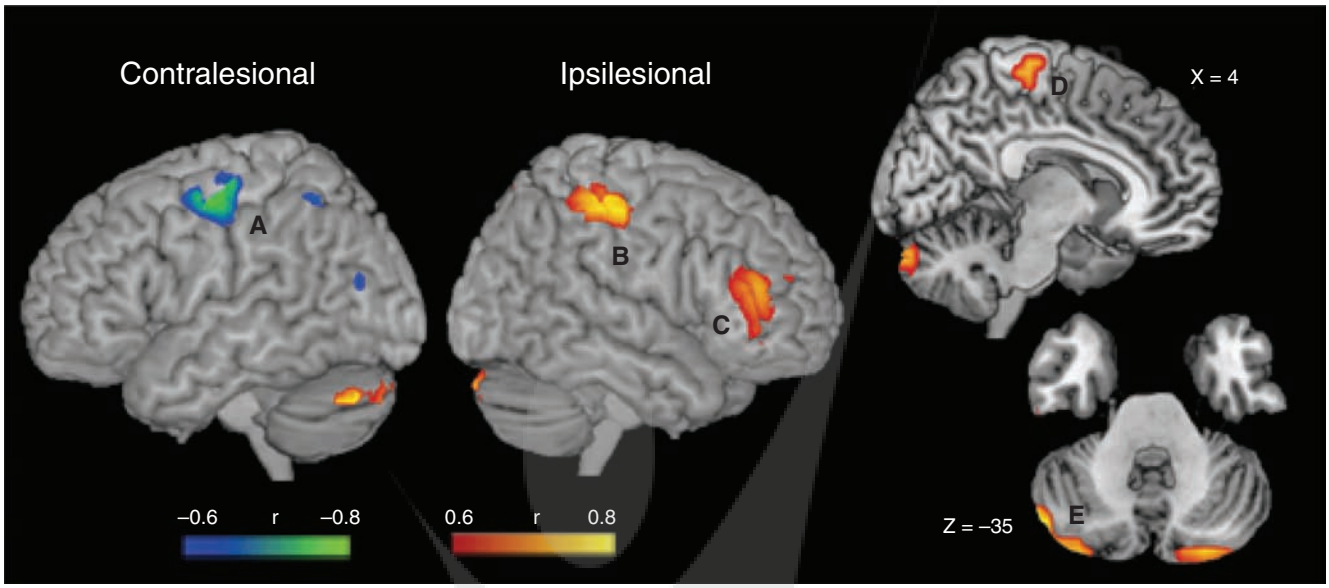

FIGURE 9.5 Predictive value of resting-state functional networks using MEG. Brain regions of neural networks at 1-month poststroke demonstrated positive (orange–yellow) and negative (blue–green) correlations with clinical recovery of the affected upper extremity by 6 months after stroke. A, B: sensorimotor cortex; C: prefrontal cortex; D: supplementary motor area; E: posterior cerebellum.

EEG/MEG Motor Coherence

The measurement of *coherence*, which is a normalized measure of correlation between each frequency band of a time-varying signal, is helpful in determining the causal role of one signal to another. This is because the phase relationship of the two signals is also determined. If the power in a particular band in one signal reliably precedes that of another, there is likely to be either a causal role for the first signal or at least the presence of a common driver for both. The most relevant measure in motor rehabilitation is motor cortex–muscle coherence (55). This is a relatively new measure, first demonstrated in epileptic patients, using electrocorticography, then in normal subjects with MEG, and finally in EEG. Although this connection involves at least two synapses (UMN-LMN and LMN-muscle), demonstration of temporal coupling between EEG signals from M1 and EMG, with the M1 signal leading the EMG, presents a strong suggestion of the causal role of M1 in muscle activation. This has been used to demonstrate the role of the nonlesioned hemisphere in movement (56).

In general, coherence can be used to suggest connectivity between brain networks (57), and a number of studies have used this measure after stroke and in response to rehabilitation (58,59). However, it is still essentially a research method, with its mechanisms and utility as a biomarker as yet unestablished.

PET/fMRI

Brain imaging techniques that are sensitive to functional activity have been used for a few decades to demonstrate brain activity during task performance. The data that they generate is, in a sense, easier to interpret, as activity is localized in particular brain regions and in the context of a defined activity. The temporal resolution of such techniques is in general poor, and high noise-to-signal ratios necessitate the discarding of much temporal information observed. Two main techniques utilized are positron emission tomography (PET) and functional MRI (fMRI). Though the basic principles underlying these imaging techniques are unrelated, they both may be used to detect the increase in blood flow that occurs with brain activity. PET uses the infusion of water labeled with oxygen-15, and in MRI flow changes are inferred from changes in the blood oxygenation level dependent (BOLD) signal. Therefore, the MRI measure is more indirect because it is not the blood flow itself that is detected, but the increase in oxygenation that occurs because the blood flow increase exceeds that needed to maintain constant oxygenation. This phenomenon is called "luxury perfusion" and may be absent in pathological conditions in which autoregulation of blood flow is disrupted. Because patients with stroke have, by definition, a deficit in blood flow, one might think that BOLD signals are not useful. However, even when infarction damages one brain region, most other regions still have sufficient autoregulation to produce luxury perfusion, although uncertainty remains as to whether this is true for all uninjured brain regions or in all cases of stroke.

PET can also be used to measure glucose metabolism using fluorine-18 radiolabeled fluorodeoxyglucose, but these measures are limited by the much longer half-life of ^{18}F. Current fMRI methodology is becoming more diverse, and includes techniques to measure blood flow directly, such as with arterial spin labeling. While there have been numerous

demonstrations of the feasibility of performing functional imaging with this technique, it has other limitations that have prevented it from replacing BOLD imaging.

In most cases, the signal values are measured relative to a reference value, which in the simplest case is in the resting condition. Typically the task condition results in an increase in BOLD signal, but some brain regions have decreased signal in response to any task (the so-called default mode network) or are suppressed by other brain regions (contralateral inhibition between homologous regions.)

M1 Activation

Although one of the advantages of whole-brain functional imaging is the large amount of data collected in each scan, this volume of information can make identifying a biomarker difficult. Data can be quantified within regions of interest (ROI), which helps create metrics that can be tested for their correlative and predictive value. Because deficits in motor function are most related to damage and reorganization of activity in the primary motor cortex, measures of M1 ROI have been tested as biomarkers. The measure that appears to have the most utility is the laterality index (LI) for a contralesional limb motor task (60). This measure has several definitions, but usually it is the difference between the M1 ROI activation of each hemisphere, divided by their sum. Thus the formula is:

$$LI = M1_{ipsilesional} - M1_{contralesional} / M1_{ipsilesional} + M1_{contralesional}$$

The LI index is defined as being positive when there is more activity in the affected hemisphere. As long as no brain area reduces activity during rest, the LI will be between –1 and 1. However, because ROI values can also represent deactivation, and have negative values, the denominator can approach zero, with the resulting absolute value of the LI becoming larger than one. (In older applications, activation was measured as a volume of significantly activated voxels, and this problem could not occur.)

But the meaning of the LI is the degree of normal lateralization of motor function. When LI is close to 1, it implies activation of the normal M1 contralateral to the limb being moved, with little or no activation in the ipsilateral M1. When it is close to –1, it implies activation only of the ipsilateral M1, and therefore potential localization of motor activity only on the contralesional cortex. A complicating factor in LI measures is the occurrence of mirror movements, involuntary movements of the unaffected side when attempting to move the affected one (61). There have been two interpretations of the abnormal LI value. One is that it represents useful reorganization of activity (60), with a decrease in LI after therapy (62). The other view is that it reflects degree of damage, with an increase (normalization) in LI after therapy (63,64). The second viewpoint has taken hold, and it is suspected that LI may predict response to therapy. But there is no example of a clinical trial in which LI was used prospectively. LI remains an interesting biomarker, but one that still requires both better definition and testing.

Bilateral and Nonprimary Areas

The LI is measured in the primary motor cortex, but many other areas are also activated during motor tasks. These include other areas on the hemispheric convexity (premotor areas) and on the medial wall (supplementary and cingulate motor areas). Because many of these areas have strong bilateral influences on movement, they are potential candidates as substrates for recovery, and have been studied extensively. However, to our knowledge, none of them has been tested as biomarkers.

Resting State

Despite the potential usefulness of the LI, consideration must be given to the fact that activated areas provide focal information about M1 and overlook the dynamic and integrative neural mechanisms contributing to these signal changes (65). Moreover, subjects are typically studied because they are able to perform a standardized task, thereby limiting the generalizability of findings to the function of the particular task and to subjects with moderate to good motor recovery (66,67). Such activation maps cannot be derived from subjects who are unable to perform a task. Therefore, one promising alternative to a task-based neuroimaging biomarker is to evaluate brain connectivity from a resting state. Functional connectivity of the resting or anesthetized brain is represented in fMRI by synchronously fluctuating, low-frequency (<0.1 Hz), BOLD signals (fcfMRI). Emerging from these intrinsic signals are consistent, spatially distinct neural systems that mirror spatial representations found in task-based studies (68,69). These slowly oscillating resting-state hemodynamic signals are thought to reflect the propagation of transient neural signals between structurally connected regions (70–72). However, a consistent relationship between the neural correlates of stroke recovery and functional connectivity findings has not yet been established, thereby confounding its interpretability as a biomarker.

Near Infrared Spectroscopy

Near infrared spectroscopy (NIRS) is an optical technique that probes cortical activity based on neurovascular coupling. This approach continuously monitors changes in oxygenated hemoglobin and deoxygenated hemoglobin in response to a motor task. One of the limitations is that NIRS provides limited spatial resolution and depth of measurement (i.e., only the superficial cerebral cortex can be monitored), but has moderate temporal resolution with resistance to motion artifact. NIRS is more convenient and appropriate in the rehabilitation setting because it is more tolerant to movement, has a lower cost than other imaging techniques, is portable, and has fewer restrictions (e.g., it can be used in patients with metal implants). Measurement recorded using NIRS was in agreement with findings using fMRI and may be useful as a biomarker of poststroke recovery (73).

Motor Synergies/EMG/Kinesiological Markers

The many examples of physiological markers described so far in this chapter have appeal because of their relationship to function and recovery. Another potential avenue for biomarkers relates to the ability to generate voluntary movement or motor markers. The potential advantage of this type of marker is that they are closer surrogate measures of participation in society, that is, the ultimate measure of recovery from stroke.

Traditionally, movement impairments observed post-stroke were defined within a synergy framework. For example, the Fugl-Meyer is perhaps the most widely used clinical assessment of impairment based on subjective ratings of movements in/out of synergy patterns (74). An increasing trend in stroke rehabilitation, however, has been the use of kinematic motion analysis to precisely and quantitatively measure voluntary movements and elucidate differences between recovery and compensation (75). Although different data acquisition systems exist for recording voluntary movements, data are typically recorded as a time-series of coordinate data (x, y, z) that are used to define segments of interest, such as an arm or a hand, and analyzed to determine joint angles, accelerations, and trajectories. These analyses can be described as kinematic and kinetic, although kinematic measures (joint angles, ranges of motion, spatial–temporal parameters) are applied more commonly as markers for upper-extremity movements compared to kinetics (forces, inverse dynamics, etc.), which are more commonly applied to gait and lower-extremity tasks.

Movement Parameters

One of the benefits of using kinematic motion analysis is the vast number of movement parameters that could potentially be used as markers of recovery. These are most commonly separated into segmental kinematics (how the body is generating movement) and end-point kinematics ("performance" on the task). Segmental kinematics is often calculated as a range of motion to accomplish a task. For example, survivors of stroke often use the trunk to accomplish a forward reaching task; this has been suggested as a common compensatory movement. End-point kinematics can take on many forms, including how quick movements can be made (e.g., peak velocity, movement time) or how smooth movements are (e.g., path length ratio, smoothness of movement). These types of measures have been implicated as important motor control factors and have been shown to be altered following a stroke. For example, Rohrer suggested that the smoothness of movements is disrupted after stroke and changes with recovery or following intervention, thereby making it a potential useful marker of motor function (76,77). One of the limitations of kinematic motion analysis is the sophisticated data acquisition units currently required, but advancements in technology such as accelerometers will expedite availability for clinical use.

NONMOTOR FUNCTIONS

This chapter has focused on biomarkers that relate mainly to motor function, but other areas have been studied as well, particularly aphasia, visual function, and neglect. We will briefly comment on aphasia.

Aphasia

Because of the usual strong, left hemisphere lateralization of language, it was apparent from early functional imaging studies that left hemisphere damage could lead to abnormal language localization (78). Soon afterward, conflicting results were published regarding whether the right hemisphere activation was compensatory and supported recovery (79) or was uncorrelated with performance (80,81). In the later studies, left hemisphere perilesional regions appeared to be more related to linguistic performance. In fact, current research indicates that right hemisphere activation is more related to linguistic errors and may reflect a failure of the damaged language system to deal with the task (82). This makes right hemisphere activation during naming or other word generative tasks a possible biomarker for aphasia.

Arcuate Fasciculus Integrity

A potential anatomical marker that may be a simpler biomarker for aphasia after stroke is the arcuate fasciculus, which has long been known to be involved in classical aphasias (those with impaired repetition), although that view is being challenged (83). Diffusion tensor imaging of the arcuate fasciculus has been shown to predict aphasia recovery (84) and should be evaluated in larger studies to determine the sensitivity of the method.

CONCLUSIONS

Establishing biomarkers is a critical step for stroke rehabilitation to facilitate the development of interventions that positively affect functional ability and quality of life. The appropriate biomarker will be a substitute (or surrogate) for clinical outcomes that can be difficult to measure. The mechanistic work of the past few decades has advanced the field to explore a multitude of potential biomarkers for recovery that can be quantitatively measured. In return, biomarkers can also be an indicator of a biological mechanism relevant to the intervention. The appropriateness of potential biomarkers, however, is not simple or straightforward. Anatomical markers have a high degree of sensitivity and reliability, but may have limited functional relevance, whereas motor markers are more functionally relevant but may have less sensitivity (11). Physiological markers, such as the presence of MEPs, represent a potential biomarker that is associated with function and the underlying anatomical structure. Continued work in the stroke rehabilitation field to more fully understand the underlying biological processes of recovery will aid in the development of biomarkers, and ultimately the development of effective interventions for survivors of stroke.

Genetics of Stroke Recovery

Kristin M. Pearson-Fuhrhop, Miriam Eshoiee, and Steven C. Cramer

Genetic factors have been found to be associated with many features of stroke in humans, including severity, recovery, brain plasticity, and treatment efficacy. Across patients, the same degree of injury can be associated with a high degree of variability in spontaneous behavioral recovery and in response to therapy. It is likely that genetic factors contribute to some of this inter-individual variation. Understanding factors related to motor recovery, neurological disorders, and pharmacological and therapeutic response could increase the efficacy of rehabilitation strategies and drastically improve quality of life for many. Further, genetic differences might also influence the amount or type of rehabilitation therapy required to induce optimal levels of brain plasticity and thereby achieve the best functional recovery. Understanding the relationship that genetic factors have with stroke recovery could therefore inform many aspects of clinical decision making.

FORMS OF GENETIC VARIATION

Genetic variation takes a number of different forms and can be studied in several ways. One nucleotide in a gene may be altered, which can result in an amino acid change in the protein or in altered transcription or translation efficacy if the nucleotide change occurs in a promoter region. Alternatively, a nucleotide may be inserted or deleted, or a segment of the gene may be repeated. A *genetic mutation* is a form of genetic variation that is rare in the population and causes a significant change in function. Examples include the single nucleotide mutation that causes sickle cell anemia or the expanded CAG repeats found in Huntington's disease. When a genetic variation occurs commonly and has a relatively small effect on behavior or phenotype, it is termed a *polymorphism*. A polymorphism may be a single nucleotide polymorphism (SNP), a variable number of tandem repeats (VNTR), or an insertion/deletion (ins/del).

The most common approach to studying the impact of genetic variation to date has been to study *single polymorphisms* and their association with diseases or traits or with endophenotypes such as brain function. A *candidate gene approach* may be used in this context, in which a polymorphism is chosen a priori based on its likely association with the condition of interest. Alternately, a *genome-wide association study* (GWAS) may be done, during which all known polymorphisms, or a very large number of them, are assessed (1). Another approach utilizes a *gene score* that sums the effects of multiple polymorphisms across a particular biological system (2–5). Other approaches include examination of exome sequencing, epigenetics, and epigenomic and transcriptomic variation (6).

GENETICS OF NEURAL PLASTICITY AND RECOVERY

Many molecular events, and therefore a number of genes, have been associated with brain plasticity and recovery from neural injury (7,8). Well-characterized genetic polymorphisms on the genes for brain-derived neurotrophic factor (BDNF), apolipoprotein E (ApoE), the serotonin transporter (5HTT), and catechol-o-methyltransferase (COMT) have been studied in relation to stroke recovery and brain plasticity. Other genetic polymorphisms are just beginning to be characterized and studied in this context.

One highly studied genetic variant is a polymorphism in the gene for BDNF. BDNF is a growth factor important to many forms of development, plasticity, learning, and repair. At position 66 in the BDNF gene, the more common valine may be replaced with methionine, resulting in 18% to 30% less activity-dependent secretion of the BDNF protein (9,10). Another highly studied genetic variation is in ApoE, which is the most abundant brain lipoprotein. A combination of polymorphisms results in the ApoE2–ApoE4 genotypes (11), which are correlated with differences in several neural repair processes as well as with the risk of Alzheimer's disease (for more in-depth review, see (8)). A third major genetic variant is located in the promotor region of the serotonin transporter gene (5-HTTLPR) and modulates gene expression. The 5-HTTLPR sequence has a 44-bp ins/del and hence occurs in either a short form (s) or long form (l). The short form is associated with susceptibility to stress and depression, including poststroke depression (12,13). Several polymorphisms related to dopamine neurotransmission have been studied, including an amino acid alteration from valine to methionine at position 108/158 of the COMT enzyme. This amino acid change results in a protein with three to four times less enzymatic activity, and thus higher synaptic dopamine availability (14).

Several of these polymorphisms have been associated with differences in outcome after neural injury in patients with stroke. These findings in human subjects are concordant with preclinical investigations, for example, in rodents, where BDNF levels have been associated with CNS repair (15–18), and treatment with exogenous BDNF can improve motor recovery (19). In humans, a study of 255 acute stroke patients found that the presence of the ApoE4 allele and BDNF Met allele were associated with poorer behavioral recovery and with greater disability after stroke (20), similar to prior findings in patients with subarachnoid hemorrhage (21). Further, the BDNF Met allele may be linked to early neurological deficit, specifically in those who have suffered a hemorrhagic stroke (22). Regarding ApoE, some data show a relationship with outcome following intracerebral hemorrhage (23). However, a meta-analysis found a relationship between ApoE genotype and outcome following subarachnoid hemorrhage but no overall relationship with death or long-term dependency in other forms of stroke (24). Data from patients with traumatic brain injury (TBI) suggest a relationship between ApoE genotype and outcome. For example, a prospective cohort study found that patients with the ApoE4 allele were more than twice as likely to have an unfavorable outcome 6 months after TBI as were those without this allele (25). A meta-analysis found that the presence of the ApoE4 allele was associated with increased risk for poor long-term outcome following TBI (26).

The choice of metric used to probe genetic associations is important. The studies mentioned here examined genetic association with stroke recovery defined by global outcome scales that measure patient function in a broad sense. However, such scales capture the final phenotype in a manner that reflects a complex collection of diverse biological processes, and therefore dilute the effect of genes on specific recovery-related processes and more distinct traits. Such traits can be behavioral (27) or anatomical, and can provide a more direct demonstration of genetic effects. As an example, in a study of patients with Alzheimer's disease, presence of the COMT Val allele, which is known to be associated with lower synaptic dopamine, was correlated with reduced gray matter in several dopamine-related structures (28). The specificity of location of these anatomical changes supports a model whereby genetic effects on the COMT enzyme result in local changes in dopamine-innervated structures.

Genetic associations might not always be apparent when the behavior of interest is evaluated in isolation, as in many cases genetic differences are most apparent through an interaction with experience or training, or when examined as a function of time. This has been suggested in many studies of 5-HTTLPR, as well as with the classic studies that described an association of genetic variation in monoamine oxidase A (MAO-A) with antisocial behavior. The importance of such interactions and distinctions is highlighted in the case of ApoE, where the E4 allele is associated with long-term functional outcome, but not initial injury severity, following stroke (20) or TBI (29). This suggests that ApoE influences the neural plasticity related to recovery rather than initial response to injury. Such studies underscore the importance of considering genetic variation in relation to experience and time, a point of particular importance when studying stroke recovery. Note that a great number of experience-related factors might be important, including features of acute care, rehabilitation therapy, home life, and psychosocial factors; these experiences may differ greatly across individuals.

IDENTIFICATION OF NEW GENETIC VARIANTS

Other polymorphisms, in addition to commonly studied genetic variants such as BDNF and ApoE, have been implicated in stroke recovery. Some are related to acute injury and early repair events. For example, recent evidence suggests an important role for inflammation-related genes in stroke outcome, including those related to leukocyte activation (interleukins) and prostaglandin production (cyclooxygenases). Marousi et al. (2011) found that SNPs in interleukin 4 and interleukin 10 were correlated with the likelihood of a recurrent ischemic event and predictive of functional outcome, respectively (30). The cyclooxygenase gene alleles COX-2 rs5275 C and COX-2 rs20417 C were associated with better outcome 90 days after stroke (31), concordant with animal model data suggesting better stroke outcomes with reduced COX-2 activity. One new polymorphism that may greatly affect stroke recovery and poststroke plasticity is found in the gene for tissue-type plasminogen activator (t-PA). The t-PA protein, known for its role as an acute reperfusion therapy after stroke, is also thought to be highly involved in neurotransmission and cortical plasticity (32). A study of postmortem human brains found a large difference in t-PA mRNA between carriers of the –7351C and T alleles (33). Thus far, this polymorphism has not been studied for its relationship to cortical plasticity in humans, but evidence from animal and postmortem studies suggests a potential modulatory influence. More research is needed to determine the exact biological consequences of these genetic variations.

GWAS are particularly helpful for identifying new genetic associations (1). A large GWAS has found and replicated an association of an HDAC9 gene variant with large vessel ischemic stroke (34). As the mechanism is not known, this association would not have been found with a candidate gene approach. Although this study pertains more to stroke pathophysiology than to poststroke repair, it highlights a point critical to any study of human stroke: genetic associations might be most accurately identified when studied in relation to distinct forms of cerebrovascular pathophysiology. Numerous, divergent biological events can result in very similar clinical phenotypes, but identification of genetic associations might necessitate identifying different pathophysiological states separately. This perspective can probably be more extensively applied to genetic studies of stroke recovery.

In addition to GWAS, gene expression studies are also useful for identifying new variants. Such an approach profiles the expressed genes from peripheral whole blood to identify unique gene-expression patterns that are associated

with a neurological disorder and its phenotypic subtypes (35). Evidence from an animal TBI model suggests that gene-expression regulation could help monitor injury progression and thereby help identify novel protein targets for future pharmacotherapy development (36); similar approaches could be extended to a restorative therapy focus. For many forms of neural injury, there has been limited clinical trial success in pharmacologically improving outcome. Examining the progression of a gene expression profile across the timecourse of recovery could uncover new recovery-related genes and pharmacological targets.

Studying these new variants, such as in the t-PA gene, along with methods for discovering new recovery-related genetic polymorphisms, such as GWAS and genetic profiling, offers promising directions to extend current research.

RELEVANCE OF GENETIC POLYMORPHISMS

The study of genetic polymorphisms related to stroke might provide insights into disease pathogenesis and outcome prediction, but the greatest clinical benefit from genetics research might come from the identification of polymorphisms that can guide details of therapy such as treatment choice, dose, or duration. Such an approach is being used in oncology, where the BRCA1 and BRCA2 mutations are used to direct the management of breast cancer in some patients (37). Similarly, variations in the CYP2C19 gene, coding for the cytochrome P450 2C19 protein, may be considered when prescribing the platelet-aggregation inhibitor clopidogrel (38–40). Barriers to effective implementation of pharmacogenomic insights include cost, awareness, and ethical concerns (41).

A number of potential opportunities exist whereby genetic factors might influence pharmacotherapy after neural injury. Although evidence is often incomplete, several drugs are commonly used following neural injury, including the dopamine precursor levodopa, selective serotonin reuptake inhibitors (SSRIs), serotonin-noradrenaline reuptake inhibitors (SNRIs), and acetylcholinesterase inhibitors (42). Genetic variations have been shown to interact with many of these drug families (8). For example, one recent study found that dopamine genetics modulated the effects of levodopa on skilled motor learning and motor cortical plasticity (43). SSRIs are given primarily to treat comorbid depression (42), but some data suggest a favorable influence on recovery as well (44). The 5HTTLPR s/l polymorphism, along with others, modulates response to antidepressant drugs in major depressive disorder (45) and may have an impact on SSRI and SNRI response in poststroke depression and rehabilitation. Genetic variations in drug-metabolizing enzymes can alter drug responses to a wide variety of pharmacological agents, including most antidepressants (46). In addition to modulating drug efficacy, genetic variation has been associated with the likelihood of medication side effects in conditions such as epilepsy (47), diabetes (48), rheumatoid arthritis (49), cancer (50), and depression (45). The increased likelihood of side effects owing to genetic variation will be a consideration during the development of drug treatments for neural injury. Particularly in conditions when multiple drugs or classes of drugs could potentially be used, pharmacogenetics might shorten the process of finding the best drug for the patient and thus reduce the number of drugs the patient must be exposed to before settling on the appropriate treatment (51). However, several ethical concerns exist, including, but not limited to, obtaining informed consent from patients who are not competent, maintaining confidentiality of such sensitive data, and balancing the uncertainty of genetic associations versus tested or standard clinical practice (51).

An understanding of genetic factors might also influence the method of treatment for neural injury through nonpharmacological forms of intervention. For example, several forms of brain stimulation, whereby cortical excitation is focally modulated, are under investigation for the treatment of stroke (52–54). Polymorphisms in genes coding for proteins key to neural plasticity could influence response to such treatment. Polymorphisms in the NMDA NR1 and NR2B subunit genes (55) and the BDNF Val66Met polymorphism (56,57) have been shown to affect experimentally induced cortical excitability and plasticity. In addition, recent evidence has found a significant positive relationship between homozygosity of the G allele in a common SNP of the transient receptor potential vanilloid 1 channel (TRPV1) gene and increased cortical excitability (58). These findings suggest differential cortical plasticity patterns across genetic groups and warrant further work studying the effects of these genotypes on cortical plasticity and motor task performance in neurologically compromised populations. As methods for modulating cortical excitation such as transcranial direct current stimulation receive increased study as a treatment for neural injury, an increased need will arise to study genetic variants related to neural plasticity and their relationship to treatment response.

OTHER FACTORS THAT INFLUENCE RECOVERY

Genetic factors, in addition to a direct influence on the mechanisms of stroke recovery, could modulate other processes that are strongly linked to recovery, such as depression, vulnerability to stress, cerebral blood flow (CBF), and cognitive impairment.

Depression

Depression has a serious negative impact on stroke recovery (59), and its clinical presentation may be modulated by several genetic and environmental factors (60,61). The 5HTTLPR s/s genotype has been robustly associated with an increased risk for depression (60,62,63), including poststroke depression (13). Studies of this polymorphism with treatment response have found that the s allele, compared to the l allele, is associated with poorer response to antidepressant drugs (45) but improved response to psychosocial therapy (61). Thus, knowing a patient's 5HTTLPR genotype may be useful for treatment planning in the management

of poststroke depression. Several other genetic factors and gene–environment interactions are being explored in the context of depression (60,62,63). In particular, polymorphisms in interleukin genes have been associated with nonremission, emotional processing, and response to pharmacological agents in subjects with depression (64,65). The overall significance of these genetic studies on understanding and treating depression remains to be clarified, however, as there are also many negative studies. In the 1,953-patient STAR*D (Sequenced Treatment Alternatives to Relieve Depression) study, 768 SNPs were examined for their relationship to major depression, and only one SNP in the gene for serotonin receptor 2A was significantly associated with treatment response (66). As the relationship between genetic factors and major depression becomes better understood, treatment and prevention of depression can become a factor in a patient's overall rehabilitation strategy. Patients with genetic susceptibility to depression might benefit most from in-person rehabilitation therapy and might also be less likely to comply with self-motivated telerehabilitation. Such patients might also be proactively prescribed an SSRI or psychosocial therapy, based on 5HTTLPR and perhaps other genotypes.

Stress

Stress is a key environmental variable brought on by the recovery process following neural injury. Vulnerability to stress has been found to have a genetic component (60). Experimental stress paradigms resulted in worse working memory performance for COMT Met/Met homozygotes than COMT Val/Val homozygotes (67,68). Of possible relevance to interpreting such findings is a study in children which found that the COMT Met allele is associated with a higher cortisol response to stress (69). Animal studies have found that the BDNF Met allele confers significant vulnerability to stress (70); consistent with this, one study suggested that meditation might indeed be more helpful for BDNF Met carriers (71).

Cerebral Blood Flow

CBF is affected by functional variants in the gene for nitric oxide synthase (72), and individuals with such polymorphisms may have a decreased ability to maintain adequate CBF following TBI (73). Using PET, it has recently been found that the BDNF Val66Met polymorphism increased resting CBF in the prefrontal cortex and hippocampus (74). Modulation of CBF could be a contributory mechanism of action for some restorative therapies, or may be a useful biomarker for some treatments, and hence such results might be useful for brain repair after stroke.

Plasticity

Neurorehabilitation relies heavily on brain plasticity, or the capability of the brain to alter function or structure in response to a range of learning and environmental events (75). Throughout the early phases of stroke and rehabilitation, perilesional neural networks are revised and restored, whereas brain regions in distributed networks are often recruited to progressively compensate and, depending on the extent of damage to a given region, adopt some of the functions of the damaged area (76–80). A large number of genetic factors may be related to the cellular and molecular mechanisms underlying CNS plasticity, with the greatest evidence amassed in relation to BDNF and ApoE (8).

CONCLUSION

With evidence from various studies suggesting that particular genetic polymorphisms may affect the extent and timecourse of spontaneous behavioral recovery following neural injury such as stroke, the need arises for strategies to modify therapy—pharmacological or otherwise—to optimize outcome in relation to genetic risk for individual patients. Understanding the role of genetic factors in relation to comorbid conditions such as major depression may also be important, including aspects with respect to preventative strategies. The ever-increasing knowledge of genetic variants holds promise to provide clinicians and researchers with useful avenues of insight for improving brain repair after stroke.

Physiological Basis of Rehabilitation Therapeutics in Stroke

Andreas R. Luft, Charlene Hafer-Macko, and Timothy Schallert

In the past decade stroke rehabilitation research has shifted its focus from empirical evidence to biological targets. Physiology, especially neurophysiology, has identified a number of potential mechanisms that can be accessed by rehabilitation interventions. These physiological targets focus upon the potential for neuroplasticity at multiple CNS levels including the sensorimotor cortex, subcortical networks, the cerebellum, and the spinal cord. Moreover, a synthesis of clinical and animal research suggests that diverse biological mechanisms, including alterations in selected neurotransmitter pathways, and growth factors that modulate neuroplastic adaptations may interact to promote recovery. Although the evidence based on randomized clinical trials is currently insufficient to generate consensus practice recommendations, increasing experimental evidence supports a rationale for further research combining pharmacotherapeutic strategies with task practice to optimize sensorimotor recovery after stroke. Finally, the biological targets to optimize stroke recovery must go beyond the CNS to include skeletal muscle and metabolic function. Following stroke there are major body composition abnormalities including structural and metabolic abnormalities in hemiparetic muscle that can worsen disability, constituting important targets for physical rehabilitation, and, potentially, for pharmacological therapies. In the following sections, we discuss these biological targets and the interventions designed to interact with them. A focus is maintained on current knowledge in human rehabilitation, followed by a brief overview of some clinical and translational research in animal models that may help to define future research directions. Rehabilitation can and must access different elements of the nervous system and body functional systems to be effective. Table 11.1 gives an overview of the biological targets and the related treatments. The text further elucidates some of the neurobiological mechanisms and derived treatments that target the brain, the spinal cord, and muscle.

CENTRAL NERVOUS SYSTEM

Stroke damages the central nervous system (CNS). The CNS is therefore the prime target for therapies aiming for cure at the origin of the disease. Three properties in the organization of the CNS theoretically allow for recovery—redundancy, plasticity, and regeneration of neural tissue—the last of these still being a theoretical capacity about which far too little is known to develop a therapeutic intervention. Redundancy implies a certain over-capacity of the CNS so that limited tissue loss can immediately be compensated. Plasticity is a double-edged sword: it can be beneficial but also detrimental if re-growing neurons reach false targets and cause additional motor impairment. Detrimental plasticity is commonly referred to as "maladaptation." In the following, redundancy and plasticity are discussed.

Studies in patients with brain lesions demonstrate that the CNS has, albeit limited, redundancy. The brain's redundancy is not like that of other organs, such as liver or kidneys, where removal of a part is easily and instantly compensated by the remaining tissue. Within a theoretical neural network, the drop-out of a limited number of single cells or cell-to-cell connections can be tolerated without much dysfunction (1). Clinically unnoticed lacunes in eloquent brain regions, that is, regions that lead to immediately detectable symptoms like hemiparesis, document this scenario. Because over-capacity declines with age, compensability also decreases.

In contrast to lesions that injure a few cells, territorial lesions that affect entire or large parts of neuronal networks, cannot go unnoticed. Compensation for such lesions can only come from parallel networks that provide the same function but are underused in the healthy, for example, because their capabilities were replaced by more potent systems during evolution. Such parallel systems could be recruited after failure of the dominant system and may provide slow functional compensation. One example for a parallel system is the rubrospinal system compensating for corticospinal injury (2). However, the number of parallel systems is certainly limited. Another form of redundancy exists between the two hemispheres of the brain. Certain lateralized functions mainly executed by one can be adopted by the other hemisphere. Swallowing is an example (3). Dysphagia typically recovers faster than other impairments due to interhemispheric compensation.

TABLE 11.1 Biological Targets and Treatment Strategies

BIOLOGICAL TARGET	MECHANISM	TREATMENT STRATEGY
Brain (cognitive systems)	Adaptations in emotional, reward, and other cognitive systems. Reorganization of speech and language networks	Psychological and motivational therapies providing reward and emotional support, social and occupational therapy Therapies based on reinforcement learning paradigms Physical therapies combining multiple tasks to train attention and distractability Speech and language therapy
Brain (sensorimotor system)	Neuroplasticity in cortical and subcortical motor systems, motor skill learning	Repetitive task-oriented physical and occupational therapy Action observation and mirror training-based approaches (see Chapter 20)
Spinal cord	Adaptations in spinal reflex circuits preventing spasticity and maladaptive reflex behaviors	Classical physical therapies (neurodevelopmental, sensory feedback)
Muscle	Reversal of muscle atrophy and phenotype alterations (stroke causes shift to fast muscle fibers), relief of spasticity	Repetitive resistive and aerobic exercise Botulinum toxin injections
Cardio-respiratory	Fitness	Aerobic exercise therapy

Plasticity of neurons is an alternative mechanism that enables recovery of function. Plasticity is the "reprogramming" of neuronal circuits by modifying their firing patterns (synaptic efficacy or weights) and/or architecture. The stimulus for plastic reorganization can occur through the use of damaged circuits, such as through active training (skilled use dependent plasticity). An alternative stimulus may arise from the stroke lesion itself, for example, through lesion-induced expression of plasticity related genes (4).

Plastic phenomena have been observed in a variety of different brain regions including cortical and subcortical areas. Depending on the research methodology used, the phenomena may reflect structural or functional plasticity or both. After lesioning CNS motor areas or their descending tracts, motor recovery is associated with plastic adaptations in motor cortex (see Chapter 7). Cortical representations of body parts, as determined by stimulating different areas of the cortex, reduce in surface area after an infarct. Motor training prevents this shrinkage of cortical maps and can even expand representations in monkeys (5). Well-recovered stroke survivors with descending tract lesions have motor cortical activation patterns that differ substantially from healthy controls (6–9) and change longitudinally over time reflecting the reorganization of the cortical motor system (10–12). Similar to animal studies, motor cortex stimulation has documented adaptations in the input-output organization of the motor cortex after stroke (13). Areas other than the motor cortices (primary motor cortex, premotor cortex, SMA, and cingulate motor areas), such as the somatosensory cortex (14) and temporal and parietal regions, may also contribute to recovery but are not as consistently involved in recovery-related plasticity processes. Functional imaging in stroke survivors with different degrees of impairment also suggests a role of the cerebellum. In well-recovered subjects cerebellar activation during movement of the affected side is stronger than in the impaired (15).

Hence, motor cortices and cerebellum are brain targets that can mediate recovery or functional compensation if properly triggered. This triggering may be a particularly successful approach considering that the lesion itself attracts neuroblasts to migrate from the subventricular zone to the cortex (16), which in turn could be "reprogrammed" by active use. This could be a first step toward a relevant regeneration of neural tissue.

Genetic determination may affect how apt the motor system is to plastic changes. The Val66met polymorphism in the BDNF gene (brain derived neurotrophic factor) was shown to be associated with reduced reorganization of motor cortex somatotopy after learning in rodents (17). The Val66met genotype in conjunction with the catechol-O-methyltransferase (COMT) Val158Met homozygous genotype was found to have reduced cortical plasticity and implicit learning in humans (18).

Rehabilitation Training Techniques Targeting CNS

Specific training therapies aim at inducing neuroplastic adaptations in the CNS. Constraint induced movement therapy (CIMT) is an effective intervention that provides sustained benefits to stroke survivors with long-term disability (19). CIMT combines active training with the paretic arm by constraining the unaffected arm; the latter helps to overcome learned nonuse of the paretic side (20). CIMT is associated with changes in cortical physiology. The representation of the paretic hand in the ipsilesional hemisphere as determined by transcranial magnetic stimulation (TMS) increases

in size after therapy; this increase correlates with improved arm function (21). The enlargement occurs into areas with decreased intracortical inhibition (22) indicating a role for a GABAergic mechanism in this form of plasticity. Plasticity mechanisms may depend on lesion location. A patient with a lesion in the primary motor area or its descending pathways (as defined by an abnormal motor evoked potential in response to TMS) showed an increased area representation and decreased cortical excitability (or increased inhibition); patients without such lesions show the opposite pattern (23). Functional imaging studies indicate that CIMT can induce plasticity in other brain areas, such as the contralesional primary motor area (reduction of activation), cerebellum, supplementary motor area, and frontal gyri (24–26).

Bilateral arm training with rhythmic auditory cueing (BATRAC) is an effective therapy for most patients (27,28). Some patients despite improving their reach do not gain movement abilities relevant for daily life. Bilaterality and rhythmicity are elements adopted from motor learning techniques possibly acting through interhemispheric signaling and movement sequencing. Patients who improve in motor impairment as measured by the Fugl–Meyer score show increased recruitment of bihemispheric premotor and motor areas (Figure 11.1) (27). In contrast, patients without functional improvement demonstrate no cortical reorganization suggesting a mechanistic link between recruitment of ipsi- and contralesional motor cortices and improved arm function.

In a larger cohort, as compared with dose matched physical therapy exercises, bilateral arm training did not mediate greater improvements but similar behavioral effects did lead to different brain reorganization patterns (29). These findings indicated that different mechanisms can be utilized to achieve similar functional improvement—raising the possibility of additive effects of different forms of therapy.

Other upper extremity training regimens also utilize neuroplasticity to improve function. Task-specific training of tracking waveforms with the paretic index finger leads to a shift in the activation of sensorimotor cortices (primary sensory, motor, and premotor cortex) from the contralesional to the ipsilesional side (30). Similar results were obtained by using a home-based task-oriented training protocol (31). In another study, a task-oriented arm training program led to increases in the activation of ipsilesional primary motor cortex as well as inferior parietal and premotor cortex (32). Activation changes were not observed in either healthy controls undergoing the same training program or in patients subjected to conventional physiotherapy techniques.

Gait training on a treadmill while facilitating paretic leg movements using somatosensory stimulation produces "healthy" patterns of cortical activation; patterns that are closer to those of healthy controls during unfacilitated treadmill walking (33). In contrast, unfacilitated treadmill walking in stroke patients is associated with abnormal activation patterns. While this observation provides no evidence for neuroplastic adaptations in the brain, it demonstrates that specific physiotherapy techniques can reverse abnormal brain activation. It is possible that the entraining of "normal" activation patterns leads to long-term encoding and a persistent functional benefit. A randomized controlled study comparing aerobic treadmill exercise to stretching demonstrated a

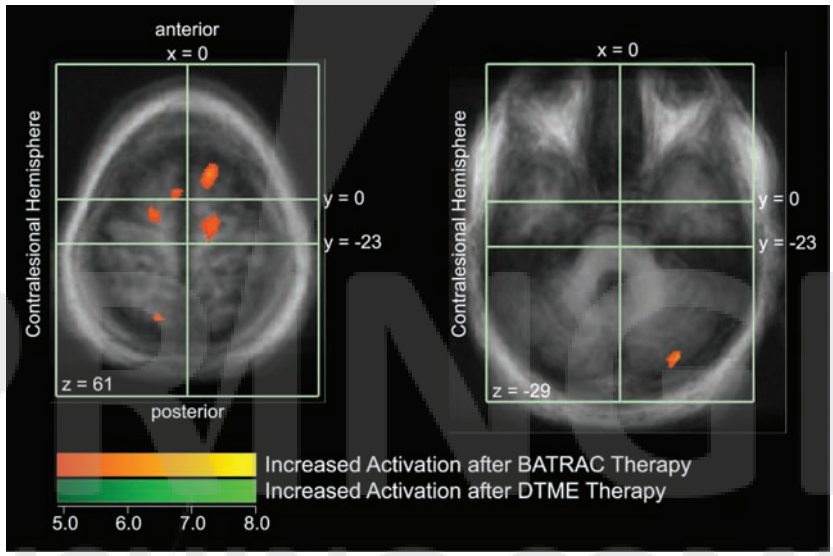

FIGURE 11.1 Evidence for neuroplastic reorganization after BATRAC. Bilateral arm training with rhythmic auditory cueing (BATRAC) recruits brain areas in both hemispheres to control the paretic limb (orange areas represent foci of novel activation after training in the BATRAC group, no increased activation was found after control dose matched physical therapy exercises).

Source: From Ref. (27). Luft AR, McCombe-Waller S, Whitall J, et al. Repetitive bilateral arm training and motor cortex activation in chronic stroke: a randomized controlled trial. *JAMA*. 2004;292(15):1853–1861. With permission of JAMA.

superiority of the treadmill interventions with respect to walking velocity and fitness. Increases in walking velocity were correlated with recruitment of subcortical brain networks, namely cerebellum-red nucleus circuits (34). This study demonstrated that subcortical networks can be modified by specific interventions that improve ambulation for chronic stroke survivors.

Other Interventions Supporting CNS Plasticity

Cortical Stimulation

CNS-neuroplasticity can be facilitated by certain adjunct treatments. One of these emerging interventions is cortical stimulation. Stimulation can be delivered transcranially either via magnetic fields (TMS) or by applying weak direct current (transcranial direct current stimulation [tDCS]). Cortical stimulation alters cortical excitability. For example, applying tDCS to the primary motor cortex (anodal stimulation) in the lesioned hemisphere, enhances excitability and results in improved use of the paretic arm (35). Also, associated with increased cortical excitability is a reduced intracortical inhibition suggesting changes in gamma-aminobutyric acid (GABA) and glutamatergic neurotransmission as the likely underlying mechanism (36). Interestingly, downregulation of excitability by applying cathodal stimulation to the contralesional hemisphere also improves arm function (37). This observation indicates that transcallosal interhemispheric signaling is part of the pathophysiology of hemiparesis. Similar results have been shown with repetitive TMS (38–40). Excitability changes that are observed following cortical stimulation are short-lived, and improve motor performance only for minutes to hours (35). In motor skill learning tDCS has been suggested to promote consolidation of a motor skill (41). Additionally, in cortical slices of mice tDCS-induced N-methyl-D-aspartate (NMDA) receptor-dependent long-term potentiation enhances BDNF secretion and activation of its receptor TrkB (tropomyosin-receptor-kinase) (42). Daily application in combination with training may provide persistent effects that are greater than those induced by training alone (38,43), but this remains to be confirmed in larger trials.

Pharmacotherapy

Systemic administration of Levodopa in combination with physiotherapy was superior to physiotherapy alone (44). In this trial, the combination treatment was given for 3 weeks during subacute recovery after a stroke that occurred 3 weeks to 6 months earlier. Amphetamines have been suggested to provide similar benefits (45), but conflicting evidence has been reported (46) (see Chapter 12). A meta-analysis based on 10 trials acknowledges benefits for motor function but found the evidence to be insufficient to allow definitive conclusions or guidelines (47). The mechanism of action for dopamine and amphetamine is thought to be the enhancement of cortical norepinephrine, but direct effects of dopamine have also been suggested (48). Inhibiting norepinephrine reuptake by reboxetine has been shown to enhance learning of a motor skill (49,50).

Sensitive animal models are necessary to better understand how certain substances affect recovery or learning. Only this knowledge will lead to optimized use by defining the delivery method, the time to use, the duration of treatment, and so on. In a rat model of motor skill learning, evidence exists that dopaminerigc neurotransmission in primary motor cortex is crucially important for successful movement learning and possibly recovery. Dopamine may take this role by mediating long term potentiation (LTP) of cortical neurons and by modulation of intracortical inhibition (51). The dopaminergic projection to motor cortex originates in the midbrain's ventral tegmental area (52).

SPINAL CORD

The spinal cord harbors reflex circuits that are inhibited by a pathway from the motor cortex to the brainstem ventromedial reticular formation (53). If a stroke injures this pathway, the reflex circuits become hyperactive leading to "upper motor neuron" (UMN) signs such as clonus and positive extensor plantar reflexes, as well as spasticity. However, these symptoms develop over time suggesting that it is not simply the removal of corticoreticulospinal signaling that causes symptoms of the UMN syndrome. Instead, slow plastic changes within the spinal cord must be involved (53). Little is known about these changes that are a deleterious form of spinal plasticity. Potential mechanisms are the sprouting of afferent axons, which in turn connect to previously inhibitory synapses converting them to excitatory synapses, or upregulation of receptor sensitivity as a consequence of denervation (53). Spasticity and muscular hypertonus leads to adaptations in muscle tissue and has biomechanical consequences, such as contractures and impaired posture.

Deleterious plasticity or "maladaptation" can occur because neurons lose their targets after injury and then rewire inappropriately. Rewiring may be maladaptive because the patterns of activation that occur during active use are missing. It has been hypothesized that maladaptive rewiring leads to the inability of newly formed synapses to undergo lasting modification of synaptic strength, and hence, learning (54). The basis for this hypothesis is that in the normal state, an oscillating balance exists between learning and recall, that is, between plastic change of synaptic strength or interneuronal connections and their stable maintenance; studies on the mechanisms of consolidation and reconsolidation after an early recall of stored information support this idea (review in (55)). By the destruction of part of the neuronal network as a result of stroke, this delicate balance is disturbed. Maladaptive rewiring leads to a permanent disruption of this balance. As a consequence, the neuronal networks are locked in a so-called "stability-plasticity dilemma" which leads to "catastrophic forgetting" of the information that was previously stored in these networks (54). This forgetting may contribute to motor paralysis in stroke survivors, that is, the forgetting of preexisting movement patterns. The classical pathophysiological

model of paralysis that emphasizes de-efferentiation is a result of interruption of CNS-muscle pathways, probably contributes as well, but is clearly not the sole explanation for paralysis; that stroke patients demonstrating plegia in neurological examinations, sometimes move their arm "subconsciously or automatically" when they wake up in the morning, underlines this idea.

Rehabilitation Training Techniques Targeting Spinal Cord

Original neurorehabilitative techniques, such as the Bobath neurodevelopmental technique (56), aim at avoiding UMN syndrome maladaptations at the level of the spinal cord. Whether or not they achieve this goal has not been demonstrated. They may also produce benefits by targeting other elements of the motor system. Proof of clinical efficacy of these techniques comes from experience more than from clinical investigations (57,58).

The spinal cord harbors "central pattern generators" that produce automated movement, such as stepping, and are under cortical and subcortical control. In animal models with spinal cord injury, these pattern generators can be modulated by gait training on a treadmill possibly reflecting spinal plasticity (59). In humans, body weight supported treadmill training (BWSTT) is advocated for spinal cord injured patients. A randomized controlled trial comparing BWSTT with overground training has shown clinical benefits for both interventions (60). This is expected assuming that any task, that is, gait-specific training whether on a treadmill or on the ground will induce activity-dependent adaptations. In humans whether these adaptations occur at the spinal level or in the brain remains to be investigated.

Spinal cord networks are specifically targeted by the antispasticity drug baclofen applied via continuous intraspinal infusion using an implanted pump. In a controlled double-blinded trial (n = 21) comparing a one-time bolus injection of baclofen versus saline, significant improvements in spascticity were documented in favor of the active drug (61). Responders to the bolus were then offered an implantation of a baclofen pump. At 12-months follow-up spasticity scores were markedly decreased.

SKELETAL MUSCLE

There are a number of skeletal muscle alterations that could propagate disability and increase cardiovascular risk after stroke. These skeletal muscle alterations include muscular atrophy and increased intramuscular adiposity (62), fiber phenotype shift (63), and changes in muscle metabolism that are linked to insulin resistance (64). Stroke leads to profound cardiovascular deconditioning that relates to gait deficit severity and body composition changes. Reduced muscle mass is fundamentally related to poor fitness and physical performance capacity after stroke (62,65).

Skeletal muscle fibers have great adaptive potential. Myosin heavy chain (MHC 1) is an important structural and regulatory contractile protein that is expressed in different isoform profiles, and thereby imparts functional diversity to muscles. Slow (MHC 1) isoform fibers are rich in mitochondria, resistant to fatigue, and less pH sensitive because of their highly oxidative metabolism (66). Fast-twitch fibers have glycolytic metabolism, have faster force generation capacity, but fatigue easily. The structural and functional characteristics of muscle fibers can be modified in response to several physiological and pathological conditions. Muscle phenotype is regulated by hormones, growth factors, changes in load, innervation patterns, aging, hypoxia, as well as electrical stimulation, and exercise. After stroke, skeletal muscle responds to altered use, loading states, and neural activation pattern. The most comprehensive study of muscle pathology reveals a shift to greater fast twitch fiber proportions in hemiparetic leg *vastus lateralis* (VL) based on ATPase staining, and a reliance on anaerobic metabolism with rapid lactate generation during isolated hemiparetic limb exercise, in contrast to oxidative metabolism during nonparetic leg exercise (67). These findings are similar to a recent study that finds a major shift to fast MHC by routine ATPase staining at pH 4.6 and MHC gel electrophoresis of hemiparetic leg *VL* muscle biopsies in 13 chronic stroke patients (63). The hemiparetic leg has elevated proportions of fast MHC isoforms compared to the nonparetic leg. These findings that are restricted to the hemiparetic leg suggest that neurological alterations may be partially responsible for the shift of muscle phenotype. The proportion of fast MHC isoform, only in the hemiparetic limb, is negatively correlated with self-selected walking speed. The shift to fast MHC after stroke in the hemiparetic leg muscle would be expected to result in a more fatigable muscle fiber type that could be more insulin resistant. Interestingly, spinal cord injury results in a parallel shift to fast MHC muscle composition, which can be reversed with partial weight suspension treadmill training (68).

Tumor necrosis factor alpha (TNF-alpha) has been implicated in muscular wasting in models of disuse, cachexia, sarcopenia, and insulin resistance. TNF-alpha may cause atrophy and insulin resistance through a number of mechanisms. It inhibits protein synthesis, reduces transcriptional factors regulating myofiber gene expression, induces protein breakdown through activating ubiquitin proteases and induction of apoptotic cell death, and alters insulin signaling (69–73). TNF-alpha mRNA expression is elevated in hemiparetic VL compared to the nonparetic leg of stroke patients and age-matched controls (64). TNF-alpha mRNA levels are 2.8-fold higher in hemiparetic muscle and 1.7-fold higher in nonparetic *VL* compared with matched controls. The findings of elevated TNF-alpha in both the hemiparetic and nonparetic muscles suggest systemic, as well as local inflammation could augment muscular atrophy and increase insulin resistance after stroke. This inflammatory mediator can negatively impact muscle mass, structural proteins, performance, and metabolism. These secondary biological abnormalities in body composition and skeletal muscle should be considered as potential targets for rehabilitation and therapeutic exercise after stroke.

Rehabilitation Training Techniques Targeting Muscle

In a small trial (n = 32) comparing robot-assisted gait training (Lokomat, Hocoma, Inc., Volketswil, Switzerland) to conventional physiotherapy (training of trunk stability, gait symmetry, and step initiation) in subacute stroke patients, Husemann et al. showed beneficial changes in whole body composition with robot training (74), that is, increase in muscle and decrease in fat mass compared to the control group over the 4 week intervention. Functional benefits were comparable between groups, but, the trial may not have been sufficiently powered to show such differences. These findings indicate that specific physiotherapy interventions can differentially affect body composition—the benefit for the stroke survivors remains to be assessed.

A systematic meta-analysis covering 21 trials using various strengthening methods—including electrical stimulation, biofeedback, muscle re-education for very weak acute or chronic stroke survivors and, in addition, resistance exercise for weak participants—demonstrated an overall benefit on strength and activity. The benefit was greater in acute than chronic and in weak than very weak subjects. The carryover between strength and activity was comparably low which was explained by the selection of muscles for strength training. Daily tasks, instead, consist of movement sequences that require the synergistic and timed action of different muscle groups. Strength training did not increase spasticity (75).

Spasticity is limiting active training to induce plastic adaptation. It is therefore desirable to relieve spasticity either through physiotherapy or pharmacotherapy. Brashear and colleagues compared butolinum toxin injections into flexor muscles with placebo in a randomized multicenter trial (76). At 4, 6, 8, and 12 weeks of follow-up, butolinum toxin was beneficial in improving muscle tone and self-reported disability without producing adverse events. It remains to be investigated whether butolinum toxin which has a time-limited effect, may enable specific training interventions that recover motor ability and prevent a relapse of spasticity.

SUMMARY

Rehabilitation training approaches for motor recovery after stroke can target all levels of the motor system (Table 11.1). Many patients require psychological and cognitive training targeting higher cognitive and language systems to understand and motivate themselves for rehabilitation and to cope with disability and related social stressors. Repetitive and task oriented training therapies target the brain's motor systems to induce neuroplastic changes that provide recovery of motor function or compensation for disability. These training therapies may be supported by pharmacological, for example, dopamine, or electrical therapies that render the motor cortex more apt to plastic changes. Spinal cord reflex mechanisms are targeted by conventional rehabilitation therapies but little is known about the ability for lasting changes in the spinal cord after stroke. Maladaptive changes in spinal cord may lead to spasticity, which together with muscle degeneration can be a limiting factor to CNS training therapies. Therefore measures to reduce spasticity, such as butolinum toxin injections and sensory feedback therapy, may be a prerequisite to further training. Muscle degeneration may be reversed by resistive and nonresistive exercise. Finally, reduced cardiovascular fitness after stroke can limit any movement effort. Aerobic exercise therapies targeting the cardiovascular and respiratory systems may enhance fitness and provide sufficient energy reserve for enduring daily life activities.

The neuroscience of rehabilitation is just at its beginning. Much needs to be learned about the brain's ability to adapt and recover, including the use of restorative approaches (e.g., via stem cells). Because a plethora of therapies already exist and will be expanded in the future, it will be crucial to learn about efficacy, prerequisites for response, treatment intensity, and sequence. Most likely we will have to tailor the rehabilitative protocol to the individual patient.

Medications and Stroke Recovery

Larry B. Goldstein

Despite decades of laboratory-based research showing that a variety of systemically administered drugs can have a profound influence on poststroke functional recovery, consistent data from prospective clinical trials demonstrating a similar effect in humans is lacking. This discrepancy between laboratory-based and clinical studies is not unique to putative poststroke pharmacologic restorative treatments. A similar disparity between the results of animal model experiments that were designed based on an understanding of a drug's neurobiological actions and the demonstration of similar effects in humans has plagued attempts to identify clinically relevant neuroprotective interventions (1,2). There are likely a variety of reasons for these failures of translational medicine, and despite the setbacks, there is reason to believe that the identification of effective pharmacological approaches for improving functional outcomes after stroke may be possible (3–5). A plethora of novel strategies, such as stem cell transplantation (6–8), hormonal administration (9–11), exogenous growth factors (12), and statins (13–15), hold promise; these, and several other therapeutic avenues, are being actively pursued. This discussion focuses on the potential effects on the recovery process of medications acting through central neurotransmitter mechanisms.

CONCEPTS AND MECHANISMS

Arguably, amphetamine is the most extensively studied systemically administered drug with the potential to modulate the recovery process after stroke or other forms of central nervous system injury. Experiments suggesting that the administration of amphetamine might affect measures of neurological function after damage to the brain or spinal cord date to at least the 1940s (16,17); however, the therapeutic potential of amphetamine was not widely recognized until publication of a series of experiments by Feeney and coworkers nearly 40 years later (18,19). These experiments showed, that when combined with task-relevant training, a single dose of *d*-amphetamine given 24 hours following unilateral sensorimotor cortex ablation increased the rate of locomotor recovery in rats. The observations were subsequently confirmed in other laboratories (20–23). Other studies found that postinjury administration of amphetamine was associated with recovery of otherwise permanent neurological deficits. For example, in cats, amphetamine given after unilateral or bilateral frontal motor cortex ablations led to a restoration of both locomotor ability (24–26) and tactile placing (27). After occipital lobe injury, amphetamine combined with visual experience resulted in the recovery of stereoscopic vision (28,29) in addition to tactile placing (30). Consistent with the data from cortical ablation models, beneficial effects were observed for the recovery of sensory function after ischemic injury to the barrel cortex in rats (31–33), as well as for recovery of motor function after middle cerebral artery distribution infarction (34), traumatic brain injury (35), and skilled reaching after both cortical ischemia (36,37) and ablation injury (38). Dextroamphetamine combined with training also led to long-term improvements in motor task performance after cortical infarction in squirrel monkeys (39). Experimental conditions and behavioral measures may, however, be critical, as not all studies found similar effects (40–43).

If administration of *d*-amphetamine can positively affect functional recovery after brain injury, understanding its pharmacology is important. Amphetamine use can be associated with cardiovascular toxicity even when given to young persons without known vascular disease to treat attention deficit disorders (44). Cardiovascular side effects may be reduced if the drug's action on recovery could be isolated from its effects on blood pressure, cerebral blood flow, and cardiac function. Although amphetamine may affect the release and activity of several neurotransmitters, including dopamine, serotonin, and norepinephrine (45), several lines of evidence suggest that its action on recovery is mediated through norepinephrine.

In rats, intraventricular infusion of norepinephrine has an effect on motor recovery similar to that of amphetamine (46). There is no effect of dopamine infusion if its conversion to norepinephrine is blocked by dopamine-beta-hydroxylase (46). Selective depletion of central norepinephrine with (N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine; DSP-4) impairs motor recovery after a later injury to the cerebral cortex (47,48). Selective injury to the locus coeruleus, the primary source of central noradrenergic projection fibers, also affects motor recovery after a subsequent injury to the rat sensorimotor cortex, although the effect varies between experiments (49–52). When performed at least two weeks

before a unilateral sensorimotor cortex ablation, bilateral, contralateral, and ipsilateral locus coeruleus lesions block locomotor recovery (52).

If the administration of *d*-amphetamine can facilitate poststroke recovery, understanding the neurobiological substrate of its action could have implications for selecting patients for treatment in clinical studies. Because each locus coeruleus has widespread projections, selective lesions of the ipsilateral and contralateral dorsal noradrenergic bundle were used to determine whether norepinephrine levels in the damaged or undamaged hemisphere correlated with recovery. In one experiment, the locus coeruleus fibers innervating each hemisphere were lesioned two weeks prior to a unilateral sensorimotor cortex injury (53). Locomotor recovery was impaired by contralateral but not ipsilateral dorsal noradrenergic bundle lesions. Further implicating norepinephrine and its effects in the opposite, noninjured hemisphere, the overall rate of recovery was correlated with norepinephrine content in the contralateral but not ipsilateral cerebral hemisphere. The observation is intriguing, as studies with functional MRI in humans find changes in the cerebral hemisphere contralateral to a stroke that correlate with motor recovery (54,55).

The neurobiological processes underlying amphetamine (and norepinephrine) modulated recovery remain uncertain. One theme that arises from laboratory experiments is that the effect of *d*-amphetamine on recovery depends on concomitant training. In the original experiments by Feeney and colleagues, the amphetamine effect was blocked if the rats were not allowed to walk rather than being trained in conjunction with drug administration (19). There was also no effect if rats were handled rather than trained, suggesting that specific locomotor experience was required (56). The drug effect on motor recovery in cats was not observed in the absence of training, and there was no reinstatement of depth perception in cats after visual cortex ablation if they were kept in the dark after being given *d*-amphetamine (25,28).

As the effect of amphetamine is long-lasting, administration might be expected to affect anatomic neuroplasticity. *D*-amphetamine, given in addition to training, led to neuronal changes in both the ipsilateral and contralateral cerebral cortex (57). The combination of postinjury training and amphetamine administration was associated with an increase in projection fibers from the contralateral, noninjured cerebral cortex to the pontine motor nuclei (38). Therefore, amphetamine may induce long-term changes in neuronal structure that could, in part, underlie its impact on recovery.

In addition to the importance of concomitant experience/training, drug effects on recovery may also depend on drug dosing and timing relative to the injury. For example, *d*-amphetamine's effect on locomotor recovery after sensorimotor cortex injury in the rat is dose-dependent (58). There was progressive benefit as the dose was increased but a progressive loss of benefit as the dose was increased further. In cats, motor recovery after cortex injury was facilitated when a series of amphetamine/training sessions were provided every four days for two weeks as compared to a single session (25). Amphetamine improved binocular depth perception in visually decorticated cats when given beginning 10 days after injury, but there was no benefit if treatment was delayed for 3 months (28).

Several principles arise from these experimental studies. Some systemically administered drugs such as *d*-amphetamine may modulate recovery after brain injury. The effect depends on concomitant behavioral experience/training. Timing and dosing are critical. For *d*-amphetamine, at least part of the drug effect appears to be exerted in the cerebral hemisphere contralateral to the injury.

PRECLINICAL PHARMACOLOGY

Noradrenergic Agents

Given the hypothesis that *d*-amphetamine acts through norepinephrine, other centrally acting noradrenergic drugs would be anticipated to affect recovery after brain injury. Motor recovery was accelerated by the norepinephrine precursor L-threo-3,4-dihydroxyphenylserine (L-DOPS) (59,60). Effects on recovery similar to amphetamine also occurred after administration of phenylpropanolamine (61), phenteramine (62), and (depending on dosing regimen) methylphenidate (63). Further illustrating the complex interaction of dose and experience, the effect of methylphenidate depended on the number and timing of treatment sessions (63). Single doses of the alpha$_2$-adrenergic receptor antagonists idazoxan and yohimbine, which act to increase synaptic norepinephrine release, facilitated motor recovery when given to rats after unilateral sensorimotor cortex injury (64–66).

Antihypertensives

Antihypertensives that cross the blood–brain barrier act on central noradrenergic receptors and have the potential to affect recovery after brain injury. The alpha$_2$-adrenergic receptor agonist clonidine (67) and the alpha$_1$-adrenergic receptor antagonists phenoxybenzamine (65) and prazosin (65,66) interfere with locomotor recovery after cortex injury. Deficits also transiently reemerge in animals that had recovered motor function when given either clonidine or prazosin (66). In contrast to drugs active at alpha-adrenergic receptors, the beta-adrenergic receptor antagonist propranolol had no effect on locomotor recovery (65).

Major Tranquilizers and Related Drugs

In Feeney's original experiments, he and co-workers not only reported that *d*-amphetamine coupled with training facilitated locomotor recovery in rats, but also that haloperidol impaired recovery (19). It was also found that haloperidol blocked *d*-amphetamine-facilitated recovery of stereoscopic vision in visually decorticated cats (29). Butyrophenones, such as fluanisone and droperidol, can reinstate neurological deficits in rats that recovered motor function after cortex injury (68). These observations raise the possibility that

dopamine, in addition to norepinephrine, might modulate recovery after brain injury. Arguing against this hypothesis, intraventricular administration of norepinephrine improves recovery similar to *d*-amphetamine, but intraventricular dopamine is neutral (46). Because haloperidol and other major tranquilizers also have effects on noradrenergic receptors (69,70), it is hypothesized that their impact on recovery is noradrenergically mediated. The relative dose-dependent detrimental effects of haloperidol and clozapine on post-sensorimotor cortex injury in rats are related to their relative potencies at noradrenergic receptors (71).

Antidepressants

Antidepressants affect the reuptake and metabolism of a variety of central neurotransmitters, including norepinephrine. Serotonin, a target of several antidepressants, modulates the release of norepinephrine through activation of 5-HT3 and possibly 5-HT1C receptors in rat hippocampal neurons (72). In addition, various antidepressants, including fluoxetine, induce neurogenesis in the hippocampus, an effect thought to underlie their delayed impact on depression (73). Facilitation of neurogenesis might have a favorable impact on recovery after brain injury. The administration of a single dose of trazodone, however, transiently slows motor recovery in rats with cortical injury and reinstates the hemiparesis in recovered animals (74). In contrast, desimpramine facilitated, whereas fluoxetine and amitriptyline had no effect on, motor recovery in experimental animal studies (74,75). Another study found that administration of fluoxetine after traumatic brain injury in rats had no impact on memory, balance, or gait (76), and chronic fluoxetine negatively affected assessments of memory and had no effect on electrophysiological measures after dentate gyrus injury in rats (77). Thus, there are only limited preclinical data supporting a direct effect of antidepressants on poststroke recovery, and the data that are available are inconsistent.

Anxiolytics

Diazepam, an indirect gamma-amino butyric acid (GABA) agonist, has a permanent and severe detrimental impact on recovery of sensory function when given after anteromedial neocortex damage in the rat, an action associated with neuroanatomical changes in the thalamus and substantia nigra (78,79). Co-administration of a benzodiazepine antagonist blocks this harmful effect (80). Because anxiolytics that do not act through the GABA/benzodiazepine receptor are neutral with respect to recovery, the detrimental actions of benzodiazepines seem to be due to a specific, receptor-mediated action (81).

Anticonvulsants

The harmful effect of diazepam and other benzodiazepines on recovery after brain injury raises concern for similar actions of other anticonvulsants. Phenobarbital delays recovery from somatosensory deficits after unilateral injury to the cerebral cortex (82), and phenytoin administration worsens sensorimotor deficits after cortex injury in rats (83). In contrast, chronic administration of carbamazepine does not affect recovery (81).

Possible Mechanisms of Neurotransmitter-Modulated Recovery

Diaschisis, a term referring to the remote metabolic depression that occurs in brain structures anatomically and functionally linked but not adjacent to the area of primary injury, can be demonstrated in both animal models (84–86) and humans (87–90). Because *d*-amphetamine's effect on recovery is evident within hours in some animal models, it was hypothesized that drugs that prolong or worsen diaschisis would be detrimental, whereas those that reverse diaschisis would be beneficial (86). Resolution of crossed cerebellar diaschisis in humans, however, is not directly associated with recovery after hemispheric stroke-related hemiparesis (91).

Long-term potentiation (LTP) refers to a change in synaptic efficiency following specific types of neurotransmitter exposure and is thought to represent a physiological mechanism for learning and memory (92). Because the initial effects of *d*-amphetamine on recovery after brain injury occur within hours, and because of the need for concomitant training, induction of LTP is an attractive potential mechanism underlying the effects of at least certain classes of drugs on recovery. LTP is mediated through the N-methyl-D-aspartate (NMDA) receptor complex and leads to activation of both pre- and postsynaptic mechanisms, resulting in a long-lasting effect on synaptic strength. In addition to the hippocampus, LTP (and its correlate, long-term depression) occurs in a variety of brain regions, including the motor (93,94) and visual cortexes (95,96). In addition to amphetamine (97–99), neurotransmitters including norepinephrine (97,98,100–103), serotonin (104), dopamine (105), GABA (106–108), and acetylcholine (100,109–111) can affect the induction of LTP. Further, the impact on recovery of a variety of drugs acting on central neurotransmitters can be explained based on their effect on LTP (112–114). The effects of norepinephrine on synaptic function and plasticity, however, are complex and may vary in different brain regions (115).

Pharmacological Effects on Poststroke Recovery in Humans

Reduction in Dependence and Disability

There have been several clinical studies assessing the effects of amphetamine on poststroke recovery in humans (Table 12.1).

The studies were small and have important differences in methodologies. An initial "proof-of-concept" study randomized eight subjects with stable poststroke motor deficits to receive either 10 mg of *d*-amphetamine or placebo

TABLE 12.1 Comparative Clinical Trials of the Effects of Amphetamine on Poststroke Motor Recovery

STUDY	N	STROKE-TREATMENT INTERVAL	*d*-AMPHETAMINE DOSE/ TREATMENT FREQUENCY	DRUG-THERAPY SESSION INTERVAL (DURATION)	OUTCOME ASSESSMENT
Crisostomo et al. (1988) (116)	8	<10 days	10 mg, one session	<3 hour (45 min)	1 day
Reding et al. (1995) (118)	21	>1 month	10 mg daily for 14 days, then 5 mg daily for 3 days	Same day (? Duration)	1 month
Walker-Batson et al. (1995) (152)	10	16–30 days	10 mg every 4 days for 10 sessions	"Peak of drug action" (? Duration)	1 week and 1 year
Sonde et al. (2001) (119)	39	5–10 days	10 mg twice weekly*	1 hour (30 min)	3 months
Martinsson et al. (2003) (120)	30	<96 hours	5 or 10 mg once or twice daily for 5 days	Same day** (15 min vs. 30–45 min)	3 months and 1 year
Treig et al. (2003) (121)	24	<6 weeks	10 mg every 4 days for 10 sessions	1 hour (45 min)	90 days and 1 year
Gladstone et al. (2006) (122)	71	5–10 days	10 mg twice weekly for 10 sessions	90 min (1 hour)	6 weeks and 3 months

**dl*-amphetamine.
**Duration of physiotherapy varied (both groups received *d*-amphetamine).
Source: From Ref. (153). Goldstein LB. Amphetamine trials and tribulations. *Stroke*. 2009;40(Suppl 1):S133–S135.

coupled with physical therapy within 10 days of ischemic stroke (116). As assessed 24 hours later, the *d*-amphetamine-treated group had a significant improvement in motor performance compared to the placebo-treated group. The study, however, involved only a small number of highly selected patients and the clinical significance of the effect was uncertain.

A second double-blind, placebo-controlled trial included 5 *d*-amphetamine- and 5 placebo-treated patients with treatment given in conjunction with physical therapy once every 4 days for 10 sessions beginning 15 to 30 days after stroke (117). Amphetamine-treated patients had significantly greater improvements in motor scores compared to placebo-treated patients, with a consolidation of the benefit after treatment was completed.

Other studies using different or similar trial designs have failed to confirm these observations. In one study, a set of randomized 24 subjects received 10 mg of amphetamine daily for 14 days followed by 5 mg for 3 days or placebo (118). The subjects were enrolled more than one month after stroke, and there was no tight coupling between drug administration and physical therapy. Compared to the previous studies, there was a longer delay between stroke and treatment, and physical therapy was not temporally linked to drug exposure. Other negative studies evaluated *dl*- rather than *d*-amphetamine (119), or used different dosing regimes, intervals between treatment sessions and treatment durations, or only included subjects with severe deficits (120). Two additional trials using a treatment and dosing regimen similar to the single positive study with longer-term follow-up also failed to find benefit (121,122).

Overall, the results of clinical trials evaluating the effect of *d*-amphetamine combined with physical therapy on poststroke motor recovery have been disappointing and have not fulfilled the promise anticipated from the extensive preclinical data. Although a meta-analysis based on 6 studies (176 patients) found a better relative change from baseline to last follow-up in motor function (weighted mean difference –6.1 points; 95% CI –10.4 to –1.9), baseline imbalances may have led to a trend for more deaths at the end of follow-up among subjects randomized to amphetamine treatment (OR 2.8, 95% CI 0.9 to 8.6) (123). As mentioned earlier, it was concluded that "too few patients have been studied to draw any definite conclusions about the effects of amphetamine treatment on recovery from stroke."

Methylphenidate is used as a psychostimulant and antidepressant in apathetic patients to improve their participation in physiotherapy (124,125). As reviewed earlier, preclinical data suggested benefit in improving motor recovery after brain injury, but the dosing and treatment schedule is critical (63). Two clinical studies did not find any treatment-associated improvement in motor recovery with methylphenidate, although cardiovascular side effects occurred (126,127).

An uncontrolled study of L-DOPS combined with physiotherapy was conducted in a group of subjects with chronic, stroke-related motor deficits (128). The subjects' average Fugl-Meyer motor score improved by 4.4 points ($P < .001$), and 10-minute walk time was shortened by 16% ($P < .001$) after 28 days of drug administration. Because the study was not controlled and physiotherapy alone can improve motor function even in the setting of established

deficits (129,130), the clinical significance of the observation is not certain.

Poststroke depression is common, and antidepressants of various classes are used not only to treat the attendant psychiatric symptoms but also to improve the patient's participation in rehabilitative interventions (131). The effects of two norepinephrine reuptake blockers (i.e., nortriptyline (132), maprotiline (133)) on poststroke disability were neutral when given chronically. Drugs increasing norepinephrine levels are anticipated to facilitate recovery based on the reviewed preclinical pharmacology. Dosing, however, may be critical. Brain norepinephrine content is reduced after chronic but not acute administration of desipramine (134). Trazadone is an antidepressant that blocks alpha$_1$-adrenergic receptors and interferes with motor recovery after cortex injury in rats (74). A small clinical trial, however, found that its chronic administration to depressed stroke patients receiving physical therapy led to improvements in their activities of daily living (135). The discrepancy could be due to different pharmacological effects of one-time versus chronic administration on norepinephrine levels, or related to its action on serotonin levels, or due to its antidepressant effects.

As noted earlier, there are scant preclinical data showing an effect of serotonergic drugs on recovery after brain injury. Despite this, a small clinical study suggested that the selective serotonin reuptake inhibitor (SSRI) fluoxetine might facilitate poststroke recovery (133). This was followed by the fluoxetine for motor recovery after acute ischemic stroke (FLAME) trial that randomly assigned 118 fluoxetine 20 mg daily or placebo for 3 months beginning 5 to 10 days after symptom onset (136) to subjects with stroke-related moderate to severe hemiparesis. Improvement at 90 days was greater in the fluoxetine group (adjusted mean 34.0 points on the Fugl-Meyer score [95% CI 29.7–38.4]) than in the placebo group (24.3 points [19.9–28.7]; $P = .003$). There was also benefit as assessed by the modified Rankin score (mRS) at 90 days, with 26% of those treated with fluoxetine compared to 9% of those who received placebo being independent (mRS 0–2, $P = .015$). The effect was independent of depression. The trial, however, included only a small number of subjects, and whether the benefit is sustained over time is not known.

A meta-analysis of the effects of SSRIs on poststroke disability included data from 13 trials of fluoxetine, 1 trial of sertraline, 3 trials of citalopram, and 5 trials of paroxetine (n = 1,310) (137). Treatment with an SSRI was superior to controls (standard mean difference 0.92, 95% CI 0.62–1.23; number needed to treat = 3) with no evidence of differences among the antidepressants. Many of the trials were small, and there was significant heterogeneity among the studies due to methodological and other differences. It was concluded that SSRIs might be associated with improved poststroke recovery but that much of the evidence is of poor quality and that larger, high-quality studies are needed.

Recovery From Aphasia

Although this discussion is primarily focused on poststroke motor recovery, clinical studies have also evaluated pharmacological approaches for reducing stroke-related language impairments (138,139). A double-blind study randomized 21 subjects who had poststroke aphasia to 10 mg *d*-amphetamine or placebo between 16 and 45 days after stroke, using a treatment schedule similar to the trial that was found beneficial for motor recovery (117). Improvement, assessed with the Porch Index of Communicative Ability, was greater one week after treatment was completed in those who received *d*-amphetamine ($P = .015$). The difference between the groups, however, was no longer significant after six months ($P = .048$) after correction for multiple comparisons. Two randomized trials found no benefit of bromocriptine on any measure of aphasia (140,141). Although there are a variety of potential explanations for this negative finding, the results are not surprising, because preclinical studies suggested that recovery is mediated through noradrenergic rather than dopaminergic mechanisms.

Piracetam is a derivative of GABA that has no effect on the synthesis, release, or uptake of GABA and has no effect on GABA postsynaptic binding but does have effects on the cholinergic system and increases synaptic norepinephrine release (142). It also has diverse effects on blood flow and platelet reactivity, but its specific mechanism of action is unknown, and there are virtually no preclinical studies assessing its potential impact on poststroke recovery. Despite this, it has been described as the first *nootropic* (cognition-enhancing) agent, and has been evaluated for improving cognition in patients with dementia (143,144), with several trials assessing its impact on recovery after stroke in humans. A small trial found a transient improvement in aphasia in subjects randomized to receive piracetam (145), with a second small study finding benefits in some language subtests at the end of six weeks of treatment (146). A third found only trends toward benefit (147). It remains unclear whether piracetam treatment results in a clinically meaningful, long-term benefit.

Impairment of Recovery

Several of the centrally acting drugs with the capacity to negatively affect poststroke recovery are commonly given to patients who have had an ischemic stroke to treat comorbid and concomitant medical problems (148). These include various antihypertensives, anti-epileptics, anxiolytics, and major tranquilizers. Whether these drugs have a detrimental effect on recovery in humans can only be assessed in retrospective studies, which have a series of inherent limitations, including unmeasured confounding. With this caveat, a retrospective cohort study (n = 58) found that the motor recoveries of stroke patients who received one or a combination of the antihypertensives clonidine or prazosin, major tranquilizers, benzodiazepines, or the anticonvulsant phenytoin had poorer recoveries than those who did not receive one of these drugs, even after adjustment for other factors,

including initial stroke severity (149). Similar results were found in a retrospective analysis of data from a prospective clinical trial focused on poststroke recovery in which nearly 40% of 96 control subjects received one or a combination of potentially harmful drugs (72% in the "detrimental" group received a benzodiazepine, 22% a major tranquilizer or related drug, 14% an alpha$_2$-adrenergic receptor agonist, 8% an alpha$_1$-adrenergic receptor antagonist, and 6% phenobarbital or phenytoin) (150). There were significant differences in recovery based on the drugs the subjects had received, with recovery being impaired in those who had received a "detrimental" drug. The finding was further replicated in an analysis of a third independent cohort (151). This study included 154 patients admitted to a rehabilitation hospital within 2 months of stroke. In this group, 19% received a benzodiazepine, 13% a major tranquilizer or related drug, 3% an alpha$_2$-adrenergic receptor agonist, 8% phenobarbital, and 3% phenytoin. After multivariable adjustment, those who received a potentially detrimental drug were found to have significantly poorer recoveries.

CONCLUSION

Preclinical studies provide clear and consistent evidence that a variety of centrally acting drugs affecting specific neurotransmitters can either favorably or unfavorably modulate recovery after brain injury. Although at least some studies suggest similar effects in humans, results have been inconsistent. The impact of important factors such as drug dose, duration and intensity of physiotherapy, and timing between injury and treatment are difficult to translate from preclinical studies. Issues related to variability in stroke severity, involved structures, and comorbid conditions further complicate trial design and could obscure a true treatment effect. Because of these and other issues, the design of efficacy trials assessing putative neurorestorative interventions is not trivial. Although a proven pharmacological approach resulting in a clinically meaningful improvement in poststroke recovery remains elusive, it is reasonable to avoid medications that may have harmful effects in patients who have had a stroke. It is also important to control for these possible harmful effects in future clinical trials assessing the outcomes of stroke patients after the acute period.

III

NEUROLOGIC IMPAIRMENTS AND THEIR TREATMENT

13

Aphasia, Apraxia of Speech, and Dysarthria

Leora R. Cherney and Steven L. Small

Speech and language problems are common sequelae of stroke that significantly impact the daily lives of stroke survivors. Reduced speech and language skills have negative ramifications for the individual's social, vocational, and recreational activities, often leading to social isolation, loneliness, loss of autonomy, restricted activities, role changes, and stigmatization (1–7). Given the importance of communication to the stroke survivor's quality of life, it is essential that rehabilitation professionals recognize and address the speech and language disorders associated with stroke.

Normal speech and language are extraordinarily complex. A number of steps are required, some accomplished sequentially and some in parallel, that incorporate the following: (a) conceptualization of an idea and generation of a communicative goal; (b) formulation of a grammatically structured sequence of verbal symbols (words), each consisting of an interacting set of ordered sounds; (c) selection of a series of neural commands or sensorimotor "programs" that will activate the speech muscles at appropriate coarticulated times, durations, and intensities; and (d) central and peripheral nervous system innervation of muscles of respiration,[1] phonation, resonance, and articulation to produce the intended acoustic signal.

Stroke can disrupt any of the stages of speech and language, resulting in one or more of the disorders of aphasia, apraxia of speech (AOS), and dysarthria. Disruption to the initial stage involving the structure and rules of the linguistic message results in *aphasia*. Impairment of the capacity to plan and program sensorimotor commands for the positioning and movement of muscles for the volitional production of speech results in AOS. It can occur without significant weakness or neuromuscular slowness and in the absence of disturbances of conscious thought or language (8). *Dysarthria* results from abnormal neuromuscular execution that affects the speed, strength, range, timing, or accuracy of speech movements. Dysarthria can affect respiration, phonation, resonance, articulation, and prosody, either singly or in combination.

Although by definition the disorders of aphasia, AOS, and dysarthria are distinguishable, in practice they often co-occur, making it challenging for even the experienced clinician to distinguish between them. Yet, distinguishing aphasia from dysarthria and both disorders from AOS can be important not only because of the neurologic implications regarding underlying pathology, but also because a specific diagnosis can have implications for selection of the appropriate management techniques and strategies.

This chapter, therefore, is divided into three parts, each of which addresses the primary characteristics of aphasia, AOS, and dysarthria, as well as assessment suggestions and management strategies. It will become obvious that the section on aphasia is far more detailed than the sections on the other two disorders. There are several reasons for this disparity, including differences in the incidence and prevalence of these disorders following stroke, the severity and persistence of the disorders, and their impact on the stroke survivor. The disparity also reflects our current knowledge of these disorders following stroke. For example, though there is a large body of literature about the characteristics of dysarthria and its assessment and treatment in general, relatively little pertains to dysarthria resulting specifically from stroke. There is far more research on the diagnosis and treatment of dysarthrias that are caused by Parkinson's disease, amyotrophic lateral sclerosis (ALS), and other progressive neuromuscular disorders. By contrast, stroke is the leading cause of aphasia, and most of the literature on aphasia relates to aphasia that is caused by stroke. Furthermore, as vascular lesions are not functionally selective—the same arteries and arterial branches supply brain areas that mediate functions important for all three disorders—the diagnosis and treatment of aphasia often must take into consideration these other disorders concomitantly.

APHASIA

Aphasia has been defined as a multimodality language disorder resulting from damage to brain areas that subserve the formulation and understanding of language and

[1] *Respiration*, by strict definition, refers to the exchange of gases between the bloodstream and the environment, whereas *ventilation* refers to the exchange of air between the lungs and the environment. However, it is customary for speech–language pathologists to refer to the breathing muscles of inhalation and exhalation as the muscles of respiration. Therefore, the term *respiration* rather than the term *ventilation* is used in this chapter.

its components (i.e., phonology, syntax, morphology, and semantics). Although it is beyond the scope of this chapter to provide a tutorial on language, it is important for those involved in aphasia rehabilitation to have a basic understanding of these different components of language to clarify the definition and to provide some basis for the discussion of rehabilitation.

Language Components

Phonology

Phonology refers to the linguistically important speech sounds or phonemes of a language and the rules for combining them. It is contrasted with *phonetics*, which is involved with the physical production of these sounds. Each consonant or vowel in a language may take a number of different pronunciations. For example, the letter *c* can sound like *k* or like *s*, and each pronunciation within that language is considered a *phoneme*. Many patients with aphasia have problems at the phonological level of processing. On the production side, they may substitute one phoneme or one syllable (combination of phonemes) for another, and on the comprehension side, patients can misinterpret particular phonemes or syllables, thereby hearing an unintended word and misinterpreting what is being said. Obviously, ascertaining these phonological errors in production is easier than in comprehension.

Syntax and Morphology

Syntax (or *grammar*) is the set of rules that governs the structure of sentences in a particular language, whereas *morphology* refers to the internal structure of words. In both cases, the structural rules have specific impacts on meaning. In English, for example, the addition of *-ed* to many regular verbs changes their tense, and the addition of *-s* to many regular nouns changes them from singular to plural. Word order plays an important role in syntactic processing in English, unlike other languages (e.g., Italian, German) where word order plays less of a role, and affixation or even semantic context are more important (9). This can lead to differences in the manifestations of aphasia across languages.

Syntactic impairments are common in aphasia. Some observers believe that grammatical processing problems are characteristic of patients with damage to the frontal part of the left perisylvian region and have called this disorder *agrammatism*. Such patients are more likely to say and understand single meaningful words, called *content words* (e.g., nouns and verbs), than they do the small *function words* (e.g., prepositions, articles). Importantly, the content words of a language form an *open class* (i.e., one to which new items can be added), whereas function words form a *closed class*. Function words do not denote objects, actions, or locations but rather play a role similar to word affixes and word order in guiding sentence production or interpretation. A less common syndrome called *paragrammatism* involves grammatical processing problems and results from damage to the posterior (temporoparietal) portion of the left perisylvian region (10,11).

Semantics

Semantics is meaning, and conveying meaning in context is the fundamental goal of communication. The study of word meanings is called *lexical semantics*. The study of sentences and their different meanings—conveying entire "thoughts" or statements—is called *sentential semantics*. The meanings of sentences are built up from a combination of the meanings of the individual (content) words in the sentence, the syntactic aspects of word order, function words, word affixes, and the higher linguistic context (i.e., the entire conversation or discourse).

Lexical semantic processing is often disrupted in aphasia. Many patients with stroke cannot find the names of objects and actions that they understand visually and functionally. They may substitute a related but unintended word for the target word. Patients with agrammatism sometimes cannot distinguish the subject from the object of a sentence, particularly if word order is less common (e.g., in a passive sentence) and the subject and object words are both able to perform the actions (e.g., the boy was kicked by the girl). This is a problem of syntax and sentential semantics.

Working Memory

Certainly it is not possible to use language without various types of memories, including memory for words, grammatical rules, affixation rules, and so forth. Separating out language-specific memory from other types of memory is a topic of significant controversy, and one that we do not address here. However, one type of memory is particularly important in the understanding of aphasia and that is *working memory*, the memory that is required to maintain the partial fragments of what is being heard or said to ensure completion of the comprehension or production of the desired word, phrase, or sentence (12). All language computations require this type of very short-term memory, and it is commonly disrupted in aphasia (13,14).

Language Modalities

As aphasia is a multimodality disorder of language, it impairs, in varying degrees, the understanding (input) and expression (output) of both oral and written language modalities. Producing and understanding oral speech requires mechanisms for encoding and decoding auditory waveforms and mechanisms for encoding and decoding the words and sentences that constitute the message. As oral speech is both the phylogenetic and ontogenetic backbone of language—it is learned first and in some cases exclusively—it is thought to be the evolutionary foundation and architectural core of the neural circuits involved in language. Patients with disorders of spoken language production and comprehension usually have concomitant problems in the written modality, reinforcing the ontogenetic coupling of these two neuroanatomical systems.

Consequently, aphasia is defined in terms of impairments in oral expression (speaking) and understanding,

and a preponderance of treatment approaches are aimed directly at this form of communication. To the extent that the oral and written modalities share underlying mechanisms, such as lexical retrieval and sentence syntax and semantics, treatment need not be modality specific. However, when the language deficit is inextricably entwined with modality-specific problems, such as AOS, treatment that targets the specific modality might be preferable.

Producing written language requires neural and motor mechanisms for encoding a message in letters and visual words and performing the somatic motor movements to write or type the visual product. Understanding written language requires distinguishing particular visual stimuli as linguistic and then decoding them into letters, words, and sentences. There is also neural circuitry to convert these visual stimuli into phonological forms. Although it has not been completely determined when and how such circuitry is used, it seems to play its most important role in the case of less common (or pretend) words with regular spellings. It can also play a role in certain reading disorders caused by stroke. Disorders of reading and writing are an integral part of the aphasia, suggesting a significant degree of common underlying neural substrate for language processing from the oral and written modalities. When a writing disorder occurs that is disproportionate to the degree of impairment in speaking, it is called *dysgraphia* (or *agraphia*). The analogous reading disorder is called *dyslexia* (or *alexia*).

Anatomy of Language

In 1861, Pierre Paul Broca presented a paper to the Anatomical Society of Paris discussing the autopsy findings of his patient with a language disorder (15). Broca found a large brain lesion in the left inferior frontal region (the frontal "convolutions") and postulated a role for this region in the physiology of language. Although neurologists prior to Broca had suspected and even published similar arguments (16), Broca is generally acknowledged as the initiator of the modern study of language and the brain through the method of clinicopathologic correlation (*lesion analysis* or *neuropsychological localization*) (17,18). Following this work, a number of additional papers were published on the brain mechanisms of language, including those by Wernicke (1874), Lichtheim (1884), Grashey (1885), and Freud (1891) (19–22). Their work led to the general notions that (a) the left perisylvian region is anatomically responsible for most of the neural mechanisms of language; (b) the codes and processes of the language output channel are anatomically instantiated by structures in and around the opercula of the left inferior frontal gyrus; and (c) the analogous codes and processes for the language input channel are anatomically centered around the posterior aspect of the superior temporal gyrus (20).

Thus, the classical zone of language, as defined by Dejerine in the late 19th and early 20th centuries, was located in the left hemisphere within the distribution of the middle cerebral artery, surrounding the sylvian fissure on the lateral surface of the hemisphere and incorporating portions of the frontal, parietal, and temporal lobes (23). The zone includes Broca's area (in the premotor region of the frontal lobe) anteriorly and Wernicke's area (auditory association cortex in the posterior portion of the superior temporal gyrus) posteriorly. Connecting Wernicke's and Broca's areas is a subcortical white matter pathway (i.e., the *arcuate fasciculus*, which is a portion of superior longitudinal fasciculus) that passes through the angular gyrus and supramarginal gyrus at the posterior rim of the sylvian fissure, where the temporal and parietal lobes come together (23). The location of these critical language areas is illustrated in Figure 13.1.

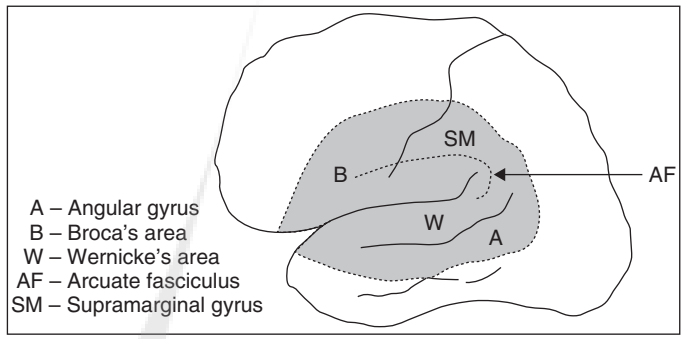

FIGURE 13.1 Diagrammatic representation of the cortical areas that are critical for language.

Source: Reprinted from Ref. (32). Albert ML, Helm-Estabrooks N. *Manual of Aphasia and Aphasia Therapy*. 2nd ed. Austin: Pro-Ed; 2004, with permission.

Since that time, much research has been done within the lesion analysis method, and some of the finer functional structures of these areas have been determined. Most recently, the development of noninvasive in vivo neuroimaging techniques, such as computer tomography (CT), positron emission tomography (PET), static and functional magnetic resonance imaging (sMRI and fMRI, respectively), electroencephalography, transcranial magnetic stimulation, and magnetoencephalography, has transformed the study of the neurologic basis of language.

In some ways, though, the anatomical localization of function has become more rather than less muddled. For example, there is a yet unresolved debate about the specific role of Broca's area during language processing (24,25). One line of research suggests that Broca's area plays a specific role in syntactic processing (26,27), whereas another line of research suggests that it serves a more general function and is responsible for a variety of tasks including working memory (24).

Behavioral data have been supplemented by functional neuroimaging (28) with increasing evidence having accrued to challenge the concept that small regions of the brain are specifically responsible for language functions such as comprehension or naming. This is not to say that brain regions do not have specific functions or that there are no neural circuits to perform these classically determined functions.

It simply appears that the homomorphic relationship between historically important brain regions and functions has broken down. The same problem holds for other brain regions, such as the thalamus, basal ganglia, and the inferior parietal lobule, and other functions (29).

Current theory therefore rejects the notion of a one-to-one correspondence between specific linguistic structural elements and focal segments of the brain. Rather, it recognizes the existence of distributed anatomical circuits, interactivity among regions, and different types of functions (28,30,31). It takes into account evidence that multiple complex and overlapping neuronal systems most likely are involved in language processing. As Albert and Helm-Estabrooks explain, the networks include cortical and subcortical components, some of which are near each other providing the basis for regional contributions to language; others are more distant, providing the basis for widely distributed parallel processing of aspects of language (32). All the regional and widely distributed networks are multiply interconnected.

Within the classical zone of language, there is extensive superposition of the neural networks critical to language. These areas of multiple overlap may correspond to what in classical neurology were called the "centers" of language (20). As these areas likely represent "critical crossroads, points of intersection, or points of integration for processing selected elements of language," a focal lesion in one of these critical locations could potentially result in a predictable aphasia deficit (32).

The Aphasia Syndromes: Assessment and Differential Diagnosis

Over the past 150 years, aphasiologists have developed several taxonomies for distinguishing various aphasia subtypes. These classification systems range from simplistic severity systems to more complex syndrome approaches (33). Perhaps the most widely used classification system is the Boston classification system, so named because it was based on early classical descriptions of aphasia subtypes and brought to the fore in the 1960s by Boston-based aphasiologists including Geschwind, Benson, Goodglass, and Kaplan (34,35). This classification system applies the early connectionist descriptions of aphasia subtypes and cortical syndromes and is still in use today by many practitioners.

Although there are compelling arguments both for and against classifying in aphasia, the use of some common classification system helps the clinician understand the basic relationships between the aphasia syndrome, various patterns of language impairments, and their source in the central nervous system (32). In addition, it provides a common language for the efficient communication of patient information within and across professional disciplines. Therefore, the assessment and differential diagnosis of the aphasia subtypes is presented first, and cautions about the application of the classification system are discussed in the following section.

Syndrome Classification of Aphasia

Three language behaviors are helpful in classifying aphasia by syndrome: fluency of verbal output, auditory comprehension, and repetition.

Assessment of Fluency

Nonfluent aphasia is characterized by language output that is slow, labored, and effortful. The individual may have difficulty initiating speech, and agility of the articulatory movements is reduced. Phrase length is short, and agrammatism is typically present. In contrast, fluent aphasia is characterized by normal prosody, easy articulation, adequate phrase length, and varied syntax.

Phrase length has been defined as the number of words produced continuously without a significant pause. However, there is variability in aphasia fluency, which is affected by several factors including the emotionality of the topic, memory demands, and vocabulary constraints. To more objectively determine phrase length, using the best average phrase length from three different narrative tasks such as describing a picture, responding to an open-ended question (e.g., What happened to you?), and responding to a historical question of emotional significance (e.g., Where were you on September 11, 2001?) has been suggested (32). A best average phrase length of five words or less is categorized as "frankly nonfluent," whereas a best average phrase length of nine words or more is categorized as "frankly fluent." Patients who are nonfluent usually have a lesion anterior to the central sulcus, and these include Broca's aphasia, transcortical motor aphasia, and global aphasia. Those with fluent aphasia typically have a lesion posterior to the central sulcus. The fluent aphasias include Wernicke's aphasia, conduction aphasia, transcortical sensory aphasia, and anomic aphasia. A third group with a best average phrase length of 6 to 8 words is called "borderline fluent" and may include individuals with nonfluent aphasia who have demonstrated some degree of recovery as well as individuals with aphasia resulting from subcortical strokes (32).

Assessment of Auditory Comprehension

The second differentiating language behavior is auditory comprehension. Auditory comprehension is poor in individuals with global aphasia, Wernicke's aphasia, and transcortical sensory aphasia. Although auditory comprehension is relatively good in the other types of aphasia, difficulties may occur with understanding more complex information such as multistep commands or a lecture. Therefore, assessment requires several tasks that range in difficulty from the single word to lengthy complex materials. Auditory comprehension is often assessed with questions that require a "yes/no" response. In these cases, it is important to ensure that the person does indeed have a reliable "yes/no" response—either verbal or nonverbal (e.g., nodding the head, thumbs up or down, pointing to the written word *yes* or *no*). As there is always a 50% chance of getting the response correct, some tests present pairs of questions, both of which must be

answered correctly for credit to be given. At the single-word level, comprehension tasks usually include identification of different objects, actions, body parts, colors, and numbers, as word frequency and semantic class influence comprehension. The ability to follow single and multistep commands should also be assessed; however, when responses require body movements or object manipulation, some individuals may fail because of their motor/limb apraxia and not because of their aphasia. At the level of complex, lengthy material, it is important to consider the familiarity of the topic, the context in which the material is presented, and whether the questions or discussions are based on factual or implied and inferential information.

Assessment of Repetition

Repetition is the third language behavior that can assist with the classification of aphasia. In particular, the presence of relatively preserved repetition skills can help identify the transcortical aphasias, whereas relatively poor repetition skills in an individual with fluent aphasia may help differentiate conduction aphasia from anomic aphasia. Repetition tasks should include words of different semantic categories and frequencies and different syllable length and phonological complexity as well as phrases and sentences of different length and complexity. When making a differential diagnosis, the examiner should consider the relative preservation or disturbance of repetition skills as compared to spontaneous conversational speech. Many problems with repetition appear to relate to limited working memory for different types of linguistic fragments.

Table 13.1 describes each of the classical aphasia syndromes and illustrates how fluency, comprehension, and repetition are differentially impaired in each type of aphasia.

Assessment of Aphasia: Other Considerations

Word Retrieval. Word-retrieval problems are a core feature of aphasia. However, as they are present in all aphasias, they do not serve to distinguish among aphasia types. Nevertheless, assessment of their severity (which may range from mild difficulty in producing a desired word during conversation to virtual inability to produce the target word in any conditions) and an analysis of the types of naming errors that occur are important for treatment planning. In addition, it is important for the practitioner to ascertain that the word-finding problems are independent of other causes such as memory problems, thought disorders, or confusional states (32). There are several ways to assess word retrieval, including presentation of objects and pictures for naming, using pictured scenes and free recall tasks such as conversation, or explaining directions for a familiar route or the procedures for completing a familiar task (e.g., making a sandwich), which allow the clinician to observe the naming difficulties in connected language. Generative naming or word-fluency tasks in which the person is asked to name as many items as possible within a particular category (e.g., animals, words starting with a specific letter) may also be used.

Reading and Writing. Similarly, virtually all individuals with aphasia display reading and writing problems, although the assessment of reading and writing skills does not contribute to the differential diagnosis of the classical aphasias. Most standardized tests of aphasia include tasks that assess reading comprehension and written expression at different levels of complexity beginning with single letters and moving to word, phrase, sentence, and paragraph levels. In addition, there are tests that are specifically aimed at assessing these skills, and a comprehensive treatment plan for aphasia should address treatment of the reading and writing problems.

Standardized Tests of Aphasia. A variety of standardized tests have been developed specifically for the assessment of aphasia. Table 13.2 lists those that are commonly used in clinical practice and characterizes the language functions that they assess. In addition to these formal tests, clinicians also use informal tasks to assess functional everyday performance; selection of these tasks depends on the individual patient's communication needs and goals.

Cognition. Although aphasia is a language disorder, examination of all domains of cognition is important for successful rehabilitation of the person with aphasia. The ability to maximize the use of residual language, compensate for language deficits, and return to independence depends to a large extent on the integrity of other aspects of cognition, which can be used to assist with communication and other functional activities of daily living. However, accurate assessment of cognitive skills in the presence of aphasia is a challenge, as many neuropsychological tests depend on language skills to varying degrees, thereby making them less reliable for use with patients with aphasia. The Mini-Mental State Examination (36), commonly used in the assessment of dementia, has poor validity for patients with aphasia who, for example, may be fully oriented to place and time but are unable to state or write the month, day, facility name, and so forth.

A commonly used test of nonverbal cognitive ability is the Ravens Colored Progressive Matrices (RCPM) (37), a test of visual analogic thinking that uses design patterns and requires a pointing response. In fact, a portion of this test has been integrated into the Western Aphasia Battery (38,39), which, in addition to yielding an aphasia quotient, also provides a cognitive quotient (CQ) score. The CQ represents a summary of scores from the RCPM together with constructional, visuospatial, and calculation tasks. In addition, the Cognitive Linguistic Quick Test (40) was designed for individuals with aphasia and provides a screening of the areas of attention, memory, and executive skills.

Classifying Aphasia Syndromes: Cautions

There are as many reasons not to use classification systems in aphasia as there are arguments in its favor; even the authors of this article are not in agreement on this issue. However, use of such systems represents a valuable shorthand, and even if these systems do not have strong validity for neurolinguistic research (41–43), they may have some advantages in the clinical setting.

TABLE 13.1 Characteristics of the Cortical Aphasias

TYPE OF APHASIA	FLUENCY	ORAL EXPRESSION: OTHER FEATURES	AUDITORY COMPREHENSION	REPETITION
Broca's aphasia	Nonfluent. Slow and effortful output. Short phrase length (less than 4 words). Disrupted prosody of speech.	Agrammatism—uses primarily substantive content words (nouns, verbs) with few function words (pronouns, prepositions, articles). Most sentences are simplified. May have an associated apraxia of speech.	Relatively good comprehension except for sentences that involve syntactic complexity.	Poor.
Wernicke's aphasia	Fluent. Well-articulated speech, often produced at an increased rate. Phrase length greater than four words.	Paraphasic errors (sound substitutions). In the severest cases, neologisms may dominate so that output consists of prosodic fluent-sounding jargon. In other cases, speech may be characterized as empty (lack of content words, perseverations).	Poor. Do not self-monitor and are often unaware that they are not communicating information.	Poor.
Anomic aphasia	Fluent. Word-finding pauses may interrupt speech flow, but average phrase length is within normal ranges.	Uses grammatically correct sentences. Clear difficulty finding words. May circumlocute or use nonspecific terms (e.g., thing, this, that) when they cannot find the word they want.	Good.	Good.
Conduction aphasia	Quite fluent with normal average phrase length. May be word-finding pauses. Attempts to self-correct phonemic paraphasias may also disrupt the fluency of speech.		Good but may show verbal short-term/working memory deficits.	Poor. Major deficit is the inability to repeat.
Global aphasia	Nonfluent. Severely impaired.	Stereotypic utterances may be present. They are produced during attempts to verbalize and consist of repetitive nonsense syllables or real words, often well articulated with prosodic variation.	Severely impaired.	Severely impaired.
Transcortical motor aphasia	Nonfluent. Slow and effortful output. Short phrase length (less than 4 words). Disrupted prosody of speech.	Impaired initiation of verbal output. Agrammatic.	Relatively good comprehension, except for sentences that involve syntactic complexity.	Major characteristic is the good repetition in relation to speech output.
Transcortical sensory aphasia	Fluent. Well-articulated speech, often produced at an increased rate. Phrase length greater than four words.	Paraphasic errors—includes both sound and word substitutions.	Poor. Do not self-monitor and are often unaware that they are not communicating information.	Major characteristic is the good repetition.
Mixed nonfluent aphasia	Nonfluent. Verbal output may be limited to stereotypic utterances, but sometimes meaningful speech is produced with articulatory effort.	Phonemic paraphasias and perseverations. Severity lies somewhere between global and Broca's aphasia; may occur as the patient recovers from global aphasia.	Auditory comprehension poor but not as severely impaired as in global aphasia.	Poor repetition.

Even a major proponent of the classification system suggests that clinicians use the system cautiously, stating that syndromes are simply suggestive of a given behavior profile and should not be rigorously applied (33). He lists several limitations, which include the following:

- Syndromes must not be tied firmly to a given site of lesion. As previously described, current theory in aphasia rejects the notion of a one-to-one correspondence between specific linguistic structural elements and focal segments of the brain. Rather, one should understand that specific regions of the brain are an essential or critical element in a widely distributed neural network; it is not the case that a particular language skill that is now deficient resides in a particular part of the brain.
- Syndromes are not static—as a person recovers, he or she may evolve from one syndrome to another, even though the anatomical locus of the lesion does not change.
- Within a given syndrome, individuals with aphasia may exhibit a wide variety of severity and symptoms.
- Not all individuals with aphasia are classifiable. Approximately 80% of individuals with aphasia conform roughly to the aphasia syndrome and anatamoclinical scheme (32). Individual differences in brain structure, lesion size and location, and etiology, as well as factors such as age, handedness, prior brain damage, presence of seizures, depression, or other medical or psychiatric disorders, may all influence brain–behavior relations.

Finally, it should be noted that this connectionist classification scheme was developed to address the cortical aphasias, yet aphasia-producing lesions may not be limited to the cortex. Lesions to the thalamus and anterior and posterior capsular putamen may also result in an aphasia that is not classifiable using the scheme (29,44,45).

Despite these limitations and cautions, the most common tests of aphasia (Western Aphasia Battery and Boston

Diagnostic Aphasia Examination) (39,46) are based on this schema. Indeed, as Brookshire (41) observed, "the connectionist model is in many respects a fiction, but it remains a useful one" (p. 176).

Recovery and Prognosis

Individuals with aphasia and their family members frequently want an assessment of prognosis. For the clinician, reliable information regarding factors associated with both positive and negative recovery impacts prognostic determination, its application to family counseling, and clinical decision making, particularly in identifying candidates for treatment. Discussions about recovery and prognosis focus on three key interrelated questions: How much recovery can be expected? What is the timecourse of recovery? Will therapy have an impact on recovery? In addition, there are many different outcome areas that can be assessed, so another question relates to which particular factors are being referred to in the discussion on prognosis (e.g., improvements in specific language modalities, improvements in communication skills, and/or improvements in quality of life).

Factors Affecting Prognosis

Basso (47) has differentiated between neurologic and anagraphic factors, which may serve as indicators of prognosis. Neurologic factors are related to etiology, size and site of lesion, and severity and type of aphasia. In addition, through modern neuroimaging technologies, there has been an increased focus on pathophysiological indicators of recovery, the long-term cerebral changes related to resolving aphasia, and the neurophysiological consequences of therapeutic interventions. Anagraphic factors include personal characteristics such as age, sex, handedness, and health status.

Neurologic Factors

One of the difficulties encountered in research on aphasia recovery and prognosis is that many of these factors are interrelated. For example, the site of lesion determines to some extent the type of aphasia; the size of lesion and type of aphasia have some implications for severity; and the type of aphasia may not be independent of age. Consider, for example, the discussion on initial severity of aphasia, lesion size and location, and their impact on recovery. Some researchers have found that initial aphasia severity is the single most important factor for ultimate language function (48,49); others have found that lesion size exerts a negative influence on recovery (48,50–54). Although the negative effect of extent of lesion on initial severity of aphasia is unquestionable, once initial severity has been taken into account, the effect of lesion size on recovery may not be clear-cut (47).

In a series of studies that looked at location and extent of lesion on CT scans and the severity of impairment in different groups of aphasic individuals, Naeser and colleagues indicated that rather than total lesion size, it is the size of the lesion within specific areas that may affect recovery from aphasia (55–57). In their study of 10 patients with Wernicke's aphasia, there was no correlation between total temporoparietal lesion size and severity of auditory comprehension dysfunction (56). However, a correlation was found between the amount of temporal lobe damage within Wernicke's area and severity of auditory comprehension dysfunction. If damage was in half or less of Wernicke's area (defined as the posterior two-thirds of the superior temporal gyrus), patients exhibited good comprehension at 6 months after onset. If the lesion involved more than half of Wernicke's area, patients exhibited poor comprehension, even at 1 year after onset. Furthermore, anterior–inferior temporal lobe extension into the middle temporal gyrus area was associated with particularly poor recovery (56).

Similarly, Kertesz and colleagues correlated outcome measures of aphasia severity and comprehension with lesion extent in 22 patients with Wernicke's aphasia (54). Like Naeser et al., they found that the extent of involvement within specific structures, rather than overall lesion size, contributed to the prediction of language recovery (54,56). The angular gyrus and the anterior mid-temporal area were important for overall language recovery, whereas the extent of involvement of the angular gyrus contributed most significantly to recovery of auditory comprehension at 1 year.

Time Frame of Recovery

Expectations for recovery include not only the amount of recovery but also the time frame in which recovery can be expected. Historically, recovery was thought to be complete by 3 to 6 months after stroke. However, more recent research indicates that recovery from aphasia continues throughout the life of the person and that the benefits of rehabilitative intervention also continue throughout this entire period.

Hillis and Heidler have suggested that functional recovery from aphasia involves at least three overlapping stages, which extend over years (58). The acute stage, occurring in the first few days after stroke, involves the recovery of transiently impaired neural tissue in the ischemic penumbra, the area of the brain surrounding the core infarct. Although this area receives sufficient blood to survive, it is not enough to function. Restoration of function occurs only following increased blood flow to this area. The second stage of recovery begins within days of the stroke; continues for weeks, months, or possibly years after onset; and involves reorganization of structure/function relationships. When the reorganization is complete, further recovery (the third stage) depends on establishing new pathways for processing components that were "cut off" by the brain damage as well as learning compensatory strategies to facilitate more effective communication.

Neurophysiology of Recovery and Rehabilitation

Neuroimaging studies are increasingly being used to examine changes in brain activation patterns after left hemisphere stroke and aphasia. Despite a number of studies, much remains to be uncovered regarding the complex process of cortical reorganization of language-related brain regions

during recovery from aphasia and the effects of therapeutic interventions on brain systems involved in language processing.

A fascinating issue relates to the degree to which language improvement during recovery and rehabilitation is sustained by left hemisphere zones spared by the lesion, by recruitment of homologous right hemisphere regions, or both. Several of the earliest imaging studies in recovering aphasic patients have reported shifts in activation to the homologous right-side territories and have interpreted these as compensatory (59–63). However, a number of research findings and dynamic models of recovery have challenged this view. Some authors have suggested that right hemisphere activation during functional imaging indexes a maladaptive response reflecting loss of active transcallosal inhibition (64–66).

But the picture is much more complex than this. The apparent contributions of the left and right hemispheres depend on when they are measured, with early activation in the right hemisphere (67–70) remaining prominent over time only with the most severe left hemisphere injury (68,71–73). Further, the left and right hemispheres do not behave as unitary organs, with different parts of the hemispheres contributing differentially depending on individual characteristics. For example, one interesting patient showed benefit from inhibitory stimulation to the right inferior frontal gyrus, yet showed worsening aphasia following a subsequent right hemisphere infarction (74). It is important to reiterate that imaging studies will show different brain responses over time, reflecting brain remodeling and reorganization processes that eventually lead to regional contributions from a variety of areas in the left and right hemispheres (75–78). The net result of this process is a reorganized network that depends on individual patient characteristics, including size and location of initial infarction and premorbid neural status, reflecting adaptive capacities of perilesional tissue and of other ipsilesional and contralesional brain regions (79–81).

Studies that directly assess functional anatomical changes occurring with language therapy are emerging, but there remains no consensus. The earliest literature reported single cases or small numbers of cases (64,82–87) and focused more on issues of laterality than on complex patterns and time courses of recovery. This research suggested positive responses in the left hemisphere with speech and language treatment. Two of the studies found that post-therapy patterns were consistent with task-dependent activity in healthy adults (82,84), one found increased activity in the perilesional cortex (83), and one found that individual variability trumped these generalizations (87). Right hemisphere activations in a variety of areas were also reported (85–87).

More recent studies reporting biological changes with therapy in more than a few patients (88,89) have shown complex patterns of remodeling across individuals and have supported theories on the importance of the preserved left hemisphere in the very best recoverers.

Clearly, many questions remain regarding recovery and the effect of rehabilitation on patterns of language organization. Nevertheless, there is a long history of behavioral treatments for aphasia, which are presented in the following text with a discussion of treatment efficacy and outcomes.

Approaches to Aphasia Rehabilitation

Taxonomy of Language Remediation Approaches

There have been several attempts to categorize the numerous treatment techniques and procedures for language remediation in adults with aphasia. For example, a literature review of articles that were published in 5 major journals and that spanned approximately 20 years (1971–1991) identified 6 broad models of aphasia treatment, each of which is discussed in the following text (90). More recently, Basso (91) presented a general taxonomy of approaches to and theoretical underpinnings of aphasia rehabilitation, based on historical trends in the latter half of the 20th century. Interestingly, her taxonomy closely agrees with the categories identified previously (90). Yet any taxonomy is a simplification—it is not always clear where one approach ends and another begins, so some specific treatments may be consistent with more than one approach. For example, Horner and colleagues note that of the articles they reviewed, the majority (21.7%) used a hybrid or multitheoretic approach (90). Other language therapies may not fit into any of the approaches, particularly when therapies from different countries worldwide are considered (92). Nevertheless, the following six categories serve as an initial guide to the rich and varied treatments for aphasia. Selection of treatments occurs with consideration of patient-specific factors such as type, severity, and chronicity of the aphasia; the presence of associated impairments; and the patient's communication environment.

Stimulation–Facilitation Approach

The stimulation–facilitation approach is a name often used synonymously with that of Hildred Schuell, who proposed and supported this approach (93,94). It is based on the philosophy that in aphasia, language is not lost, but rather cannot be accessed. Aphasia is considered to be unidimensional in nature, so individuals with aphasia share many similarities in behavioral impairment and differ only in terms of severity. Therefore, regardless of the type of aphasia or site and size of the neurologic lesion, language rehabilitation can be essentially the same for all patients.

As the auditory modality is of prime importance in language processing and is also a key area of deficit in aphasia, treatment involves repetitive intensive auditory stimulation. The presentation of the auditory stimulation, which is designed to elicit a maximum number of responses, is sometimes paired with stimulation in other modalities. Error responses occur when stimulation is insufficient. Therefore, they are not corrected but are followed by additional stimulation, which if adequate, is likely to elicit the correct response. Although the assumptions underlying this approach have undergone serious debate, the stimulation method has been the predominant approach to treatment in the United States since the 1960s.

Modality Model Approach

In contrast to the premise that aphasia is unidimensional, proponents of the modality model view language as modality bound and aphasia as a modality-specific performance deficit involving one or more modalities. The goal of treatment is to remediate the specific input or output modalities, singly or in combination. One way that this can be accomplished is by systematically pairing weak and strong modalities to "de-block" impaired performance. This principle can be applied regardless of the specific modality that is being treated. For example, when confrontation naming is difficult, repetition may be used to help the patient produce the correct response; then, immediately after de-blocking has occurred through the use of repetition, the target response may be accessed in the previously inaccessible modality (i.e., confrontation naming) (95).

Luria's functional reorganization approach, which has widely influenced aphasia research and therapy, is consistent with the modality model. According to Luria, when brain tissue is destroyed, its original function cannot be restored to its previous form, but it can be performed by means of a partially new neural organization (96,97). Therapy therefore is directed toward reorganization and transfer of the function to other brain structures or functional systems. With intersystemic organization, new functional systems are created through the use of other undamaged links. With intrasystemic organization, the impaired function is carried out at a different level of the same functional system, either at a lower and more automatic level or at a higher and more voluntary level. Precise identification of which modalities are damaged and which are preserved makes it possible to develop and implement different training procedures.

Processing Approach

The processing approach is based on the cognitive neuropsychological models of normal language processes that have been developed for specific language tasks such as reading, spelling, naming, or sentence production (98). These information-processing models assume that a complex cognitive function consists of a system of distributed and interconnected modules or mental representations that allow processing of different types of information in cascade fashion. The representations and processes do not necessarily correspond to locations in the brain, but reflect functional components of a cognitive operation. Rehabilitation begins, for each individual patient, with identification of which cognitive processes and representations underlying the language task are impaired and which processes and representations are intact. For example, the task of reading words aloud involves the graphemic input lexicon, whereas repetition of words involves the phonological input lexicon. However, both tasks involve the semantic system and the phonological output lexicon. By comparing performance across tasks, inferences about the integrity of these cognitive processes can be made. Treatment then focuses on either the remediation of the impaired cognitive processes, compensation via the intact cognitive processes, or both. The primary contribution of the processing approach is that it guides the choice of interventions; however, it does not provide direct motivation for specific treatment strategies (98). There are many studies, mostly single case descriptions, in which cognitive analyses have been used to focus treatment (99); examples can be found in Hillis (2002).

Nondominant Hemisphere Approach

Several treatment approaches are based on the premise that the hemisphere that is nondominant for language has specific abilities, such as visual–spatial, affective–prosodic, and paralinguistic abilities, that can be used to facilitate communication. Melodic intonation therapy (MIT) is perhaps the best known of these treatment approaches (100–103). MIT is a hierarchically structured program that uses intonation and rhythm to increase the patient's ability to independently produce high-probability phrases and sentences. The steps of MIT range from intoning a melodic line with synchronous left-hand tapping to answering questions using drilled phrases and sentences. MIT may be most appropriate for those with large left hemisphere lesions whose recovery may depend more on the right than the left hemisphere (104); some limited evidence for its efficacy has recently emerged (105). Other remediation approaches that are consistent with the nondominant hemisphere mediation model utilize drawing as a communicative function (106,107) and encourage humor within the therapy session (108).

Linguistic Approach

The linguistic (neurolinguistic) approach is based on the principle that language has an internal organization that can be described by a specialized system of rules. In aphasia, there is disruption of lexical–semantic, syntactic, and/or phonologic performance. Treatment therefore focuses on restoring language performance using neurolinguistic principles that are specific for each linguistic impairment. For example, the sentence production program for aphasia systematically trains syntax using a story completion format (109). Selection of syntactic structures was based on a study of agrammatism that identified a hierarchy of difficulty across 14 grammatical constructions, with imperative intransitive statements being the easiest and future tense statements being the most difficult. Another sentence-production training approach, cuing verb treatments, is based on the notion that the verb is the central constituent in sentence structure (110). In this approach, verbs are presented as the central core of the simple active sentence; patients are trained to produce the verb and, in response to a "wh"-question cuing strategy, also produce specific sentence constituents (usually noun phrases) that are assigned to various thematic roles by the verb (e.g., agent, theme). A recent extension of this treatment is called Verb Network Strengthening Treatment (VNeST) (111,112). The basic task of VNeST is to generate agent and patient pairs to a target verb (e.g., chef/sugar, carpenter/lumber, surveyor/land for measure) with the intent of strengthening the connections between the verb and its thematic roles.

Based on aspects of formal linguistic theory and neurolinguistic research, and consistent with Chomsky's conceptual framework, Thompson and colleagues have developed a series of treatment strategies to improve sentence comprehension and production of complex sentences such as "wh"-questions and passives (113–115). Of particular clinical relevance is a finding that has been called the "complexity hypothesis" (116,117). The hypothesis suggests that there is more generalization of improvements from treated to untreated grammatical forms when treatment begins with more complex structures than when treatment is limited to simple forms. This contrasts with traditional treatment, which typically is hierarchically organized and starts at a simple level and gradually increases in level of difficulty.

A similar finding has been noted in the area of semantics. There is an extensive literature examining recovery of naming in patients with aphasia (118,119). One form of treatment, called semantic feature analysis, was developed to strengthen the semantic attributes or features of target words (120–124). The treatment involves repeated practice associating the target word with its various defining characteristics (e.g., *robin: has wings, has beak, lays eggs, flies, is small, builds nest, lives in trees, is a bird*). More recently, it has been demonstrated that when the treatment uses target words that are less typical of their category and therefore more complex (e.g., *penguin, ostrich are not typical of birds because they do not fly or live in trees*), generalization of treatment effects is greater than when typical targets are used (125–128). This hypothesis has been called the "semantic complexity hypothesis" and provides further support for the notion that treatment should not necessarily be provided in a hierarchical fashion from easy to more difficult (125–128).

Functional Communication Approach

In the functional communication or pragmatic approach, therapists are no longer interested only in the accuracy of the linguistic message, but rather focus on the patient's ability to communicate the intent of the message. Communication involves more than just speaking and understanding, but reflects the application of pragmatic rules and the ability to use language in a context. Therefore, treatment includes compensatory strategies for circumventing communication breakdown as well as strategies for communication breakdown repair. One of the best-known pragmatic approaches is PACE (Promoting Aphasic's Communicative Effectiveness) (129). In the PACE technique, four major treatment principles have been delineated in an attempt to incorporate rules of natural communication into semistructured treatment: the clinician and patient participate equally as senders and receivers of messages; the interaction incorporates the exchange of new information between clinician and patient; patients freely choose the channels through which they will communicate—words, gestures, drawing, or any other communication device; and the clinicians' feedback is based on the patient's success in communicating the message.

Other approaches such as practicing scripted conversations (130–134), ensuring a positive communication environment by training communication partners to use conversational supports (135), extending treatment into natural communication settings including aphasia communication groups (136), and removing environmental barriers to participation in community activities (137) may also be considered "functional" approaches. However, the term "social approach" may better describe some of these treatments, as they are *explicitly* designed to improve communication, life participation, and/or personal well-being (138–143).

Life Participation Approach to Aphasia

Recently, an umbrella philosophy called the life participation approach to aphasia (LPAA) has fueled even greater interest in the social approaches to the management of aphasia (139). The LPAA is a set of values that guides intervention, assessment, and research. It calls for a broadening and refocusing of clinical practice, suggesting that the focus of aphasia treatment should be on "re-engagement in life" for the person with aphasia.

The LPAA has applicability throughout and beyond the period of formal rehabilitation, beginning with initial assessment and intervention and continuing, after hospital discharge, until the person with aphasia no longer elects to have communication support. All those affected by aphasia are regarded as legitimate targets for intervention, including not only the person with aphasia but also family members, coworkers, and individuals in the community who may interact with the person with aphasia. According to the LPAA, treatment includes facilitating the achievement of life goals. Therefore, in addition to work on improving and/or compensating for the language impairment, clinicians should be prepared to work on anything in which aphasia is a barrier to life participation, even if the activity is not directly related to communication. This may include targeting environmental factors outside of the individual, as a highly supportive environment can lessen the consequences of aphasia on a person's life, whatever the language impairment (139).

Biological Approaches to Language Remediation

As we acquire new knowledge about aphasia and brain–behavior relations, additional approaches to treatment that are not easily categorized with the present taxonomy are emerging. For example, Small has advocated for a biological model of aphasia rehabilitation in which the goal of remediation is to alter brain anatomy and physiology so that language function can be restored (144,145). To effect the necessary neural changes, both novel biological treatments and speech–language treatment are necessary. The biological treatment stimulates or repairs the injured brain area, while the language treatments are provided to retrain the new circuitry and integrate it with the preserved, existing tissue.

Pharmacotherapy

Pharmacotherapy is the most frequently used biological therapy for aphasia. To date, the majority of studies have

TABLE 13.3 Drugs With Potentially Deleterious Effects on Stroke Recovery

- Benzodiazepines
- Clonidine
- Haloperidol
- Phenothiazines
- Phenytoin
- Prazosin

investigated the effects of four groups of neurotransmitters on language deficits in aphasia (146,147). These include the following: dopamine agonists such as bromocriptine (148–152); dextro-amphetamine and other agents that affect catecholamine systems (153,154); cholinergic medications such as donepezil (155,156) and galantamine (157), acetylcholinesterase inhibitors; and the nootropic agent, piracetam (158,159). A recent study evaluated the NMDA receptor antagonist memantine (160). Systematic reviews of this literature have concluded that efficacy of pharmacologic agents remains questionable, although some appear to have promise (146,147). However, the majority of the studies concerned the chronic stage of aphasia, and the authors suggest that the adjuvant pharmacologic treatment may best be applied before most neural reorganization has taken place. Treatments are notably ineffective (at worst) and less efficient (at best) when given alone than with associated speech language therapy (146). This finding resonates with Small's suggestion that pharmacologic treatment has promise but only when accompanied by concomitant language therapy (144,145,147).

Any discussion of aphasia and pharmacology must also consider the deleterious effects that some drugs may have on stroke recovery, including aphasia recovery. A retrospective study of medication use during aphasia rehabilitation indicated that more than 80% of all patients were taking some medicine at the time of their stroke and that 65% were taking multiple medications (161). Included in this list were such drugs as adrenergic blockers and benzodiazepines, which are known to impede stroke recovery in animal studies. Deleterious effects have been reported for neuroleptics (haloperidol), thiazides, and tricyclic antidepressant agents (161,162). Therefore, drugs that potentially interfere with catecholaminergic or GABAergic function or are thought to delay recovery by empirical study (i.e., the drugs in Table 13.3) should be avoided, if possible, during aphasia rehabilitation (43).

Cortical Stimulation

A relatively new area of investigation is the direct application of stimulation to the cerebral cortex to facilitate brain plasticity and enhance stroke recovery. There are several methods of delivering cortical brain stimulation transcranially—these include direct epidural cortical stimulation (163,164), repetitive transcranial magnetic stimulation (rTMS) (165–168), and transcranial direct current stimulation (tDCS) (169,170), each of which have been applied to the rehabilitation of language after stroke. Results suggest a potential role for cortical stimulation as an adjuvant strategy in aphasia rehabilitation.

There is only one study that assesses the safety and efficacy of direct epidural cortical stimulation in combination with intensive speech–language therapy on individuals with chronic aphasia (163,164). Eight participants received intensive behavioral therapy using a combination of articulation drills, oral reading, and conversational practice, delivered 3 hours daily for 6 weeks. Four of these participants also underwent fMRI-guided surgical implantation of an epidural stimulation device, which was activated for all therapy sessions. Behavioral data were collected before treatment, immediately after treatment, and at 6 and 12 weeks following the termination of therapy. Imaging data were collected before and after treatment. Results indicated that investigational subjects showed a mean aphasia quotient change of 8.0 points immediately after therapy at 6-week follow-up and 12.3 points at 12 weeks. The control group had smaller mean changes of 4.6, 5.5, and 3.6 points, respectively. Similar changes were noted on subjective caregiver ratings of the participants' language and communication skills, with larger changes being noted for the investigational group as compared to the control group at all time points. Functional imaging suggested increased consolidation of activity in interventional subjects. Therefore, though behavioral speech–language therapy improved the nonfluent aphasia, independent of cortical stimulation, the epidural stimulation of the ipsilesional premotor cortex may have augmented this effect. The largest effects between the groups were evident after completion of the therapy. The neural mechanisms underlying these effects were manifested in the brain by decreases in the volume of activity globally and in particular regions. Although the number of patients enrolled in this trial precludes strong conclusions, epidural stimulation could play an adjunctive role in the treatment of nonfluent aphasia.

Although further investigation of the effects of direct epidural cortical stimulation is warranted, the clinical applicability of this procedure may be limited by the invasiveness of the procedure, which requires neurosurgical implantation of the electrodes. A less invasive therapy for language remediation in aphasia is repetitive rTMS (165–168). Based on the premise that overactivity of the right hemisphere language homologues may be maladaptive and interfere with, rather than promote, aphasia recovery, rTMS was applied to the right hemisphere to reduce its cortical excitability. Preliminary results obtained in four individuals with chronic nonfluent aphasia indicated improved picture naming following 10 sessions of rTMS (165).

tDCS may also have potential for clinical use in view of its noninvasive application, ease of administration, and relatively low cost. tDCS is a method of delivering weak polarizing electrical currents to the cortex via two electrodes placed on the scalp: an active electrode placed on the site overlying the cortical target and a reference electrode usually placed over the contralateral supraorbital area. The nature of the

effect depends on the polarity of the current. Anodal tDCS has an excitatory effect believed to result from the partial depolarization of superficial cortical axons, whereas cathodal tDCS induces inhibition via presumed hyperpolarization. Studies on the efficacy of tDCS are emerging (169,170), and may, in the future, provide promise, especially when linked with intensive language treatment.

Treatment Intensity, Constraint-Induced Aphasia Therapy, and Computers

Regardless of the treatment approach, a critical question remains regarding how much treatment is optimal and at what frequency. The question of treatment intensity is of considerable importance in the light of recent work in neuroscience demonstrating that the neuroplasticity of the adult brain can be impacted by several experience-dependent principles, including intensity of training (171). In addition, a growing literature suggests that with intensive treatment, individuals with chronic aphasia continue to demonstrate language recovery for years after stroke. For example, Bhogal et al. (2003) conducted a literature review which suggests that intensive speech–language therapy delivered over a short period of time (average of 8.8 hours per week for 11.2 weeks) resulted in significant improvements, whereas lower-intensity therapy provided over a longer period of time (average of 2 hours per week over 22.9 weeks) did not result in positive change (172).

Pulvermuller, Meinzer, and their colleagues have spurred increased interest in treatment intensity with their studies of constraint-induced language therapy (CILT) for individuals with aphasia (173–177). With CILT (also called Intensive Language Action Therapy), verbal responses in an interactive communication context (e.g., requesting cards) are elicited through modeling and shaping. Importantly, responses are constrained to the verbal modality, that is, there is "forced use" of verbal productions, whereas use of other communication modalities is discouraged. In addition, CILT emphasizes the importance of massed practice, and treatment is typically provided on an intensive schedule, 3 hours per day for 2 weeks. Despite positive findings reported for CILT, it has been difficult to determine whether the treatment results emanate from the constrained forced language use, the intensity of the treatment schedule, or a combination of these two factors (178–179).

Nevertheless, it is generally agreed that intensity of speech–language therapy is an important component of aphasia intervention (179–181). However, providing intensive treatment to individuals in the early acute stage may not be feasible; patients may be too ill or may not have sufficient endurance to tolerate the prescribed treatment (182). For patients with chronic aphasia, treatment can be costly, and the current health care environment in the United States does not typically recognize its value. As a result, clinicians and researchers in the field are left searching for cost-effective ways to deliver aphasia treatment. One method of providing less costly but intensive treatment is via the computer.

A well-documented body of literature supports the positive effects of computerized treatment for aphasia (183–186). Although many earlier computer-based therapy programs relied on predefined exercises that were fairly inflexible, more recent programs have been designed to allow specifically for treatment that is interactive and individualized to clients' needs. Two examples of aphasia treatment software that have undergone extensive efficacy research are AphasiaScripts™ (130–133) and SentenceShaper (187). The AphasiaScripts™ software program uses an animated agent or virtual therapist that is programmed to produce natural speech with correct movements of the speech articulators. This virtual therapist serves as the conversational partner, whereas the person with aphasia repetitively practices prerecorded individualized conversational scripts with varying degrees of support and cues that are generated by the computer (130). Similarly, the SentenceShaper helps the person with aphasia practice self-generated short stories, but without the benefit of a virtual conversational partner (187).

As computer technology becomes more accessible and researchers and clinicians continue to explore the utilization and benefit of computerized treatments in clinical practice, computer treatment is becoming more commonplace. Nevertheless, computer therapy, even when practiced by individuals with aphasia independently in their homes, does not negate or diminish the importance of the experienced practitioner. The clinician plays a critical role in all aspects of treatment planning and development, whereas the computer provides the intensive, massed practice required for automatization of the learned narrative or conversational script—a laborious and time-consuming process when provided by a therapist.

Efficacy of Aphasia Treatment

Any discussion about language remediation in adults must also address the basic question of whether aphasia treatment works. One source of confusion surrounding this issue is the concept of remediation versus eradication. At present, there is no aphasia therapy that cures aphasia. Yet there is ample evidence that frequent sessions of aphasia therapy over a long period of time can lead to continued improvement.

To date, the historical record of clinical outcomes for treatments of aphasia is extensive (188). Over time, experimental methodologies in the field of aphasia have improved (e.g., measuring the change in communication behavior from pretest to posttest; controlling for time after onset; setting clear exclusion and inclusion criteria to establish homogeneous groups; introducing no-treatment control groups or using deferred treatment groups; random assignment; and controls on the type(s), amount, and duration of treatment), so that findings have become less ambiguous and support the conclusion that treatment for aphasia is both efficacious and effective (188). Although there are relatively few randomized clinical trials of aphasia treatment (189,190), more than 100 single-subject aphasia treatment studies have appeared in the literature. In addition, meta-analyses applied to the aphasia treatment literature have concluded

that aphasia treatment is effective (191–193). In two of these meta-analyses, based on 21 studies and 55 studies, respectively (191,192), it was also concluded that recovery of treated individuals was, on average, nearly twice as extensive as the recovery of untreated individuals when treatment was begun before 3 months after onset. Treatment also brought about appreciable gains when begun after 3 months after onset, and treatment brought about significant effects even in individuals with severe aphasia.

Treatment Outcomes

Returning to the question of what constitutes "outcome" in aphasia treatment, Kagan et al. (2008) have developed a framework that serves as a guide for categorizing different measures of outcome (194). Based on the World Health Organization's International Classification of Functioning, Disability and Health (ICF) (195), the Living with Aphasia: Framework for Outcome Measurement (A-FROM) model is pictured in Figure 13.2. The A-FROM framework consists of the following overlapping domains:

- *The participation domain*: This includes the life situations specific to an individual, such as life roles (e.g., mother, teacher); responsibilities (e.g., managing finances, performing a job); relationships (e.g., engaging in conversation, making friends); activities of choice (e.g., leisure and recreation, community participation); and tasks engaged in by an individual (e.g., writing letters, cashing a check—described as "Activities" in the ICF).

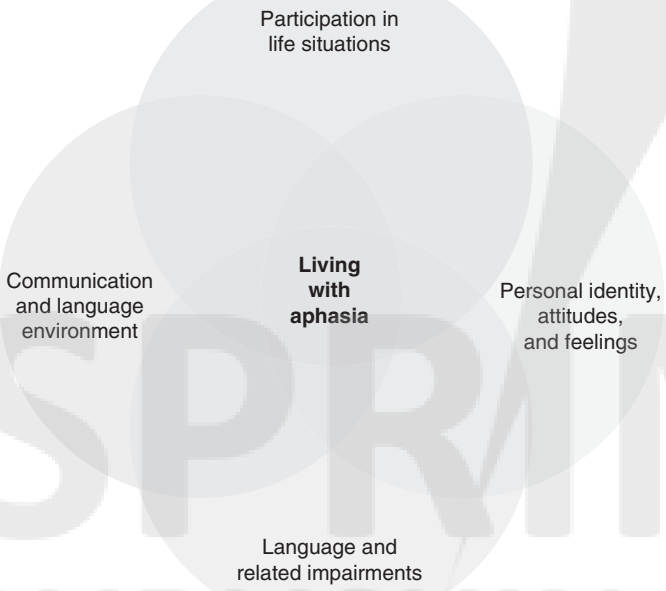

FIGURE 13.2 Living with aphasia: framework for outcome measurement (A-FROM).

Source: Reprinted with permission from the Aphasia Institute, Toronto, Canada.

- *Language and related impairments domain*: This is the correlate of the "Body Function" domain of the ICF and includes outcomes in the realm of language and cognitive processing, such as auditory comprehension (e.g., pointing to pictures named); reading (e.g., matching a written word to a picture); speaking (e.g., word finding, sentence formulation); and writing (e.g., writing the names of objects).
- *Communication and language environment domain*: This is the correlate of the ICF "Environmental Context" domain and includes aspects of external context that might facilitate or impede language, communication, or participation of people with aphasia, such as physical environment (e.g., signage, lighting, written supports); social environment (e.g., attitudes of people, skills of partners); and political environment (e.g., policies supporting participation).
- *Personal factors/identity domain*: This includes ICF factors such as age, gender, and culture, but expands the ICF domain to include internal factors that vary as a consequence of aphasia, such as confidence and personal identity.
- *Living with aphasia domain*: This is a dynamic interaction of four life domains, capturing elements of quality of life (how satisfied someone is with his or her life).

The A-FROM is not intended to be prescriptive in relation to aphasia intervention, but rather serves as a guide for selecting outcome domains across diverse aphasia interventions (194). The ultimate goal of any intervention is to make a difference to the everyday experiences of individuals with aphasia and their families, and there are multiple ways for clinicians to work toward accomplishing this (196). Thus, the A-FROM can also serve as a guide for the clinician to use when counseling patients and their families about the goals of rehabilitation and the specific focus of any one or more treatments within the context of the overriding goal of living successfully with aphasia. Although the A-FROM was developed to address specifically the outcomes of those with aphasia, its breadth makes it applicable to any type of communication disorder, including AOS and dysarthria, which are discussed in the next sections.

APRAXIA OF SPEECH

AOS is a disorder that is distinguishable at a theoretical level from both aphasia and dysarthria, but remains somewhat controversial at a more practical level. The main problem is that it still has an unclear neurologic and functional basis and has no universally agreed-upon definition (197).

Traditionally, AOS was defined as a disorder of motor programming, "an articulatory disorder resulting from impairment, due to brain damage, of the capacity to program the positioning of speech musculature for the volitional production of phonemes and the sequencing of muscle movements for the production of words" (198). More recently,

Van der Merwe (2009) has suggested that AOS is a disorder of motor *planning* rather than a disturbance in the *programming* of movements for speech. Difficulties arise at an earlier stage of speech processing in which the neural codes for specifying the spatial and temporal characteristics of the output are computed (199).

Neurologically, both hypotheses assume that specification and programming are mediated by the cortical association areas, including the lateral premotor cortex, the supplementary motor area, the prefrontal areas, and the posterior parietal areas. In contrast, some studies have observed AOS from isolated damage to the anterior portion of the insula, concluding that the insula must be damaged for AOS to occur (200,201). These findings are not without dispute, as other studies have demonstrated that AOS occurs in the absence of insular damage (202–204), and there may be alternative explanations for the data on the insula (205).

CHARACTERISTICS OF AOS

Despite the debate about AOS, there is general consensus that AOS is a disorder of articulation and prosody of speech. Numerous articulatory characteristics have been specified. For example, based on previous reports (198,206,207), Freed (2000) compiled a list of as many as 14 articulatory characteristics that occur most commonly (208). However, not all patients with AOS display all characteristics. Differences in the manifestation of AOS may be related to the possible existence of AOS subtypes, to various concomitant effects of a coexisting aphasia, to variability associated with AOS severity, or use of different compensatory strategies (8).

Nevertheless, there are some core symptoms of AOS that consistently form part of the diagnostic description, and these have been identified in a report by the Cochrane collaboration as follows (209):

- Effortful "groping" (that is trial-and-error attempts) at finding the correct articulatory positions for the target phonemes and therefore difficulty producing the correct sounds
- Inconsistent or variable errors (i.e., the same sounds are not always in error, and each attempt at a word could produce a different error)
- More consonant than vowel errors
- Articulatory errors that are characterized by perceived substitutions, distortions, omissions, and repetitions; phonemes and words often approximate the target; they sound similar but are not exactly the same as the target sound or word
- Difficulty in producing consonants that are adjacent to each other (e.g., *str*, *bl*, *kr*, *spl*) resulting in a tendency to insert additional vowels
- Awareness of errors

Prosodically, the rate of connected speech in AOS is usually slower than normal. Equal stress may be placed on the syllables in an utterance. Inappropriate pauses may occur at the start of a word or between syllables. These pauses may result from articulatory groping or because each syllable is being produced individually rather than being produced fluently by blending one syllable into another. The normal variations of pitch and loudness are restricted. In some cases, the altered prosody may lead to the perception of a foreign accent in monolingual speakers (210,211), although this may not be the only underlying mechanism of foreign accent syndrome (212). There are several explanations for the rate and prosodic abnormalities of AOS. They may be a fundamental feature of the disorder, a simple by-product of the articulation deficits, or they could reflect efforts at compensation for the articulation deficit.

An issue that is commonly discussed is whether AOS always co-occurs with Broca's aphasia or nonfluent aphasia, or whether it is isolable neurologically. Many of the articulatory and prosodic perceptual features of AOS have been confirmed by acoustic and physiologic studies (8). These studies also have provided data supporting the conclusion that many of the features of AOS reflect a phonetic disorder of motor planning and programming rather than deficits that are fundamentally linguistic in character (8,206).

In addition, Duffy (2013) asserts that most definitions of Broca's aphasia do not explicitly recognize the existence of a motor speech programming disorder, despite the description of poor "articulatory agility" and speech that is slow, labored or effortful, reduced in phrase length, and abnormal in prosody. Although these characteristics are consistent with those of AOS, individuals with Broca's aphasia also have grammatical and syntactical errors and problems with word retrieval, as well as problems with auditory comprehension, reading, and writing. Therefore, a reasonable conclusion is that patients with Broca's or nonfluent aphasia usually have AOS, but the aphasic components of Broca's aphasia include additional deficits that are outside of the definition of AOS (8).

Assessment of AOS

Most clinicians assess AOS with a comprehensive motor speech evaluation (8,208). This involves assessing muscle strength and tone and speed, range, and accuracy of movements during single and repetitive movements in both nonspeech and speech activities. It also includes specific tasks to assess phonation, articulation, resonance, prosody, and respiratory support for speech.

Tasks that require the patient to sequence speech sounds are particularly sensitive to the presence of AOS. These tasks include alternating motion rates (repetition of the same sound such as *pa*) and sequential motion rates (repetition of different sounds requiring multiple articulatory positions such as *pa-ta-ka*). Other sensitive tasks include repetition of words of increasing length (e.g., *fan*, *fancy*, *fantastic*), multisyllabic words with complex phoneme combinations, and phrases and sentences. In addition, connected speech is analyzed by asking patients to read paragraphs aloud and through spontaneous conversation.

Before making a diagnosis of AOS, it is important to rule out other conditions that may cause speech difficulties. For example, the muscle weakness and incoordination of a dysarthria can cause slow, labored, or awkward movements that result in a speech disorder. However, in AOS, the abnormal movements affecting speech are more obvious during voluntary movements. The patient may have no difficulty automatically saying *goodbye* when leaving the company of someone but may be unable to say *goodbye* out of context. Similarly, speech may sound quite good during production of automatic sequences such as counting, saying the days of the week, or reciting a familiar poem.

There are only a few published tests for AOS. These include the Apraxia Battery for Adults (213) and the Comprehensive Apraxia Test (214). Neither test provides data that discriminate impairments resulting from AOS, aphasia, or dysarthria. Therefore, the clinician must make the differential diagnosis based on observations of performance during the assessment tasks (8).

Treatment of AOS

Most treatments for AOS are behavioral, yet they are diverse in terms of their focus and theoretical underpinnings (215). Four general groups of treatments for AOS have been identified (216,217). Although these approaches are not mutually exclusive, and some treatments use a combination of techniques that cross one or more categories, the availability of a categorization scheme can be helpful for treatment planning. Importantly, almost all approaches for which there is some evidence of efficacy incorporate principles of motor learning (8).

The most common group of treatments for AOS target improved positioning and movements of the articulators and have been referred to as *articulatory kinematic* treatments (216). In general, these treatments tend to be time-intensive, repetitive, and highly structured, progressing from simple to complex verbal productions of targeted phonemes, words, and phrases. Emphasis is placed on self-monitoring and self-correction, with feedback from the clinician helping to facilitate this.

Several specific strategies are incorporated, to various degrees, into these types of treatments. During imitation, the patient simply watches and listens as the clinician provides a model that the patient then attempts to reproduce. A variation of imitation is called "integral stimulation" in which the patient is instructed to "watch me, listen to me, and say it with me" while the clinician exaggerates the presentation of the stimulus to make it as salient as possible (218,219). Another strategy is phonetic derivation, the progressive approximation or shaping of the positioning and movement of the articulators using sounds and movements that the patient can already make to teach the placement and movement of sounds that he or she cannot make. For example, patients may be instructed to put their lips together and blow to assist with the production of *p* and *b* sounds, thereby using a nonspeech posture to help produce the target speech sounds.

Phonetic placement techniques make use of explicit verbal, written, and graphic descriptions of how a sound is made in combination with physical manipulation of the articulators. An example of a program that includes direct instruction for speech production is PROMPT (Prompts for Restructuring Oral Muscular Phonetic Targets) (220). In PROMPT, the clinician provides a complex combination of auditory, visual, tactile, and kinesthetic cues to the face and neck to represent the various positions of the articulators during speech and to signify various aspects of speech production, including relative timing of speech segments.

Instrumental biofeedback such as electromagnetic articulography (EMA) has been used to provide visual feedback about articulatory movements during treatment. Kinematic and auditory perceptual data have revealed improvement in the accuracy and generalization of effects for at least some speakers and some treated sounds (221,222).

Darley et al. (1975) have emphasized the use of phonemic drills involving repeated production, as many as 10 to 20 times, of the same consonant–vowel combinations. Careful selection of the target sounds is essential (198). The drills begin with just a single vowel, and consonants are slowly added. The first consonant is typically the *m*, which is highly visible and often the easiest to produce. The position of the vowel in the word is alternated between the initial position (*ma*), the final position (*am*), and then the medial position (*ama*). Different combinations of consonant–vowel syllables that gradually increase in complexity and length are practiced before moving to real words, two-word combinations, and phrases. Similar drills have been described by Dabul and Bollier (1976), who set the criteria for each target combination of 60 one-syllable repetitions or 20 two-syllable repetitions in 15 seconds before moving to combinations at the next level of difficulty (223). Another theoretically motivated treatment approach, called Speech Motor Learning, also utilizes syllable drills (224).

Although treatment may begin at the level of the individual phoneme or speech sound, especially for more severe cases, there is general agreement that, as much as possible, target stimuli should be made up of functional words that are immediately useful to the patient (209,218). To promote generalization of sound production to words, the key word technique involves practicing the target sounds in a core vocabulary, and then expanding the limited number of words into a larger set.

Sound Production Treatment (SPT) is an articulatory-kinematic treatment that has received more extensive and systematic study than any other specific treatment for AOS (8). In SPT, movement patterns for sounds are practiced and refined by using syllables and words with minimally different contrasts (e.g., fan/van, bye/pie). Stimuli are determined by the patient's unique error patterns. Little clinical assistance is given initially but when errors occur, modeling-repetition, integral stimulation, articulatory placement cueing, and verbal feedback are provided (219,225–227).

A second group of treatments addresses speech rate and the rhythmic, temporal, or prosodic aspects of speech

production (228,229). In these techniques, an external source of control is applied to the speaker's productions, such as finger counting, hand tapping, and/or a metronome. Some studies have also used computer-generated controls of rate and rhythm (230,231). The underlying premise of these treatments is that AOS is characterized by disruptions in the timing of speech production, although the mechanism responsible for behavioral change is not well understood. Some techniques have also incorporated speech prolongation and reduced rate as part of the rhythm control. The additional slowing of speech production may provide extra time for motor planning and/or programming, as well as for processing of sensory feedback.

A third group of treatments reflects the concept of *intersystemic facilitation/reorganization*. These approaches are based on the premise of using relatively intact systems or modalities to facilitate speech production. Gestural reorganization has been studied most frequently, with the gestures serving as a relatively intact nonverbal ability that helps to reorganize speech. In most studies, the gestures are paired with verbalizations during treatment (232). The use of singing in the treatment of AOS may also be considered a form of intersystemic facilitation/reorganization (233).

The final approach to working with AOS involves the use of *alternative and/or augmentative communication* (AAC) methods to substitute for or supplement verbal communication. Selection of the AAC approach should be highly individualized and may include one or more of the following: picture and word communication books; writing or drawing; gestures; alphabet supplementation; voice output aids; and informed communication partners. Goals may vary from instruction of a consistent "yes/no" response to conversational practice and role playing in simulated situations (234,235).

As Peach (2004) points out, however, few treatments have been reported where the individual had a pure AOS (236). Usually, patients tend to have a coexisting/accompanying aphasia. Therefore, selection of treatments must consider the severity of the accompanying aphasia. There are a few treatment programs that have addressed aspects of both the AOS and the aphasia, including MIT and conversational scripting (237) discussed previously, as well as a technique called oral reading for language in aphasia (ORLA) (238). ORLA combines integral stimulation of sentences, multimodality-paced choral reading, and rhythmic pointing and has been used successfully with individuals with nonfluent aphasia and AOS (238).

Efficacy of Treatments for AOS

Several recent reviews of treatments for AOS are available (197,209,216,217). A Cochrane review of interventions for AOS following stroke did not identify any trials that matched the search criteria of randomized controlled trials of nondrug interventions for adults with AOS in which the primary outcome was functional speech at 6-month follow-up (209). Therefore, the authors concluded that rehabilitation approaches for AOS following stroke "have yet to be supported or refuted by randomized trials" (209).

In contrast to the Cochrane group, a systematic review of the evidence for treatment of AOS was conducted by a committee of the Academy of Neurologic Communication Disorders and Sciences (ANCDS) using search criteria of "providing data pertinent to the effects of treatment with at least one person with AOS" (216,217). From a total of 59 data-based treatment reports that met these criteria, the committee concluded that, taken as a whole, individuals with AOS "show gains in measured performance as a result of treatment," even when the AOS is chronic. They acknowledge that study quality was generally weak, with methodological issues relating to insufficient description of the subjects and their AOS, trial design that often lacked experimental control, inclusion of small numbers of subjects, and outcome measures that were not always reliable and valid (239). Still, a growing body of evidence is available to support the articulatory kinematic treatments, and evidence for the other types of treatments for AOS is "promising, but limited" (217).

In conclusion, AOS is a condition with a range of severities and manifestations. Although future research continues to address the question of treatment efficacy, clinicians working with individuals with AOS have a repertoire of different approaches from which to choose and adapt to the unique characteristics and needs of their patients.

DYSARTHRIA

Dysarthria is a collective term for the group of speech disorders that result from paralysis, weakness, or incoordination of the speech musculature following damage to the central or peripheral nervous system (198,240,241). The definition of dysarthria includes disturbances of any of the basic components underlying speech production (i.e., respiration, phonation, articulation, resonance, and prosody).

Classifying the Dysarthrias

In clinical practice, the most common approach used to classify the dysarthrias is the perceptual method. Its premise is that each type of dysarthria sounds different and that these perceptual differences can be tied to specific underlying neuropathologies (198,240,241). Based on cluster analysis of listener judgments of speech dimensions, six distinctive types of dysarthria—flaccid, spastic, ataxic, hypokinetic, hyperkinetic, and mixed—were identified initially (240,241). A seventh dysarthria type, unilateral upper motor neuron (UUMN) dysarthria (206), was later recognized and subsequently described by Duffy (1995). Examples of the perceptual dimensions used to characterize the different dysarthrias are listed in Table 13.4 (242).

Although theoretically a stroke could cause damage to the central and peripheral nervous system resulting in any type of dysarthria, vascular incidents within the central nervous system typically affect certain cortical areas, the cerebellum, or

TABLE 13.4 Sample Speech Dimensions and Characteristics Rated in the Perceptual Method of Classifying Dysarthria

SPEECH DIMENSIONS	SAMPLE CHARACTERISTICS
Pitch characteristics	Pitch level (decreased, increased), pitch breaks, monopitch, tremor
Loudness	Overall loudness (decreased), monoloudness, excess loudness variation, alternating loudness
Vocal quality	Harsh, hoarse (wet), breathiness (continuous), breathiness (transient), strained/strangled, voice stoppages, hypernasality, hyponasality, nasal emission
Ventilation	Audible inspiration, forced inspiration-expiration, grunt at end of expiration
Prosody	Rate (fast, slow), phrases (short), increased rate in segments of speech, inappropriate silences, short rushes of speech, excess and equal stress
Articulation	Imprecise consonants, distorted vowels, irregular articulatory breakdown
Overall	Intelligibility, bizarreness

Source: Reprinted with permission from Hammen VL. Motor speech problems associated with stroke: the dysarthrias. *Top Stroke Rehabil*. 1994;1(2):68.

the brainstem. Therefore, the most common dysarthrias following a stroke are UUMN dysarthria, spastic, ataxic, flaccid, and mixed dysarthrias. Each of these dysarthrias is discussed with an emphasis on the characteristic perceptual features of the associated disordered speech. However, a summative narrative review of the characteristics of dysarthria after stroke indicated that regardless of stroke location, imprecise articulation and slow speaking rate are consistent features, whereas voice disturbances, especially harshness, and reduced prosodic variation are also common (243).

UUMN Dysarthria

UUMN dysarthria, as its name implies, is caused by unilateral cortical damage involving the upper motor neurons. As a result, there is damage to the lower face, with weakness of the lips and tongue on the opposite side from the lesion. Movements, therefore, are slow and reduced in range of motion, with the main perceptual characteristic of UUMN dysarthria being imprecise consonant production. However, intelligibility of speech is usually only mildly affected. In some patients, the resultant dysarthria is transient. In others, the effects of the dysarthria can be persistent so that referral to speech therapy is appropriate (8,206).

Effects of UUMN damage on other structures of speech production (velum, pharynx, larynx) are less well understood. Because the upper motor neurons on the unaffected side provide sufficient innervation to the cranial nerves serving the two sides of these structures, they should not be affected. However, there is some individual variability in anatomy that could alter this, and a harsh vocal quality and hypernasality have been noted in some patients.

Spastic Dysarthria

Spastic dysarthria occurs from a single stroke in the brainstem or from more than one lesion that causes bilateral upper motor neuron damage affecting both the pyramidal and extrapyramidal systems. The symptoms reflect the combined effects of both systems on the speech muscles. Weakness and spasticity result in slow movement and reduced range and force. The weakness and slowness are most evident in movements of the tongue and lips, leading to imprecise consonant production, vowel distortions, and a slow rate of speech. The effect of spasticity on the velum causes incomplete velopharyngeal closure and hypernasality. Spasticity in the laryngeal muscles results in hyperadduction of the vocal folds, which is perceived as a harsh and strained–strangled vocal quality. Because of difficulty forcing subglottic air through hyperadducted vocal folds, the person may speak in short phrases in conversational speech. In addition, the frequent inhalations of air interrupt the normal rhythm of speech. Prosodically, a low pitch as well as monopitch and monoloudness may be present. Spastic dysarthria may be associated with pseudobulbar affect in which uncontrollable laughing or crying accompanies the damage to the upper motor neurons of the brain stem.

Flaccid Dysarthria

Flaccid dysarthria results from injury to the lower motor neurons in one or more of the cranial or spinal nerves. It reflects problems in the nuclei, axons, or neuromuscular junctions that make up the motor units of the final common pathway. Weakness, hypotonia, and diminished reflexes are the primary characteristics, and atrophy, fasciculations, and fibrillations commonly accompany them.

The effects of flaccid dysarthria on respiration, phonation, articulation, resonance, and prosody vary depending on which cranial nerves are affected. The cranial nerves of speech production are the trigeminal nerve (V), facial nerve (VII), glossopharyngeal nerve (IX), vagus nerve (X), accessory nerve (XI), and hypoglossal nerve (XII). Damage to the facial and hypoglossal nerves most often causes imprecise consonant production, ranging in severity from only mild distortions to

complete unintelligibility. Bilateral facial nerve involvement can affect production of bilabial (*p*, *b*, *m*) and labiodental (*f*, *v*) phonemes, as well as consonants and vowels that require lip rounding. Bilateral damage to the hypoglossal nerve likely results in misarticulation of phonemes requiring tongue elevation (e.g., *l*, *r*). Damage to the trigeminal nerve can also affect articulation because of difficulty elevating the jaw sufficiently to bring the articulators into contact with each other.

Hypernasality is one of the most noticeable signs of flaccid dysarthria, although it is not unique to that condition. Nasal emission (escape of air through the nasal cavity) may also occur because of incomplete velopharyngeal closure. At the laryngeal level, damage to the recurrent branch of the vagus nerve that provides innervation to almost all of the intrinsic muscles of the larynx leads to incomplete adduction of the vocal folds during phonation and a resulting breathy voice quality.

The spinal nerves are also important because they innervate the muscles of respiration. If the cervical and thoracic spinal nerves responsible for innervating the diaphragm and the intercostal muscles are damaged, then decreased inhalation or impaired control of exhalation during speech leads to reduced subglottic air pressure for speech and, therefore, reduced loudness, shortened phrase lengths, and a strained vocal quality.

Ataxic Dysarthria

Ataxic dysarthria is associated with cerebellar damage or damage to the neural pathways that connect the cerebellum to other parts of the central nervous system. Cerebellar damage disrupts the timing, force, range, and direction of movements needed to maintain normal articulation. Articulation deficits are a major problem, with imprecise consonant articulation being the most prevalent speech error. Often the articulation errors are inconsistent, varying from utterance to utterance and giving the speech the characteristic described as irregular articulatory breakdowns.

Prosodic errors also are prominent in ataxic dysarthria. Many speakers tend to put equal stress on syllables or words that would normally have varied stress patterns. They also tend to put excessive stress on syllables or words that are not normally stressed to any degree, giving the impression that each syllable or word is produced separately. In addition, ataxic speech is characterized by prolonged phonemes and prolonged intervals between phonemes, contributing to an overall slow rate of speech.

Cerebellar damage may cause tremors that affect various body parts, and when the laryngeal or respiratory muscles are involved, the result can be a voice tremor. Cerebellar damage can also cause uncoordinated movements in the respiratory muscles. Exaggerated movements of the respiratory muscles can lead to excessive loudness variations during many speech tasks, including conversation.

Mixed Dysarthrias

When neurologic damage extends into two or more parts of the motor system, the resulting dysarthria is called a mixed dysarthria. For example, a flaccid–ataxic mixed dysarthria results from involvement of both the lower motor neurons and the cerebellum. A flaccid–spastic mixed dysarthria may result from a brainstem stroke in which the lower and upper motor neurons are in close proximity to each other. The speech characteristics of a mixed dysarthria reflect a combination of the characteristics found in the single or pure dysarthrias, with the location and extent of the neurologic damage determining which characteristics are likely to appear. Thus, the relative prominence of each dysarthria type can vary from patient to patient. For example, in one individual with a flaccid–spastic dysarthria, the flaccid component (e.g., nasal emission) may be much more evident than the spastic component (e.g., strained–strangled voice quality), whereas the opposite may be apparent in another individual.

Assessment of Dysarthria

Most clinicians assess dysarthria with a comprehensive motor speech evaluation that is similar to the assessment described previously for AOS (8,208). The motor speech examination includes tasks designed to describe the speech characteristics and the underlying neuromuscular features that influence speech production. Speech characteristics include those at the levels of respiration, phonation, articulation, resonance, and prosody, whereas the "salient" features of neuromuscular function include muscle strength, speed, range, accuracy, steadiness, and tone (8).

The oral mechanism (lips, tongue, jaw, velum, pharynx, larynx) is examined at rest and during nonspeech activities to provide confirmatory evidence and information about the size, strength, range, tone, steadiness, speed, and accuracy of orofacial structures and movements. Speech tasks include vowel prolongation during which pitch, loudness, voice quality, and duration are observed. Alternating motion rates for assessing the speed and regularity of rapid repetitive articulatory movements and sequential motion rates for assessing the ability to move quickly from one articulatory position to another are also included in the motor speech assessment.

Contextual speech, such as reading a paragraph aloud, retelling a story, or responding in conversation, shows how well all the components of speech are integrated. Judgments of speech intelligibility are also made. These may include estimates by the clinician or formal assessment with standard intelligibility tests such as the Frenchay Dysarthria Assessment (244) and the Assessment of Intelligibility of Dysarthric Speech (245).

Many acoustic and physiologic tests are available to study motor speech disorders, and they have the potential to quantify and explain clinical perceptual observations and to increase our understanding of the pathophysiologic underpinnings of dysarthric speech (8). However, they are not yet standard practice, and their use is limited primarily to the research laboratory.

Treatment of Dysarthria

The impact of stroke-related dysarthria transcends the physiological impairment (246). Therefore, a successful management program should address both the impairment and the activity/participation limitations imposed by the impairment. Treatment techniques for the impairment focus on improving the physiologic support for speech, including respiration, phonation, articulation, and resonance, with an emphasis on muscle tone, strength, movement precision, and coordination. Treatment techniques at the level of activity and participation may include modifying speech through compensatory speaking strategies, developing alternative and augmentative means of communication, and controlling the environment and communicative interactions to maximize communication.

Body positioning can influence respiratory support for speech (247,248). Therefore, postural adjustments, particularly for patients in wheelchairs, may be a simple way to improve respiratory drive for speech. However, improvements in respiratory support are ideally targeted during actual speech production. Some patients may simply need to practice inhaling more deeply or using more force when exhaling during speech. When the number of words produced on a single exhalation of air is limited, chunking utterances into short syntactic units with normal pauses within and between sentences may facilitate production.

For work at the phonological level, effort closure techniques are exercises that help the vocal folds adduct by providing overall increased muscle contractions in the torso and neck regions (247,248). Examples of effort closure techniques include pushing or pulling with both hands against the bottom of one's chair or clasping one's hands together and squeezing as hard as possible. Such exercises may improve vocal fold strength, resulting in increased loudness and reduced breathy voice quality (247). In contrast, hyperadduction of the vocal folds is treated with various tension-reducing strategies emphasizing easy onset of phonation such as "yawn-sigh," "chewing," or "chanting" techniques. Various forms of muscle relaxation exercises of the head and neck areas, enhanced with biofeedback, have also been noted in the literature (247).

Consultation with medical staff outside the usual rehabilitation team may be indicated for some patients. For example, if vocal folds are not functioning adequately, an otolaryngologist may determine if injectible substances or thyroplasty surgery might improve laryngeal functioning. When a patient has velopharyngeal weakness, a prosthodontist may fit a prosthetic device such as a palatal lift.

Many clinicians incorporate oral strengthening exercises for muscle weakness of the tongue, lips, and jaw into their treatment program. These oral exercises take the form of moving the articulators in various directions against some sort of resistance, followed by attempts to hold them in their position of maximum range. Strengthening exercises for the velum include various blowing and sucking tasks (249). The value of these strengthening exercises for muscle weakness is controversial, and to date, there are no definitive research studies to support their use in the recovery of speech production.

Strategies to improve intelligibility of speech focus on increasing the precision of articulation, controlling the rate of speech, and improving prosody so that communication sounds more natural. Direct instruction on the correct placement of the articulators during production of a specific sound helps the patient understand how to produce the sound correctly as well as the cause of the sound errors, thereby preventing errors from occurring.

Overarticulation or exaggeration of consonants helps the patient to better articulate words, in particular those sounds that are in the middle or at the ends of words. Minimal contrast drills with words that vary by only one vowel or consonant are also helpful. The differences between the words may be in the voicing (*park/bark*), the manner of production (*dime/mime*), or the place of production (*sea/she*) (8). Rate control can be accomplished by reciting words and syllables to a metronome or by finger or hand tapping to set the pace of appropriate syllable production (250). Slowing the speaking rate is often helpful because the patient may have more time to achieve articulatory placements. When speakers pause more often to slow down their rate, the listener is also given more time to process what is being said. Problems with intonation, stress, and rhythm contribute to the unnaturalness of speech. Treatment may include pitch range exercise or contrastive stress drills in which words, phrases, and sentences are practiced with different stress patterns each time.

Environmental modification may involve altering the number of listeners, the amount of noise, and the distance between the speaker and listener and improving eye contact. Modifications may also include informing new listeners about speech disorders and how best to communicate and strategies for repairing breakdowns in communication (e.g., repeating utterances, rephrasing, spelling, writing, and answering clarifying questions).

If a speaker remains unable to communicate satisfactorily using speech, augmentative or alternative communication modes should be considered (251). Selection of one or more systems depends on factors such as the motor, sensory, cognitive, and linguistic abilities of the patient. AAC devices may range from simple picture boards or spelling boards to portable amplification systems to high-tech electronic devices.

Efficacy of Dysarthria Treatment

A series of recent systematic reviews has addressed the efficacy of techniques for the management of dysarthria. These reviews have included behavioral procedures for managing respiratory and phonatory dysfunction (248) and velopharyngeal dysfunction (249); behavioral techniques for the treatment of loudness, rate, and prosody (250); and speech supplementation techniques (e.g., indicating the first letter or the topic of the sentences) for those with severe dysarthria (251). Although

results from the majority of the studies indicated positive outcomes, many of the studies included very small numbers of subjects, and few of the studies were specific to patients with stroke. More recently, a growing number of studies have investigated behavioral interventions specifically targeting stroke-related dysarthria and the results have been positive (252–256).

Despite these findings, a Cochrane review of speech and language therapy for dysarthria caused by nonprogressive brain damage (stroke) did not identify any randomized controlled trials that met their standards of inclusion (257). The review concluded that "there is no evidence of the quality required to support or refute the effectiveness of speech and language therapy interventions for dysarthrias following nonprogressive brain damage." Nevertheless, as noted by Yorkston, Spenser, and Duffy (2003), "treatments for which there is evidence of effectiveness do not necessarily represent the most appropriate or the most effective treatments that are available; they only represent the treatments for which evidence about treatment effects have been acquired." They further note that there are many techniques and treatments for which there is expert opinion about effectiveness or lack thereof (248).

Future research demonstrating the efficacy and effectiveness of the various treatment approaches for dysarthria using rigorous scientific methodologies is critical. A focus on more homogeneous groups of individuals based on etiology may serve to expand our knowledge base of dysarthria resulting specifically from stroke. An essential question is whether the potential facilitation of speech relearning could have a significant effect on reducing functional limitations and improving quality of life for people with dysarthria. Hopefully, further research will provide clarification and lead to more effective treatments for individuals with dysarthria.

ACKNOWLEDGMENT

Preparation of this manuscript was supported in part by grants R01 DC011754 (to LRC) and R33 DC008638 (to SLS) from the National Institute on Deafness and Other Communication Disorders, and the Brain Network Recovery grant (to SLS) from the McDonnell Foundation.

Dysphagia

Marlís González-Fernández, Denise M. Monahan, Koichiro Matsuo, and Jeffrey B. Palmer

EPIDEMIOLOGY

Swallowing dysfunction, or dysphagia, is common after stroke. The true incidence of dysphagia after acute stroke is unclear, but estimates range from 20% to 90%, largely dependent on timing and method of ascertainment (1). Conservative estimates of the true incidence report that nearly 50% of acute stroke survivors experience dysphagia within the first few days after stroke (2–4). Dysphagia is associated with development of pneumonia, dehydration, and malnutrition; increased length of stay; and mortality after stroke (5–8). Dysphagia has traditionally been associated with brainstem and bilateral cerebral infarctions (1,9), but in recent years it has been shown to occur in isolated cerebral infarctions as well. The incidence may be as high as 25% for left hemisphere and 15% for right hemisphere lesions (6,10).

Aspiration Pneumonia

Aspiration, the passage of food or other foreign material through the vocal folds, is common in stroke survivors with dysphagia. The risk of aspiration pneumonia is increased threefold in stroke survivors with dysphagia and between 11- and 20-fold in patients with aspiration confirmed by videofluorography (3,11). Aspiration can sometimes be detected by clinical examination, but silent aspiration, that is, aspiration without cough, occurs in up to two-thirds of stroke survivors (12). Although aspiration on videofluorography is associated with an increased risk of pneumonia, the risk of dehydration and death is similar to the risk of other dysphagic stroke survivors (13). The material aspirated is also an important consideration. The effects of the aspirated material depend largely on the amount, bacterial load, acid content, and physical characteristics (14,15).

Aspiration of gastric material usually leads to chemical pneumonia, with bacterial infection occurring as a complication 2 to 3 days after injury in cases where the pH of the gastric content is higher due to antacids, proton pump inhibitors, or H2-receptor blockers (15). Aspiration of material with a pH greater than 2.5 causes severe lung injury with parenchymal inflammation, which can lead to adult respiratory distress syndrome (16). Gastric colonization with gram negative bacteria has been documented in patients receiving enteral feeding, placing them at risk for combined chemical and bacterial pneumonia after aspiration of gastric contents (17).

Bacterial pneumonia is predominantly related to aspiration of oral flora and upper airway colonization (14,15); thus, multiple organisms can be isolated (18). Good oral care can reduce the risk of pneumonia by reducing the bacterial load (19).

Malnutrition

Malnutrition in stroke survivors has been reported in 8% to 34% cases (20,21). Malnutrition has also been associated with poor outcomes after stroke, including longer lengths of stay and increased number of complications such as pressure ulcers, falls, tachycardia, and infections (22). Details on nutrition and nutritional interventions after stroke are detailed in Chapter 34.

Recovery of Swallow Function After Stroke

Swallowing dysfunction generally resolves for about half of stroke survivors within 7 days, and only 11% to 13% have persistent swallowing dysfunction after 6 months (23,24). Prognosis is dependent on many factors related to medical status, dysphagia, and rehabilitation potential. Severity of stroke, recurrent stroke, low serum albumin levels, dependence on tube feedings, need for ultra-thickened liquids, and aspiration documented on a videofluorographic swallowing study (VFSS) have been linked to poor outcomes (25,26). Advanced age, impaired cognition, and dependence on a wheelchair are also linked to poor outcomes (27). The best outcomes occur when individuals receive early assessment and treatment of dysphagia with a structured, interdisciplinary team approach.

SWALLOWING PHYSIOLOGY

The process of swallowing, or deglutition, is a series of complex volitional and reflexive movements with two critical biomechanical functions:

1. The food passage propelling the food bolus carried from the oral cavity to the stomach
2. Airway protection insulating the nasal passages, larynx, and lower respiratory tract from the pharynx during food passage

The main anatomical structures involved include the oral cavity, pharynx, larynx, and esophagus (Figure 14.1).

Swallowing Stages

The swallowing process is classically divided into four stages according to the location of the bolus (28). After ingestion, food is prepared for propulsion to the pharynx (oral preparatory stage). The tongue pushes the bolus through the fauces and into the pharynx (oral propulsive stage). Stereotyped movements of pharyngeal structures move the bolus from the pharynx to the esophagus through the upper esophageal sphincter (UES) (pharyngeal stage). Finally, peristalsis and gravity carry the bolus down the esophagus and through the lower esophageal sphincter (LES) to the stomach (esophageal stage). According to the traditional model of swallowing, the oral preparatory stage is initiated voluntarily, but once oral propulsion starts, the rest of the process follows immediately. The total duration of food transit to the esophagus occurs in less than one second in normal adults.

Oral Stage: Differences Between Drinking and Eating

Although the general sequence of an oral swallow is the same for liquid and solid boluses, there are differences relative to preparation and timing. Once ingested, liquids are collected by the tongue and maintained between the tongue's dorsal surface and hard palate surrounded by the upper dental arch until the oral propulsive stage is started (Figure 14.2). Liquids are prevented from leaking into the oropharynx before the swallow initiation by a seal created by the soft

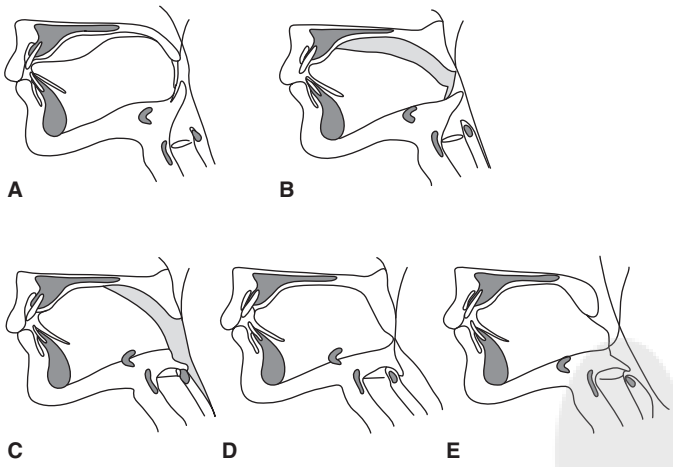

FIGURE 14.2 Normal swallowing of a liquid bolus. These drawings are based on an actual videofluorographic sequence recorded in the lateral projection. (A) The bolus is held between the anterior surface of the tongue and hard palate, in a ready-to-swallow position. The tongue presses against the palate both in front of and behind the bolus to prevent spillage. (B) The bolus is propelled from the oral cavity to the pharynx through the fauces. The anterior tongue pushes the bolus against the hard palate just behind the upper incisor. The posterior tongue drops away from the palate. (C) The soft palate elevates, closing off the nasopharynx. The area of the tongue–palate contact spreads posteriorly, squeezing the bolus backward to the pharynx. The larynx elevates, and the epiglottis tilts downward. (D) The upper esophageal sphincter opens. The tongue base retracts to contact the pharyngeal wall, which contracts around the bolus, starting superiorly and then progressing downward toward the esophagus. (E) The soft palate descends, and the larynx and pharynx reopen. The upper esophageal sphincter returns to its usual closed state after the bolus passes.

palate and dorsal tongue contact. Although this posterior oral seal is usually effective in young, healthy individuals, it is often incomplete, and some liquid may enter the pharynx before the onset of oral propulsion. In contrast to single liquid boluses, during continuous drinking, for example, as seen during drinking with a straw, the bolus often advances to the level of the valleculae prior to swallow initiation (29).

The oral propulsive stage starts when the tip of the tongue makes contact with the hard palate just behind the upper anterior teeth. The tongue surface moves upward and the tongue–palate contact area expands posteriorly, squeezing the bolus into the pharynx.

Eating solid food is quite different from drinking liquid because the food requires significant processing before it is ready to be swallowed (30,31). The process model, a recent development in understanding the physiology of swallowing, incorporates critical aspects of mastication and oral food transport (31,32). When solid food is placed in the mouth, the tongue shifts backward and then rotates its surface to one side. This movement pulls the food back to the molar region and places it on the occlusal surfaces of the postcanine teeth during stage I transport (Figure 14.3A). Then food particles are reduced in size by mastication and softened with saliva until the consistency of the food is optimized for the swallow (food processing). The movements of the jaw, tongue, cheek, soft palate, and hyoid are rhythmical and linked to each other, spatially and temporally, during food processing (33–36). Processed food particles are placed on the dorsal tongue surface and squeezed back to the pharynx during stage II transport (Figure 14.3B), with a mechanism that is nearly identical to that indicated for the oral propulsive stage described earlier. Stage II transport occurs intermittently during food processing cycles so that a food bolus forms in the oropharynx and gradually accumulates for several seconds before the pharyngeal swallow. When sufficient food has accumulated, the pharyngeal stage of swallowing is initiated.

Pharyngeal Stage

The location of the bolus at the initiation of pharyngeal swallowing differs between drinking and eating. The bolus is usually maintained in the mouth during discrete liquid swallows, but it can be in the oropharynx during sequential

swallows or with solid food (29–31,37). The leading edge of the bolus is often in the hypopharynx at swallow onset when eating food with mixed consistencies (liquids and solids) (38).

The pharyngeal stage is a rapid sequence of overlapping and nearly synchronous events (39–42) (Figure 14.2C–D):

1. The soft palate elevates and contacts the lateral and posterior wall of the pharynx, closing the nasopharynx.
2. The base (pharyngeal surface) of the tongue retracts, pushing the bolus posteriorly and downward. The pharyngeal wall contracts around the tongue, both from the back and from the sides, squeezing the bolus. The pharyngeal contraction is sequential, beginning at the top of the pharynx and proceeding downward (43). The pharynx also shortens vertically, reducing its volume (44).
3. The hyoid bone and larynx are pulled upward and forward by contraction of the suprahyoid muscles and thyrohyoid muscle. The anterior and superior movements of these structures are critical for airway protection and opening of the UES (45).
4. Prior to UES opening, the vocal folds close to seal the glottis (46–48). The arytenoid cartilages tilt forward to contact the base of the epiglottis. The anterior and superior movements of the hyoid and larynx tuck the larynx under the base of the tongue and fold the epiglottis backward to seal the laryngeal vestibule. The downward bolus movement and tongue base retraction also helps epiglottal tilt (49). To prevent inhalation of food, breathing ceases briefly during swallowing (deglutitive apnea) for approximately 0.4 to 1.0 seconds (50,51). Breathing resumes in the expiratory phase.
5. Opening of the UES is essential for the bolus to reach the esophagus. The UES is held closed at rest by tonic contraction of the cricopharyngeus muscle (45,52). Muscles just above and below the cricopharyngeus may also assist in UES closure. During a swallow, these muscles relax, and the UES opens. Three important factors contribute to this opening:
   - The active relaxation of the cricopharyngeus muscle
   - Contraction of the suprahyoid muscles that move the hyoid bone and larynx forward, effectively pulling the sphincter open (45)
   - The pressure of the descending bolus (53) pushes the UES outward, assisting in its opening

Esophageal Stage

The bolus transit mechanism in the esophagus is different from that of the pharynx. The cervical esophagus (upper one-third) is composed mainly of striated muscle, but the thoracic esophagus (lower two-thirds) is smooth muscle. Peristalsis is controlled by autonomic nerves. Once the bolus passes the UES and enters the esophagus, a peristaltic wave carries the bolus down to the stomach. Gravity assists peristalsis in the upright position. The LES contracts tonically between swallows to prevent gastroesophageal reflux, and relaxes to allow bolus passage into the stomach.

NEURAL CONTROL OF SWALLOWING

Swallowing is a complex process that involves sequential muscle contraction and inhibition of more than 30 muscles (54). The major muscles involved in swallowing and their innervation are detailed in Table 14.1. Similar to respiratory control, swallowing functions are controlled primarily by centers in the brainstem. Although the main center controlling swallowing is in the brainstem, the cerebral cortex and other supratentorial structures also have a role in swallowing control.

Brainstem: Central Pattern Generator

The swallowing central pattern generator (CPG) generates the sequential pattern of motor activities required for a swallow. The pattern for muscle contraction and inhibition is dependent on three distinct components:

1. The afferent input to the CPG in the brainstem (sensory and supramedullary)
2. The efferent output that provides innervation to the swallowing muscles
3. The interneuronal network that integrates afferent and efferent input in the CPG (55)

The CPG is located within the nucleus tractus solitarius (NTS) and the reticular formation surrounding both the NTS and above the nucleus ambiguus (NA) in the rostral and ventrolateral medulla (55,56). The CPG is organized into two main regions with distinct functions:

1. The dorsal group involved in triggering, shaping, and timing of the sequential swallowing pattern
2. The ventral group that distributes the swallowing drive to the various pools of motor neurons involved in swallowing (56)

Sensory (afferent) input from the mechanoreceptors, chemoreceptors, and thermoreceptors in the oral cavity, pharynx, and larynx to the CPG has been implicated in swallowing initiation, facilitation, and airway protection (1,57–61). General sensory neurons from the oral cavity synapse in the trigeminal sensory nuclei, whereas those from the pharynx and larynx travel in branches of cranial nerves IX, X, and XI and synapse in the NTS (62).

The ventral CPG premotor neurons have connections with the trigeminal (V), facial (VII), hypoglossal (XII) motor neurons, and the NA (IX and X) that innervate the swallowing muscles (56). The output from the CPG can be modified by sensory feedback. Motor timing varies with bolus characteristics and other variables (63).

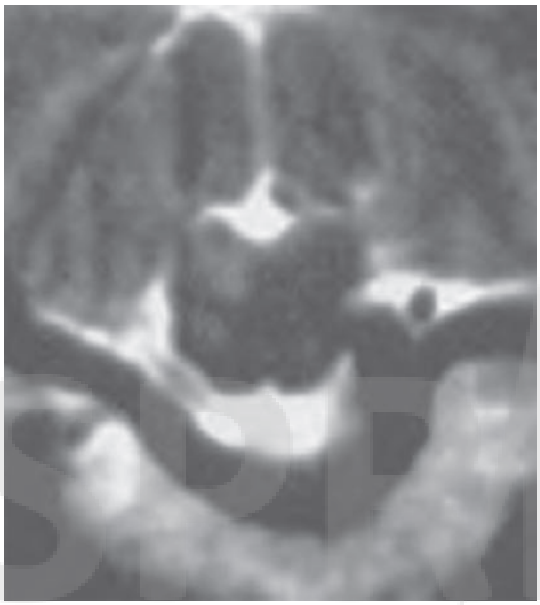
Wallenberg Syndrome: Disruption of the Swallowing Central Pattern Generator

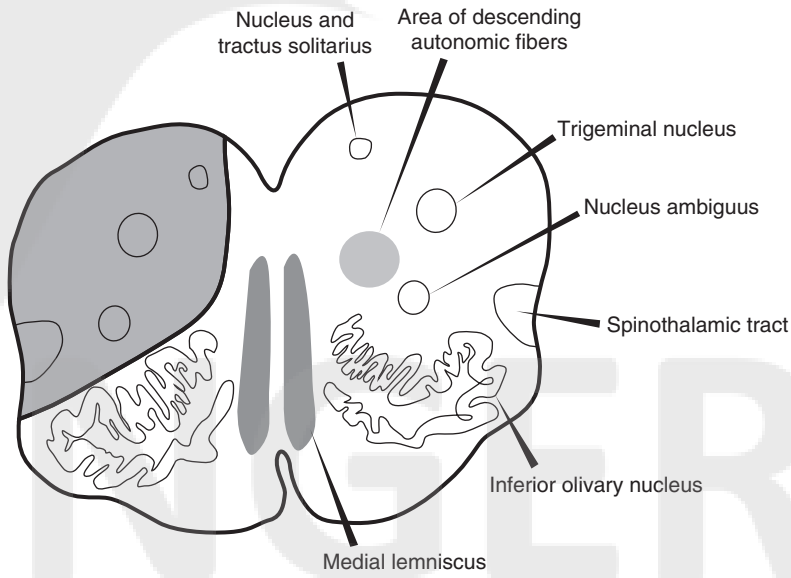
Disruption of the swallow CPG can result in a severe and long-standing dysphagia associated with aspiration (57,64). Wallenberg, or lateral medullary, syndrome results from occlusion of the vertebral, posterior inferior cerebellar, or medullary perforator arteries. Lateral medullary infarction (LMI) can affect the NTS, NA, and motor nuclei of the cranial nerves involved in swallowing (Figure 14.4). Involvement of the NA produces weakness or paralysis of the ipsilateral muscles of the pharynx, larynx, and soft palate. Involvement of the NTS can hamper initiation and coordination of the pharyngeal swallow.

Electrophysiological evidence suggests that, in LMI, the swallowing function is affected bilaterally, indicating an acute disconnection syndrome to the contralateral swallowing centers (57). The mechanism for recovery of swallowing after LMI is poorly understood.

Supramedullary Control of Swallowing

Although the swallowing CPG is located in the brainstem, mounting evidence suggests that several supratentorial structures, most prominently the cerebral cortex, have an essential role in the regulation of swallowing (65–67). Voluntary





A B

FIGURE 14.4 Lateral medullary syndrome, axial cut through the rostral medulla. (A) MRI (B) Diagram. Lateral medullary syndrome causes dysphagia by affecting the NTS and NA. Other deficits include—Contralateral loss of pain and temperature: Involvement of the spinothalamic tract. Ipsilateral loss of pain and temperature sensation on the face: Involvement of the descending nucleus and tract of V. Ipsilateral Horner's syndrome (ptosis, meiosis, and anhidrosis): Involvement of descending autonomic fibers. Ipsilateral ataxia: Involvement of the inferior cerebellar peduncle (restiform body).

initiation of swallowing requires integrity of the motor areas of the cerebral cortex (59). Studies using positron emission tomography (PET) have identified multiple, asymmetric loci associated with swallowing, including the right orbitofrontal cortex, left mesial premotor cortex and cingulate, right caudolateral sensorimotor cortex, right anterior insula, bilateral medial cerebellum, and bilateral temporopolar cortices (68). The strongest activation has been seen in the sensorimotor cortices, insula, and cerebellum. Swallowing is represented asymmetrically in the cortex, and there is no clear right or left laterality (69). Studies in stroke survivors have shown that the size of the swallowing area in the unaffected cortex determines the presence or absence of dysphagia (70). The cortical representation of swallowing within the motor and premotor cortex has been shown to be bilateral but markedly asymmetric (71). Using this theoretical framework, one would expect individuals with strokes of the hemisphere with higher swallowing representation to have a predisposition to dysphagia.

Although mechanisms of recovery of the swallowing function remain unclear, studies using transcranial magnetic stimulation suggest that recovery of the swallowing function after a cortical stroke is associated with compensatory cortical reorganization in the undamaged hemisphere (72). In spite of the obvious contributions of the cerebral cortex, insula, cerebellum, and others to the normal swallowing mechanism, it is still unclear how these areas are integrated with the brainstem to produce functional and voluntary swallowing. It is also unclear why recovery does not occur in some cases of unilateral supratentorial stroke.

Suprabulbar Palsy: Disruption of the Corticobulbar System

Disruption of the corticobulbar system may result in suprabulbar palsy (SBP). SBP, or pseudobulbar palsy, is a clinical syndrome characterized by dysphagia, dysarthria, dysphonia, impairment of voluntary movements of tongue and facial muscles, and emotional lability. The most common cause of SBP is multiple bilateral lacunar infarcts, but it is also associated with amyotrophic lateral sclerosis (ALS), Parkinson's disease, and multiple sclerosis. Swallowing difficulties in these patients are common and range from mild, subclinical findings to severe dysphagia precluding oral feeding.

Studies in SBP patients suggest that the basal ganglia and associated neural pathways play a role in the pathogenesis of dysphagia after stroke and that progressive involvement of the excitatory and inhibitory corticobulbar fibers is responsible for the difficulties that SBP patients experience (73). The swallowing problems in SBP cases are primarily difficulties in triggering a swallow and a dysfunctional cricopharyngeal sphincter that is hyperactive and uncoordinated (73). Slowing of oropharyngeal swallowing and saliva accumulation in the mouth was also associated with extrapyramidal dysfunction.

SWALLOWING IN THE ELDERLY

Because stroke occurs often in the elderly, it is important to consider specific deficits that might be present prior to a cerebrovascular event that can impact dysphagia outcomes after a stroke.

Dentition generally worsens with age. This is further worsened by the development of oral infections, such as periodontal disease or dental caries. With aging, masticatory muscles weaken, masticatory forces decrease, and speed of jaw motion slows. These factors result in increased mastication time and reduced efficiency (74). Despite the increase in mastication time, the bolus size at the time of swallow onset is larger in the elderly than in the young, primarily because of the decrease in masticatory function. Strength of labial closure and tongue–palate pressure also decreases. Although saliva secretion is stable with aging, disease, atrophy of the salivary glands, or medication side effects can cause xerostomia, or dry mouth, in elderly individuals (75,76).

The duration of transit from the oral cavity to the pharynx increases with age (53). The time interval from arrival of the bolus at the pharynx until onset of laryngeal elevation is also extended. Because of this time interval increase, laryngeal penetration is more frequent in the elderly, but aspiration is not (77–79).

Aging also affects UES function. Decreased UES compliance and reduced hyolaryngeal elevation reduce UES opening, resulting in increased hypopharyngeal intrabolus pressure during transsphincteric flow (53). The interval from the onset of the oral stage to the UES opening is delayed in the elderly, but the intervals from the onset of pharyngeal stage or from the onset of glottal closure until UES relaxation are not affected by age (53,61). Aging lowers resting pressure and shortens the length of the UES, but no significant effect is seen on the LES (80).

Aging increases the duration of swallow apnea, but it does not change the typical resumption of breathing in the expiratory phase after a swallow (40,81,82).

Dysphagia Rehabilitation

Rehabilitation of dysphagia includes improving overall function, increasing swallowing function by correcting underlying physiologic abnormalities, using compensation for unsafe or inefficient swallowing, and preventing complications such as aspiration pneumonia and malnutrition.

Abnormal Swallowing After Stroke

The specific dysphagia symptoms following stroke depend on the site of the lesion and differ in severity between individuals with the same site of lesion. Deficits may be unilateral or bilateral and may affect sensory and/or motor components of the swallow. Labial weakness can result in an inability to competently ingest a bolus from a utensil and in difficulty containing the bolus in the mouth. Lingual and buccal weakness may result in inadequate bolus formation

and propulsion, leading to ineffective oral clearance and piecemeal swallowing. Impaired mandibular and tongue movements result in ineffective mastication of solid foods. Sensory deficits may result in pocketing of oral residue into one or both cheeks or retention of food on the lips and tongue after swallowing.

Pharyngeal dysfunction can result in delayed swallow initiation, ineffective bolus propulsion, and retention of food after swallowing. Velopharyngeal inadequacy can cause nasal regurgitation. Impaired laryngeal elevation, vocal cord dysfunction, or epiglottic inversion result in ineffective airway protection. This places individuals at risk for laryngeal penetration (food material entering the larynx above the level of the vocal cords) or aspiration (food material passing through the vocal cords). An ineffective cough, caused by vocal cord dysmotility, weakness of expiratory muscles, or impaired coordination of glottal adduction with expiration, hampers clearance of aspirated material. Laryngeal sensory impairments can result in silent aspiration, in which there is lack of cough response to aspiration. Impaired opening of the UES can result in pharyngeal food retention, placing individuals at risk for aspiration after the swallow. Esophageal dysmotility leads to ineffective esophageal clearance and reflux. Esophageal dysfunction typically is not a problem after stroke, but should be considered, as it may coexist with oral and pharyngeal impairments.

The presence of a tracheostomy tube presents additional challenges. A tracheostomy tube is associated with altered laryngopharyngeal aerodynamics, eliminating the normal post-swallow expiration through the pharynx, reducing laryngeal sensation, and limiting ability to effectively cough and clear aspirated material.

Evaluation of Dysphagia

Early assessment and management of dysphagia reduce pneumonia rates and length of stay, and improve overall outcome from stroke (83–85). An interdisciplinary team's involvement in the dysphagia evaluation process is crucial to address the complex needs of the dysphagic individual. This team should include a physician, speech–language pathologist, dietician, occupational therapist, nurse, and other subspecialties as needed. Speech–language pathologists have substantial training in evaluation and treatment of dysphagia and should be consulted whenever a problem with oral or pharyngeal swallowing is suspected.

Comprehensive assessment of swallow functioning after stroke begins with a thorough medical history. Specific lesion localization may be useful in predicting presence and severity of dysphagia, as a large percentage of brainstem lesions, especially lateral medullary infarcts, result in severe dysphagia (10). However, dysphagia can also be present in cases with no brainstem involvement, particularly in cases of multiple or bilateral cerebral infarction. Medical history and current medical status, including cardiac, pulmonary, neurologic, and nutritional information, must be considered. Medications, such as barbiturates, benzodiazepines, antihistamines, or antidepressants, may negatively affect physical or neurologic function and limit an individual's participation in the rehabilitation process. A clear description of dysphagia-related symptoms, such as choking or coughing with food or liquids, vomiting, or the sensation of food stuck in the throat, provides information regarding possible deficits and indicates the need for further evaluation. The sensation of food sticking in the throat or chest is an important symptom of dysphagia. The sensation of food sticking in the throat has poor localizing value, as it may be seen in cases of esophageal as well as pharyngeal dysphagia. The sensation of food sticking in the chest, in contrast, is generally associated with esophageal problems.

Dysphagia Screening

Given the high prevalence of dysphagia and its complications, a swallowing screening examination should be completed as part of every stroke survivor's initial assessment. Elements commonly evaluated on bedside screening are described in Table 14.2. Dysphagia screening is part of the practice guidelines for adult stroke rehabilitation care (86). The goals of swallowing screening examination are to identify possible signs of dysphagia and aspiration and identify patients in need of further evaluation. The water swallow test is commonly used as a screening tool. The patient continuously drinks a predetermined amount of water, usually three or four ounces, and clinicians observe for signs of aspiration or dysphagia (87–89). Other screening tests include items from history as well (90). This screening is usually performed by trained medical personnel. Results of this screening must be interpreted with caution, as they have limited predictive ability, cannot detect silent aspiration, cannot determine safety with other forms of food/liquids, and cannot provide information regarding the mechanism of dysphagia. It is essential to have a high index of suspicion to improve sensitivity of screening. Several validated tools

TABLE 14.2 Elements Commonly Evaluated on Bedside Screening

General assessment
1. History of dysphagia or enteral feeding
2. Conciousness level: Altered alertness or arousal
3. Postural control
4. Difficulty managing oral secretions
5. Weak voluntary cough
Swallow challenge (One teaspoon of water followed by three ounces of water)
1. No laryngeal elevation
2. Coughing
3. Choking
4. Wet or "gurgly" vocal quality

are available in the literature, all with strengths and shortcomings that should be taken into account when choosing a screening tool for a particular setting.

Physical Examination

A physical examination of the upper aerodigestive tract, including cranial nerve testing, should be performed to assess structure and function. Symmetry, strength, and range of motion of the facial and oral muscles are examined in isolated and purposeful movements. Sensation to facial, lingual, labial, and palatal stimulation is assessed. Drooling and secretion management should be noted, as they are associated with the ability to manage food and liquid boluses. Hearing and vision skills should be screened as well. Symmetry and strength of movement of the velopharynx is demonstrated through vocalization and by eliciting a gag reflex. The presence or absence of a gag reflex should not be used as a predictor of safety in swallowing. Some normal individuals have an absent gag reflex; individuals with severe dysphagia can have intact gag reflexes (91).

The larynx is manually palpated for abnormalities at rest and during a volitional swallow of saliva (Figure 14.5). Laryngeal function is assessed further by eliciting a volitional cough and assessing vocal quality. Ventilatory control is observed at rest, during speech, and through sustained phonation. Cognition and communication skills, including orientation, attention, memory, and insight, should be examined, as impairments in cognition can negatively impact outcomes (92,93).

Clinical Swallow Evaluation

If the presence of dysphagia is suggested by the screening examination or the patient complains of symptoms associated with swallowing dysfunction, that individual should be referred for a complete clinical swallow evaluation (CSE).

FIGURE 14.5 Palpation of the larynx. Each finger is used to palpate a different structure: middle finger, hyoid bone; fourth finger, top of thyroid cartilage; fifth finger, cricothyroid notch.

The clinical (or bedside) swallow evaluation examines an individual's potential risk for dysphagia and aspiration with various food and liquid consistencies and is usually performed by a speech–language pathologist. Findings are used to guide decision making on further instrumental examinations, safe means of alimentation, and an appropriate treatment plan. During a CSE, clinicians complete a thorough oral, pharyngeal, and laryngeal motor and sensory assessment. Liquids and solid foods are presented. Oral function is observed for ability to manage substances with adequate lip, tongue, and jaw control and movement. This includes adequate mastication and maneuvering of liquid and solid boluses and ability to propel boluses into the pharynx without oral residual. The timing and strength of the pharyngeal swallow is assessed through palpation of the tongue base, hyoid, and larynx. Clinicians look for signs of overt aspiration before, during, or after the swallow occurs. Although silent aspiration cannot be reliably detected during a bedside examination, several clinical signs are associated with risk of aspiration. These include dysphonia, dysarthria, weak cough, abnormal laryngeal elevation, impaired control of secretions, cough after swallow, and voice change after swallow (94–97).

Clinical tools provide additional information and assist in making judgments during the CSE. Using cervical auscultation with a stethoscope, clinicians may listen to the sounds of swallowing for coordination, timing, and pre- and postswallow breath sounds. Clear classifications of the sounds heard and their physiological implications have yet to be described (98,99). Decline in pulse oximetry during swallowing has been explored as a tool to predict aspiration; however, evidence has been contradictory (100,101).

Checklists have been suggested as tools to help guide assessment. One formal CSE tool is the Mann Assessment of Swallowing Ability (MASA), a standardized swallowing test that uses a checklist to place individuals in categories that describe their risk of dysphagia and aspiration (102).

The CSE relies on indirect information to make judgments regarding swallow abnormalities. Although clinician judgments regarding the presence of abnormal oral and pharyngeal function have reasonable reliability, they are not perfect, and they may fail to identify some patients with dysphagia and aspiration. In addition, the presence or absence of aspiration, the timing and cause of aspiration, and the effectiveness of compensatory maneuvers cannot be reliably determined with a CSE (28,88,100). Instrumental examination of swallowing is essential to the comprehensive assessment of patients with clinical signs of dysphagia or at high risk of silent aspiration.

Instrumental Assessment Tools

Videofluorographic Swallowing Studies

The VFSS is the gold standard in swallowing assessment. This procedure is typically performed by a speech–language pathologist along with a radiologist or

TABLE 14.3 Penetration-Aspiration Scale

ASPIRATION RISK	SCORE	CLASSIFICATION	DESCRIPTION
No risk	1	Normal	No airway invasion
	2	Mild	Bolus enters into airway, remains above the vocal folds with clearing
Risk of aspiration	3	Moderate	Bolus enters into airway, remains above the vocal folds without clearing
	4	Moderate	Bolus contacts vocal folds with airway clearing
	5	Moderate	Bolus contacts vocal folds without airway clearing
Positive aspiration	6	Severe	Bolus enters trachea; clears into the larynx or out of the airway
	7	Severe	Bolus enters trachea; not cleared despite attempts
	8	Severe	Bolus enters trachea; no attempt is made to clear

Source: From Ref. (104). Rosenbek JC, Robbins JA, Roecker EB, et al. A penetration-aspiration scale. *Dysphagia*. 1996;11:93–98.

physiatrist. During a VFSS, the patient ingests liquids and solids with barium or other radiopaque contrast while motion radiographic images are produced and recorded. The purpose of this test is to identify the structural or functional abnormalities related to swallowing and to identify circumstances for safe swallowing (103). Clinicians make observations of structure and function that cannot be made during a CSE. These include oral bolus control and propulsion, pharyngeal transport, timing and coordination of the swallow, presence and depth of laryngeal penetration or aspiration, and possible causes of aspiration or laryngeal penetration. In this context, *laryngeal penetration* is defined as contrast entering the larynx but not passing through the vocal folds. *Aspiration* is defined as contrast passing through the larynx and vocal folds. The penetration-aspiration scale (104) is a semiquantitative tool for describing the degree or severity of laryngeal penetration and aspiration (Table 14.3). However, it is not typically used in clinical practice.

Use of standardized VFSS procedure improves its reliability and clinical utility (Table 14.4) (105). Images of the swallow should be obtained in both the lateral and anteroposterior views to determine laterality of swallow dysfunction. Observations are made regarding motions of the tongue, jaw, soft palate, epiglottis, hyoid bone, larynx, pharyngeal walls, and UES. Additional observations are made regarding timing and extent of bolus flow, including timing of swallow, retention of contrast after swallowing, and the presence of penetration or aspiration. Performing and interpreting a VFSS require analysis of the mechanism of swallowing dysfunction. This analysis will suggest opportunities for treatment. The VFSS also provides opportunity to test compensatory maneuvers such as modifications of posture or bolus characteristics that may improve the safety and efficiency of swallowing.

Radiation exposure limits the duration of the VFSS, so the VFSS is brief and provides only a window into the swallow function. However, the radiation dose and relative risk of radiation-related complications are low (106).

TABLE 14.4 Videofluorographic Swallow Study Protocol

Lateral projection, patient sitting upright in usual position of comfort
Speech sample ("candy, candy") to visualize velar motion
Command swallow: 5 mL of thin liquid from a spoon
Drink thin liquid from a cup (patient controls rate and volume)
Command swallow: 5 mL nectar-thick liquid from a spoon
Drink nectar-thick liquid from a cup (patient controls rate and volume)
Eat 1 tsp pudding from spoon
Eat 1 tsp soft food (e.g., chicken salad sandwich spread) from a spoon
Eat shortbread cookie (e.g., ½ of a Lorna Doone)
Compensatory techniques as appropriate
Other food consistencies as indicated

Anteroposterior (AP) projection, sitting upright (neck slightly extended if safe)
Phonation of "e" (as in "he") several times in succession to visualize motion of vocal folds and arytenoids
Command swallow: thin or nectar-thick liquid, 5 or 10 mL
Compensatory techniques or other foods as appropriate
Additional swallows as needed for imaging the esophagus

Fiberoptic Endoscopic Evaluation of Swallowing

The fiberoptic endoscopic evaluation of swallowing (FEES) is a bedside procedure in which a nasally inserted flexible endoscope is used to directly view the nasopharynx and larynx during swallowing (Figure 14.6). During this procedure, individuals swallow various consistencies of food and liquids dyed for visualization.

The FEES is a useful procedure for evaluating the laryngeal and pharyngeal anatomy and assessing vocal cord function (107,108), and it is highly sensitive for detecting silent aspiration (109). However, the pharynx is not directly visible during a swallow because its closure produces a white-out

effect on the image. The FEES is ideal for cases where radiation exposure is a concern. Its portability makes it a valuable tool for critical care patients or patients who are unable to tolerate transportation to a radiology suite. Disadvantages of the FEES procedure include the inability to:

- Observe a swallow directly
- Observe critical pharyngeal swallow events
- Observe the oral and esophageal stages of swallowing

The inability to evaluate tongue base retraction, pharyngeal constriction, epiglottic tilt, and UES opening limit the utility of FEES for analyzing swallow mechanics and pathophysiology.

Other Tools

Other instrumental tools can be useful in further assessing swallowing. Esophagoscopy is useful in assessing anatomical abnormalities of the esophagus. Functional or physiological disorders are better assessed with radiologic studies. Manometry measures pressure in the pharynx and in the esophagus during swallowing. It is primarily used to analyze motor disorders of the esophagus. Electromyography (EMG) is useful in diagnosing dysphagia in motor unit disorders and as a biofeedback tool in dysphagia therapy. It provides little information regarding the mechanism of swallowing, so it cannot be a guide for rehabilitation. Ultrasound may be used in the diagnosis of oral dysfunction, but it does not provide information on pharyngeal or esophageal function.

Treatment of Dysphagia After Stroke

The primary treatment principles in dysphagia management are amelioration of the underlying disease process, prevention of complications, compensation for an unsafe swallow, improvement of swallowing via therapy, and use of environmental modifications. A basic tenet of dysphagia rehabilitation is that the best exercise for swallowing is swallowing. This means it is important to determine the circumstances for safe swallowing before initiating a swallowing therapy program. Successful management of dysphagia requires adherence to these principles. As with evaluation, therapeutic management of the dysphagic stroke survivor requires an interdisciplinary approach.

Prior to initiation of dysphagia therapy, the stroke survivor must be stabilized medically. This includes preventing recurrent stroke, minimizing or preventing complications, and ensuring proper management of general health functions (110). Depending on the clinical presentation, a period where the patient receives no oral feeding might be indicated. Recent studies have demonstrated no difference in outcomes when comparing early tube feedings and avoidance of it (111,112). In addition to inability to safely take oral nutrition due to dysphagia, nutritional intake may be reduced by poor appetite caused by depression and medication effects, lack of dentures, cognitive levels, or impaired arm function. Nutritional status should be closely monitored by following body weight and blood chemistries (113). Intravenous fluids may be required to improve fluid intake. Some individuals may be able to tolerate supplemental water and ice chips despite dysphagia. Allowing water intake as part of the therapeutic diet may increase compliance with dietary recommendations and overall satisfaction (114), but it may lead to aspiration. Dysphagia management teams need to carefully consider an individual's risk of developing pneumonia, taking into account CSE and instrumental assessment results prior to allowing water in patients who aspirate.

Swallowing therapy is associated with successful outcomes, including return to oral feeding (115). Therapeutic programs must be individualized to the physiological and behavioral needs of the individual. A number of therapy techniques can be utilized to compensate for oral and pharyngeal control deficits and reduce the occurrence of penetration and aspiration. Environmental modifications should be employed, including reduction of distractions, proper seating and positioning, modifying bolus volume and rate, use of straws, and use of adaptive equipment.

Direct Swallowing Therapy Techniques

Direct swallowing therapy focuses on diet modification and behavioral compensations to improve swallowing efficiency and safety while allowing for oral nutrition. The

therapy plan is individualized and based on the mechanism of swallowing dysfunction in the particular individual with dysphagia. A VFSS is necessary to determine the circumstances for safe swallowing for a dysphagic stroke survivor and should be performed prior to initiating direct swallowing therapy.

Regular solid foods may be too difficult to effectively masticate and manipulate. Solid foods can be mechanically altered to make them softer, reduce particle size, or simplify consistencies to assist in mastication and food transport. Liquid viscosities can be altered to compensate for specific deficits. Thin liquids are generally the most difficult liquid consistency to tolerate for most dysphagic stroke survivors because they are difficult to control and may be aspirated before or during the swallow. Use of various levels of thickened liquids provides better oral and pharyngeal control and timing and may prevent aspiration. For other individuals, thin liquids are better tolerated because the major issue is lack of propulsive force or poor opening of the UES. Patients with these deficits may retain liquids in the pharynx and aspirate after swallowing. The National Dysphagia Diet, published by the American Dietetic Association, provides labels and descriptions of frequently used levels of food and liquid consistencies (Table 14.5) (116). Given the variety of swallowing in pathophysiology, these descriptions are not comprehensive, and clinicians must individualize diets based on specific findings in clinical and instrumental exams.

Altered bolus presentations—liquids by teaspoon, elimination of straws, decreased volume—can reduce aspiration risk and improve bolus transport in some patients. These strategies must be tested during the VFSS to determine their effectiveness and safety before their use in therapeutic diets. In addition to diet modifications, postural maneuvers are frequently utilized to facilitate safe and efficient swallowing. These postures are not effective for all dysphagic individuals and can be dangerous if utilized inappropriately. Careful clinical examination and testing during instrumental assessment ensure their appropriate use.

The chin tuck maneuver reduces laryngeal penetration and aspiration by improving laryngeal closure and preventing posterior loss of control of the bolus (28,117,118). This is accomplished by reducing the laryngohyoid distance and the hyoid-mandibular distance. The chin tuck maneuver also weakens pharyngeal contractions and can cause aspiration in patients with weakened pharyngeal muscles and tongue base retraction (37,119).

Rotation of the head to the affected (weak) side is useful in individuals with unilateral pharyngeal weakness and impaired UES opening. This maneuver alters the bolus pathway and propels the bolus through the pharynx on the unaffected side. Head rotation also aids in UES dynamics and pharyngeal clearance (120). Tilting the head away from the weak side can also divert the bolus through the stronger side of the pharynx.

Use of neck extension posture can be beneficial for individuals with impaired anteroposterior oral propulsion. Extending the neck provides gravity assist for the bolus to move through the oral cavity. Caution should be used when attempting this technique if pharyngeal control is impaired, as it may cause aspiration. A reclining position can be useful in individuals who retain food in the pharynx after the swallow and experience overflow aspiration. The reclining posture elevates the laryngeal aditus (entry) relative to the hypopharynx, inhibiting overflow aspiration.

Two related behavioral techniques can be used to reduce aspiration. The supraglottic swallow technique involves holding the breath before and during swallowing and coughing after swallow. This produces closure of the larynx prior to swallowing to prevent aspiration. In the super-supraglottic swallow, the breath holding is combined with valsalva maneuver, which closes the laryngeal vestibule in addition to adducting the vocal folds (121).

Several compensatory techniques can improve pharyngeal clearance. The effortful swallow technique is used to compensate for impaired pharyngeal constriction. Individuals are instructed to swallow hard. This technique assists pharyngeal clearance by increasing tongue base retraction (122).

TABLE 14.5 National Dysphagia Diet

NDD SOLIDS	DESCRIPTION
Level 1	Dysphagia—Pureed (homogenous, very cohesive, pudding-like, requiring very little chewing ability)
Level 2	Dysphagia—Mechanical altered (cohesive, moist, semi-solid foods, requiring some chewing)
Level 3	Dysphagia—Advanced (soft foods that require more chewing ability) (all foods allowed)
Regular	
NDD liquids	**Description in centipoise (cP)**
Thin	1–50 cP (liquid viscosity similar to water[a])
Nectar	51–350 cP (liquid viscosity similar to cream soup)
Honey-like	351–1, 1,750 cP (liquid viscosity similar to honey or molasses)
Spoon-thick	Greater than 1,750 cP (liquid viscosity similar to ketchup)

[a]Water has a viscosity of 1 centipoise at 20°C (68°F).

When food is retained in the pharynx after a swallow, a subsequent liquid swallow can be used to clear residue. If residue occurs consistently, it may be useful to alternate solids and liquids. The double-swallow technique uses a volitional swallow to assist in clearing pharyngeal residue. In the case of severe retention after swallowing, individuals often require three or more volitional swallows. The Mendelsohn maneuver increases the extent and duration of the UES opening by voluntarily prolonging contraction of the suprahyoid muscles (123). This can improve pharyngeal clearance.

Intraoral prostheses can be beneficial in selected individuals with decreased lingual and palatal strength and range of motion (124). Palatal augmentation assists individuals with oral stage transfer deficits. A device is fitted to improve contact of the tongue with the hard palate. Apalatal lift prosthesis elevates the palate to compensate for velopharyngeal insufficiency. Use of a one-way speaking valve for individuals with tracheostomy restores expiratory airflow after the swallow, allowing for coughing and clearing the airway.

Oral sensory stimulation involves use of altered temperature and taste to improve timing of the pharyngeal swallow. This technique is based on the premise that oral afferent information assists in swallowing initiation. Presentation of a sour bolus improves onset of oral swallow, reduces pharyngeal delay time, and improves swallow efficiency (125). Presentation of larger bolus volumes acts similarly by increasing swallow response time. Stimulation of the faucial arches with a chilled laryngeal mirror improves the swallow initiation when provided immediately before the swallow (126).

Neuromuscular electrical stimulation (NMES) is another modality used for the treatment of oropharyngeal dysphagia. The first device designed solely to provide NMES for swallowing therapy was approved by U.S. FDA in 2002 (VitalStim®, EMPI, Danbury, CT). A similar device was approved in 2011 (eSwallow™ Dysphagia therapy unit, eSwallow USA, Scottsboro, AL). Tetanic stimulation is delivered via surface electrodes overlying the submental and anterior neck muscles, and individuals are asked to swallow (127). It is suggested that NMES contracts the muscles used for swallowing and improves the swallow function (128). Although this technique is increasing in popularity among clinicians, its effects on swallow biomechanics are not well understood. Initial evidence indicates that NMES can stimulate only superficial muscles and not the pharyngeal muscles. The purpose of stimulation, at least in part, is to increase laryngeal elevation. There is evidence, however, that it can promote laryngeal descent in some cases (129–131). A study in chronic poststroke dysphagia suggested that sensory-only electrical stimulation reduces episodes of penetration or aspiration (130). NMES may instead be useful as a resistance exercise in individuals with reduced laryngeal elevation (130,132).

Long-term outcome studies using NMES are emerging in the literature. Unfortunately, heterogeneity in patient populations, outcome measures, and small sample size limits the comparability and conclusions of the various studies (133). The largest controlled study in the literature (99 subjects) compared surface electrical stimulation to thermal tactile stimulation in stroke survivors (134). The study reports that both interventions were effective in improving swallowing function but that the proportion of patients with sustained 2-year improvement was higher in the electrical stimulation group when compared to the thermal-tactile stimulation group. Unfortunately, lack of randomization and standardization of time poststroke (to account for spontaneous recovery) confound the results. Further research into the immediate and long-term outcomes of NMES treatment is necessary to determine its role in dysphagia treatment.

Indirect Swallowing Therapy Techniques

Indirect therapy involves the use of exercise to improve flexibility, strength, and coordination of the oral, pharyngeal, and respiratory muscles for swallowing. Common indirect therapy techniques are summarized in Table 14.6.

Oral exercises are designed to target motions used in the oral stages of swallowing. Oral control exercises include rapid lingual lateralization, rotary lingual movements, suck-and-swallow movements to assist in posterior bolus propulsion, simulated chewing via lateralization of gauze or sponges to improve bolus manipulation, and simulated labial seal to reduce labial leakage.

Oral muscles can be strengthened with resistance exercise. Lingual muscles are strengthened by pushing the tongue against a tongue blade, pushing the tongue into a cheek, and pulling the tongue posteriorly while being held anteriorly. Devices are being used to supplement lingual strengthening exercises. The Iowa Oral Performance Instrument (IOPI) is a handheld device that uses a plastic bulb positioned between the tongue and the soft palate to measure tongue pressure. Pressure is measured in kPa and displayed in the device and a series of lights change color from red to green with increasing pressure, providing the patient with biofeedback (135). The Madison Oral Strengthening Therapeutic (MOST®) device incorporates five air-filled sensors in a custom-molded mouthpiece attached to a laptop computer to accomplish the same goal (136). The Madison Oral-Lever Resistance Exercise (MORE®) device, currently in development, is intended for over-the-counter use by patients who need to perform independent exercises to increase or maintain tongue strength (137).

Labial muscles are strengthened by maintaining closure on a moving tongue blade and squeezing lips closed to resistance. Mandibular strengthening is achieved by opening and closing the jaw to resistance. Oral flexibility is improved through lateral, anterior, and rotary stretching of the tongue; protrusion and retraction of the lips; and mandibular opening and closure.

Pharyngeal exercises are designed to improve the range of motion and strength of the tongue base, pharyngeal muscles, and laryngeal muscles. Lingual protrusion and retraction improves tongue base contact with the pharyngeal wall. The Masako tongue-holding maneuver increases strength and

TABLE 14.6 Common Indirect Therapy Techniques With Brief Descriptions

THERAPY TECHNIQUES	BRIEF DESCRIPTION
Oral cavity	
Oral motor control exercises (jaw, tongue, lip)	Jaw opening and closing Tongue rotation, lateralization, protrusion, retraction Lip protrusion, lateralization, opening/closing Stretching and increasing range of motion
Relaxation and ROM (jaw, tongue, lip)	Opening/closing the jaw against resistance
Resistance exercise (jaw, tongue, lip)	Pushing the tongue against resistance
Pharynx	
Laryngeal elevation exercise	Volitional laryngeal elevation by saying a high-pitched "ee"
Vocal cord adduction exercise	Pushing wall or table, uttering "ah" simultaneously
Masako maneuver	Swallowing with the tongue tip held anteriorly outside the mouth
Sensory stimulation	Tactile stimulation of the faucial arches with cold or sour stimuli
UES opening	
Shaker exercise	Active head raising (neck flexion) in the supine position
UES dilatation	Expansion of a balloon catheter in the UES

Abbreviation: ROM, range of motion.

duration of tongue base contact with the pharyngeal wall. In this technique, the tongue tip is held anteriorly outside of the mouth while swallowing (138). Shaker exercises strengthen the anterior submental muscles, improving the UES opening during the swallow and thereby reducing food retention in the pharynx (139,140). In this exercise, the patient lies supine and lifts the head against resistance of gravity, flexing the neck, and looking at the toes (Figure 14.7). The patient lifts the head three times for 1 minute each and then performs 30 consecutive head lifts without holding. The patient holds the mouth closed during this exercise to focus resistance on the submental muscles.

Laryngeal muscles are stimulated through sustained elevation exercises. Maintaining a high-pitch sound (e.g., "ee"), performing effortful swallows, and using the Mendelsohn maneuver can improve laryngeal elevation during swallowing. Hard glottal attacks (forceful volitional closure of the vocal cords) and pushing-pulling exercises (phonation while pulling or pushing an object like a chair) improve vocal cord adduction to strengthen the cough response and vocal cord closure during swallowing.

EMG biofeedback is an adjunct therapy that allows individuals to visualize the force of muscle contraction. By increasing awareness of muscle activity, individuals are often able to effect greater control of those muscles (141). EMG can be used to record submental and infrahyoid activity during swallowing therapy, assisting the patient in contracting those muscles. EMG may be beneficial in training effortful swallows, sustained pharyngeal contraction, lip closure, and tongue mobility (142). Laryngoscopy can provide visual feedback when teaching a patient to perform laryngeal exercises. It provides direct visualization of the vocal cords and larynx, and it can be useful in completing vocal cord adduction exercises and learning breath control techniques such as the supraglottic swallow.

Pharyngeal Bypass

When safe alimentation is not possible, pharyngeal bypass measures may be employed, eliminating the need for oropharyngeal swallowing and providing nutrition and hydration. Short-term feeding—that is, less than 30 days—can be accomplished via nasogastric (NG) tubes. NG tubes have risks, and they can result in numerous complications, including reflux aspiration, improper positioning, dislodgement, and ulceration of pharyngeal and esophageal tissue. Long-term feeding options include percutaneous gastrostomy (PEG) tubes and percutaneous jejunostomy (PEJ) tubes. Although use of a PEG tube does not prevent aspiration pneumonia in acute stroke (143,144), there is a reduction in the number of aspiration cases when compared to continued oral feeding (145). Aspiration and pneumonia from PEG tubes can be minimized through measures such as head elevation, good hygiene with bag and line handling, continuous drip feeding (as opposed to bolus feeding), and consistent monitoring for gastric residue (146). PEJ tubes are indicated for individuals with chronic aspiration of tube feedings or impaired gastric motility (147). PEG tubes can provide uninterrupted feeding, which is not possible with NG feeding, resulting in improved nutrition (148). Many

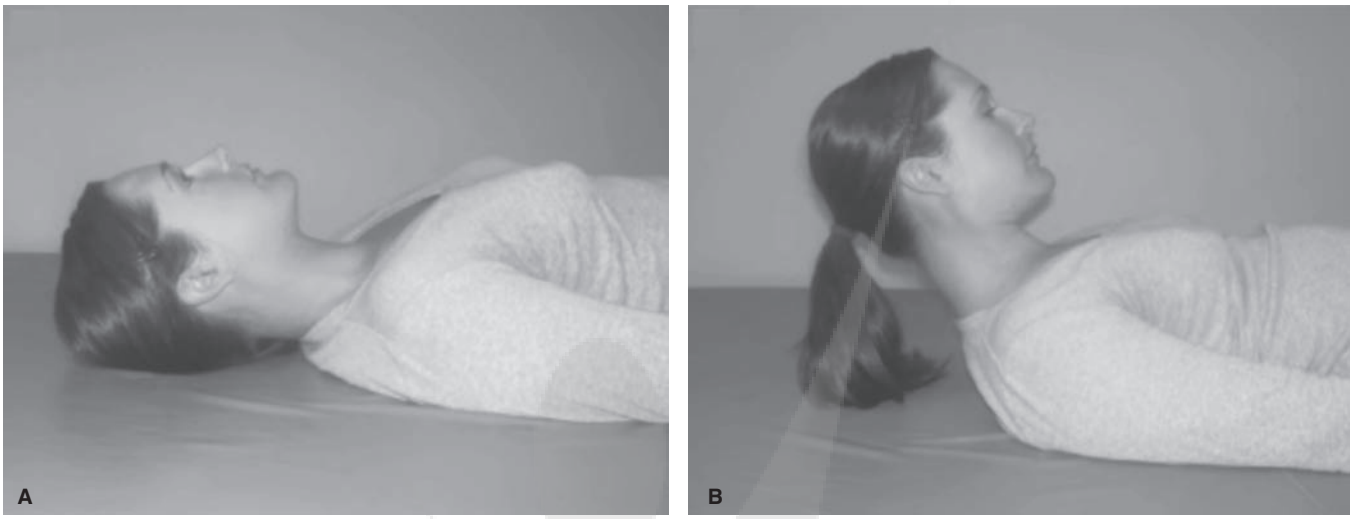

FIGURE 14.7 Shaker exercises. (A) The patient is instructed to lie flat on his or her back on the floor or bed. (B) Patient holds the head off the floor or bed, looking at his or her feet, for 1 minute without raising the shoulders from the floor or bed. The second part of the exercise involves the same movement (without sustaining the head lift) for 30 repetitions.

individuals who return to oral nutrition after stroke benefit from PEG use to allow exercise and therapeutic oral feeding to continue (149). As with any surgery, infection is a risk with insertion and use of PEG or PEJ tubes.

Surgical and Pharmacological Management

Surgical options for dysphagia are rarely used in the United States. One exception to this is dilatation of the esophagus or UES, which is performed in the case of stricture, web, or stenosis. Cricopharyngeal myotomy is a surgical procedure that disrupts the cricopharyngeus muscle to reduce UES pressure and improve bolus flow from the pharynx to the esophagus. Laryngeal diversion procedures are performed in cases of severe intractable aspiration caused by dysphagia (150,151). The larynx is separated from the upper airway, and a permanent tracheostomy is performed (152). Although laryngeal diversion eliminates aspiration, significant consequences include loss or reduction of upper airway functions like phonation, cough, or smell as well as potential for persistent pharyngeal dysphagia.

There are no specific pharmacological treatments for oral or pharyngeal dysphagia, but some symptoms may be managed with medication. Anticholinergic medications can reduce salivary flow in individuals with sialorrhea and chronic aspiration of oral secretions (153). Botulinum toxin injections have been used in cases of oromandibular or lingual dystonia, trismus, cricopharyngeal dysfunction, and sialorrhea. Botulinum toxin injections carry some risk of exacerbating dysphagia.

Additional Considerations

Oral care is an often overlooked, but critical, concept in dysphagia management. Proper oral care (including tooth

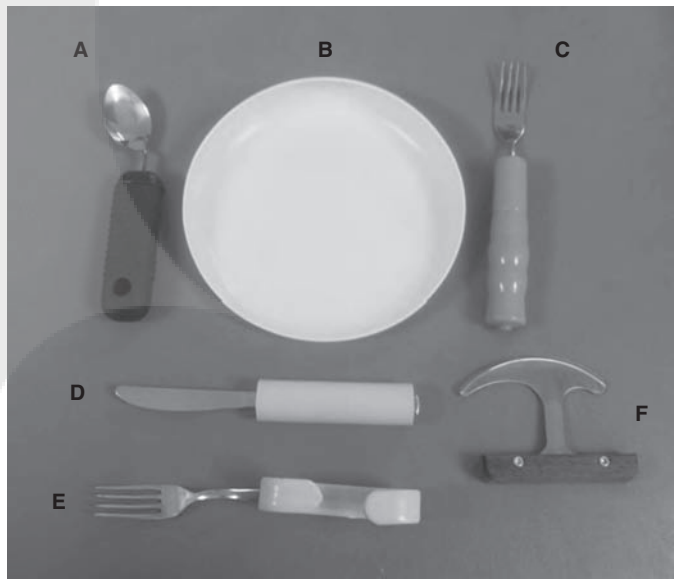

FIGURE 14.8 Assistive devices used for feeding. (A) Wide grip, weighted utensils. These utensils have soft-ribbed handles and bendable shafts. They are weighted to help keep hands steady. The extra handle weight provides help for individuals with limited hand control. The shaft can be bent for either right- or left-handed use. (B) Tapered front scoop dish. Nonskid feet keep the plate from sliding. Curved edge simplifies scooping food. Specially suited for individuals who have limited flexibility, motor coordination, or feed using one hand (e.g., one who had a hemiparetic stroke). (C) Universal grip aid. These aids can be used with conventional flatware, and provide better grip by increasing friction and handle size. (D) Foam grip aid. Increases handle size, providing a large, more comfortable grip and better control of the utensil. (E) Universal feeding cuff. For individuals with little to no grip. Securely attaches the utensil to the hand for feeding. (F) Rocking "T" knife. For individuals with a weak grasp. Cuts food with a rocking motion. Wooden handle fits the hand and safety edge reduces risk of injury.

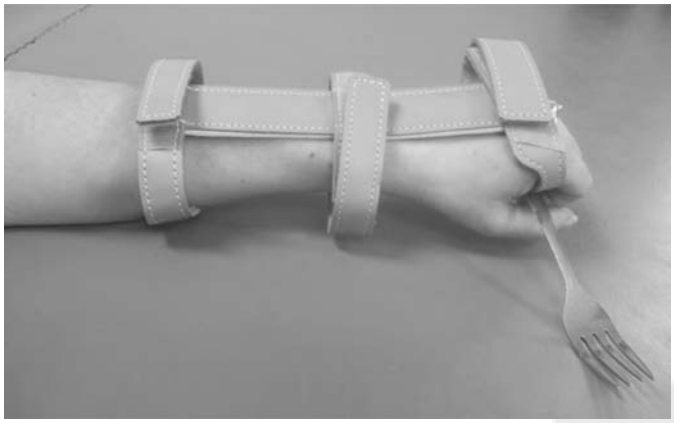

FIGURE 14.9 Wrist support with universal cuff. Allows self-feeding for individuals with weak grip and weak wrist or wrist drop.

brushing, flossing, and rinsing) before and after meals reduces the bacterial load in the mouth, thereby reducing the risk of developing aspiration pneumonia (19). Proper positioning is important in dysphagia management (154). Individuals should be seated upright during and after meals to maximize effectiveness of rehabilitation techniques and reduce the risk of gastroesophageal reflux with subsequent aspiration. Adaptive equipment is used by individuals with motor disabilities in order to improve self-feeding. Some examples of adaptive equipment are shown in Figures 14.8 and 14.9.

CONCLUSION

Although dysphagia after stroke has been associated with increased incidence of complications, morbidity, and mortality, early identification of feeding difficulties can affect long-term outcomes and improve quality of life. Early assessment and treatment are vital to preventing complications during the acute phase and allow normal recovery of the swallowing function. For those individuals whose swallowing function does not recover spontaneously, sophisticated therapeutic options that can be tailored to address individual needs are available. Current research in the field is focusing on standardization of screening, bedside, and instrumental assessments and identification of new therapeutic interventions that are tailored to the specific brain-based deficits.

Right Hemispheric Neurobehavioral Syndromes

Joanne A. Byars and Kenneth M. Heilman

RIGHT HEMISPHERIC NEUROBEHAVIORAL SYNDROMES

This chapter provides an overview of some of the major neurobehavioral syndromes associated with right hemisphere strokes. The most common and disabling disorders associated with isolated right hemisphere injury fall into three principal domains: the neglect syndrome; emotional disorders, including disorders of emotional communication and emotional experience; and visuospatial disorders. We review the most common components of these major right hemisphere neurobehavioral syndromes. We omit some of the less common neurobehavioral disorders that can arise from right hemisphere disease—including some forms of amusia, identity disorders such as prosopagnosia, delusional misidentifications such as Capgras and reduplicative para-amnesia, disorders of automatic speech, and auditory agnosia for familiar voices. Patients with right hemispheric injury can also develop changes in mood and affect, such as inappropriate jocularity, emotional flattening, euphoria, and depression. Chapter 31 reviews these mood disturbances, so we do not discuss them here.

NEGLECT AND RELATED DISORDERS

Definitions

Neglect consists of the failure to report, respond, or orient to meaningful or novel stimuli presented in a portion of space, in spite of adequate elementary motor and sensory function (1).

Neglect, a common and severely disabling neurobehavioral disorder, most commonly arises from discrete lesions of the right hemisphere, such as cerebral infarctions and hemorrhages. However, tumors, trauma, and degenerative diseases involving the right hemisphere may also cause neglect. Of all the behavioral disorders caused by focal hemispheric brain damage, neglect (diagnosed at the time of an acute injury) carries the poorest prognosis for independent living, even worse than the prognosis for global aphasia.

Neglect syndromes may present a variety of clinical features. Table 15.1 characterizes the different dimensions that may distinguish various types of neglect and the modes by which they manifest involvement.

We discuss next the signs and symptoms associated with the different forms of this disorder, the means by which clinicians can test for neglect and related disorders, and the management and treatment of these disorders. We also briefly review the pathophysiology of neglect.

Clinical Syndromes, Signs, and Testing

Sensory Inattention

Unawareness. Selective unawareness constitutes the most profound form of sensory inattention. Sensory inattention is often classified by its modality (tactile, visual, or auditory) and its distribution (hemispatial or personal). Ipsilesional attentional bias and inability to disengage from stimuli in ipsilesional space may accompany contralesional sensory inattention.

To clinically test for inattention, the examiner presents the patient with stimuli (visual, tactile, and auditory) or no stimuli, alternating to either the ipsilesional or contralesional sides of the body in random order. With each presentation of a stimulus or nonstimulus, the examiner says, "Now!" Attention allows a person to determine whether something is present or not present; thus, patients may make errors by failing to recognize the absence of stimuli, as well as failing to recognize stimuli that do occur. The patient then tells the examiner if the stimulus occurred on the right, left, or not at all. If the patient makes more errors on one than the other side (e.g., more contralesional than ipsilesional errors), it constitutes evidence of unilateral sensory inattention.

When a patient consistently fails to detect contralesional stimuli, the question arises whether he or she may have a primary sensory defect rather than inattention, as these two disorders may initially resemble each other. However, several maneuvers may help dissociate inattention from a primary sensory defect caused by deafferentation. In the tactile modality, sometimes moving the patient's left hand from contralesional to ipsilesional hemispace may allow the person to detect tactile stimulation applied to the hand. Cold water caloric stimulation can also help differentiate hemianesthesia (such as from thalamic lesions) from inattention: if a patient has left-sided inattention, cold water caloric stimulation of the left ear will allow

TABLE 15.1 Forms of Neglect

		MODES OF INVOLVEMENT					
DIMENSIONS OF NEGLECT	Input/output	Afferent: attentional (sensory) neglect			Efferent: intentional (motor) neglect		
	Sensorimotor modality	Visual	Auditory	Tactile	Limb movement		Eye gaze
	Domain	Spatial		Personal		Representational	
	Temporal distribution	Occurs with single unilateral stimulus/movement			Only occurs with bilateral simultaneous stimuli/movements		
	Spatial distribution	Frame of reference			Location		
		Viewer-centered	Environment-centered	Object-centered	Horizontal (left vs. right; ipsilesional vs. contralesional)	Vertical (up vs. down)	Radial (proximal vs. distal)

this person to feel the tactile stimulus, but it will not help overcome a true sensory loss (2). In the visual modality, inattention may be viewer-centered hemispatial, whereas a true hemianopia is hemiretinal (Figure 15.1). Thus, the patients with visual inattention who cannot detect visual stimuli (for example, the examiner's moving fingers) in contralesional hemispace might detect these stimuli if their eyes are deviated to the ipsilesional side (such that the contralesional retinal field now falls in the ipsilesional hemispace) (3). If a patient has a true hemianopia, the defect will be retinotopic, and they will remain unable to see stimuli presented to the contralesional visual field even when their eyes deviate to the ipsilesional hemispace. Hemispheric lesions do not cause contralesional hemispatial deafness, so if a patient fails to detect auditory stimuli (e.g., snapping fingers or speech) presented on one side of space, he or she has inattention. Even a premorbid unilateral hearing loss could not account for this hemispatial unawareness. Psychophysiologic techniques such as evoked potentials also may help demonstrate that a defect is inattention rather than deafferentation, and structural imaging may clarify whether or not the lesion injures afferent pathways.

Sensory Extinction to Simultaneous Stimulation (Extinction). Many patients who initially experience unawareness of stimuli may recover and regain the ability to detect isolated stimuli, but when receiving bilateral simultaneous stimulation, they fail to detect the contralesional stimulus—a phenomenon known as *extinction* (1). Many patients never demonstrate inattention to unilateral stimuli, but they still might demonstrate sensory extinction. Extinction may occur in visual, tactile, and auditory modalities. Extinction most often involves a failure to appreciate a contralesional stimulus when both sides of the body receive simultaneous stimulation; however, when two stimuli are given on one side of the body, extinction may also cause the stimulus closest to the contralesional position to go undetected (Figure 15.2) (4).

Action-Intentional (Motor) Neglect

Motor Neglect. Motor neglect—or action-intentional neglect—can occur in several forms, distinguished by the means of testing and the behavior demonstrated by the patient.

Motor neglect, or limb akinesia, can resemble a hemiplegia, but brain imaging and transcranial magnetic stimulation will reveal an intact corticospinal motor system (5). Unlike patients with true hemiplegia, who will attempt to move their weak limbs, these patients often do not appear to be attempting to move. Some patients have hemispatial akinesia, in which they experience contralesional limb akinesia only when the limb is on the contralesional side of the body, but they can use the limb when it is brought over to the ipsilesional side. Other patients have difficulty moving their heads, eyes, or even arms in a contralesional direction, a disorder known as *directional akinesia*. Some patients can move their eyes, heads, or arms in both directions, but at rest they deviate their eyes, arms, or heads to the ipsilesional side. These findings constitute intentional directional bias. The term "gaze palsy"—sometimes used to describe the ocular manifestation of this bias—represents a misnomer, as these patients do not have paralysis or weakness. This gaze preference may be related to inattention of one side of space, a directional akinesia of eye movements, or both.

Hypokinesia is a milder form of intentional neglect in which patients can move their limbs, head, and eyes, but experience a delay in initiating these movements (1). Measuring reaction times effectively tests for hypokinesia. Hypokinesia can occur in specific limbs (limb hypokinesia), in a specific hemispace (hemispatial akinesia), and in a specific direction (directional hypokinesia). Directional akinesia and hemispatial hypokinesia can be observed during eye and head movements.

Motor impersistence is the inability to sustain a movement or posture (1). When testing for motor impersistence, the examiner asks the patient to maintain a posture for a given period of time. Motor impersistence, like hypokinesia, may involve the limbs, eyes, or head, and can occur in a particular hemispace or direction.

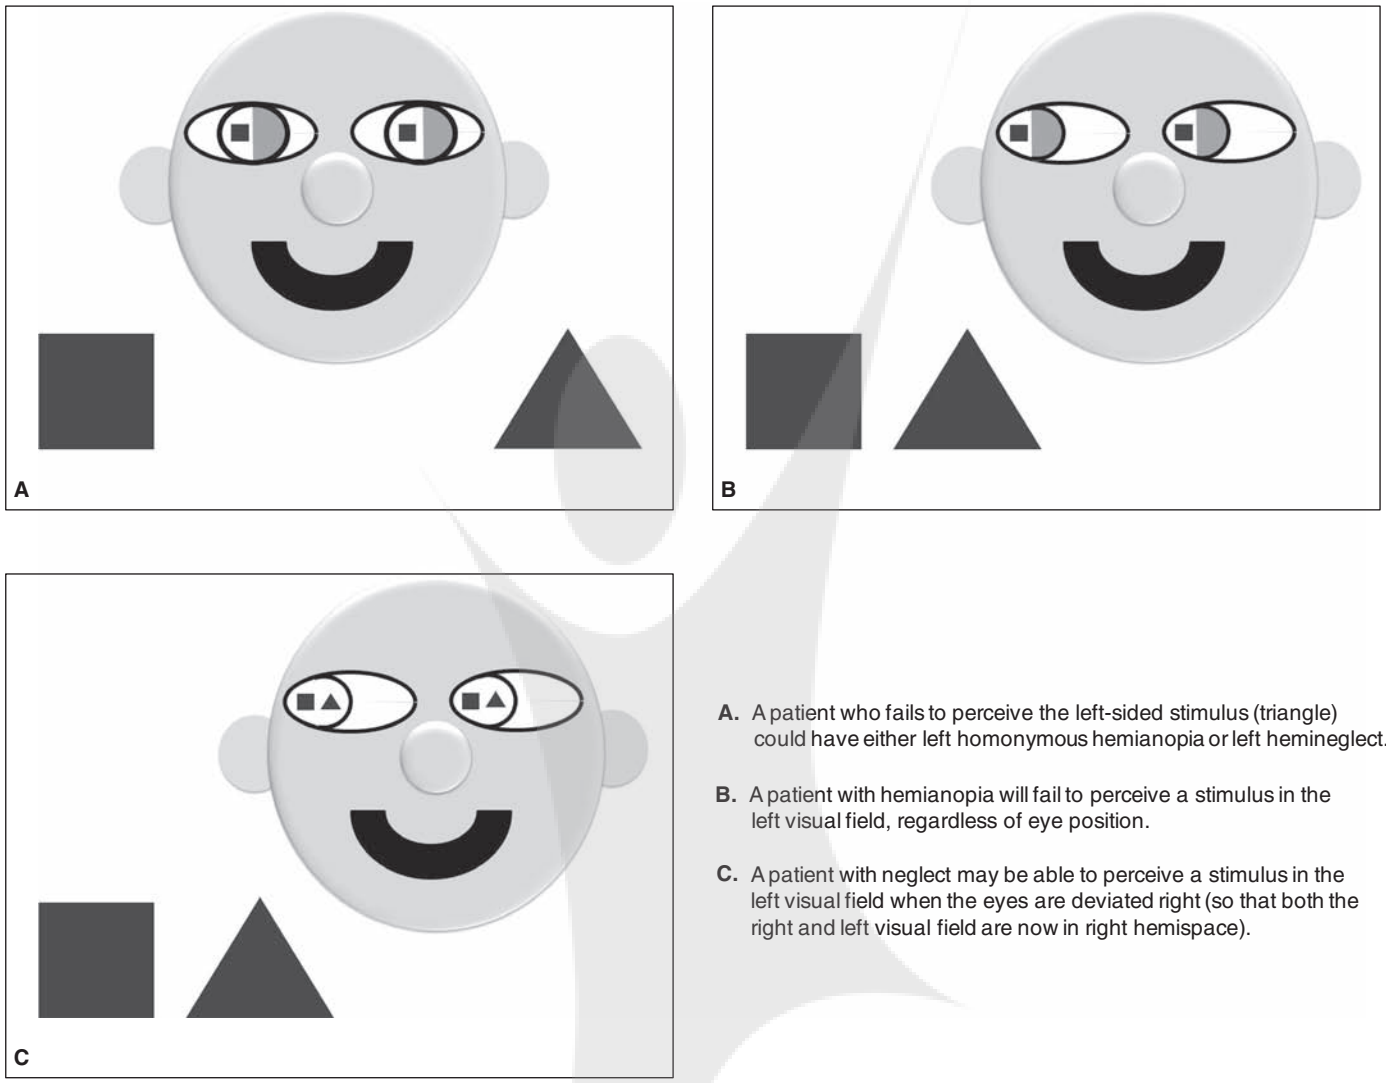

FIGURE 15.1 Hemianopia versus hemineglect.

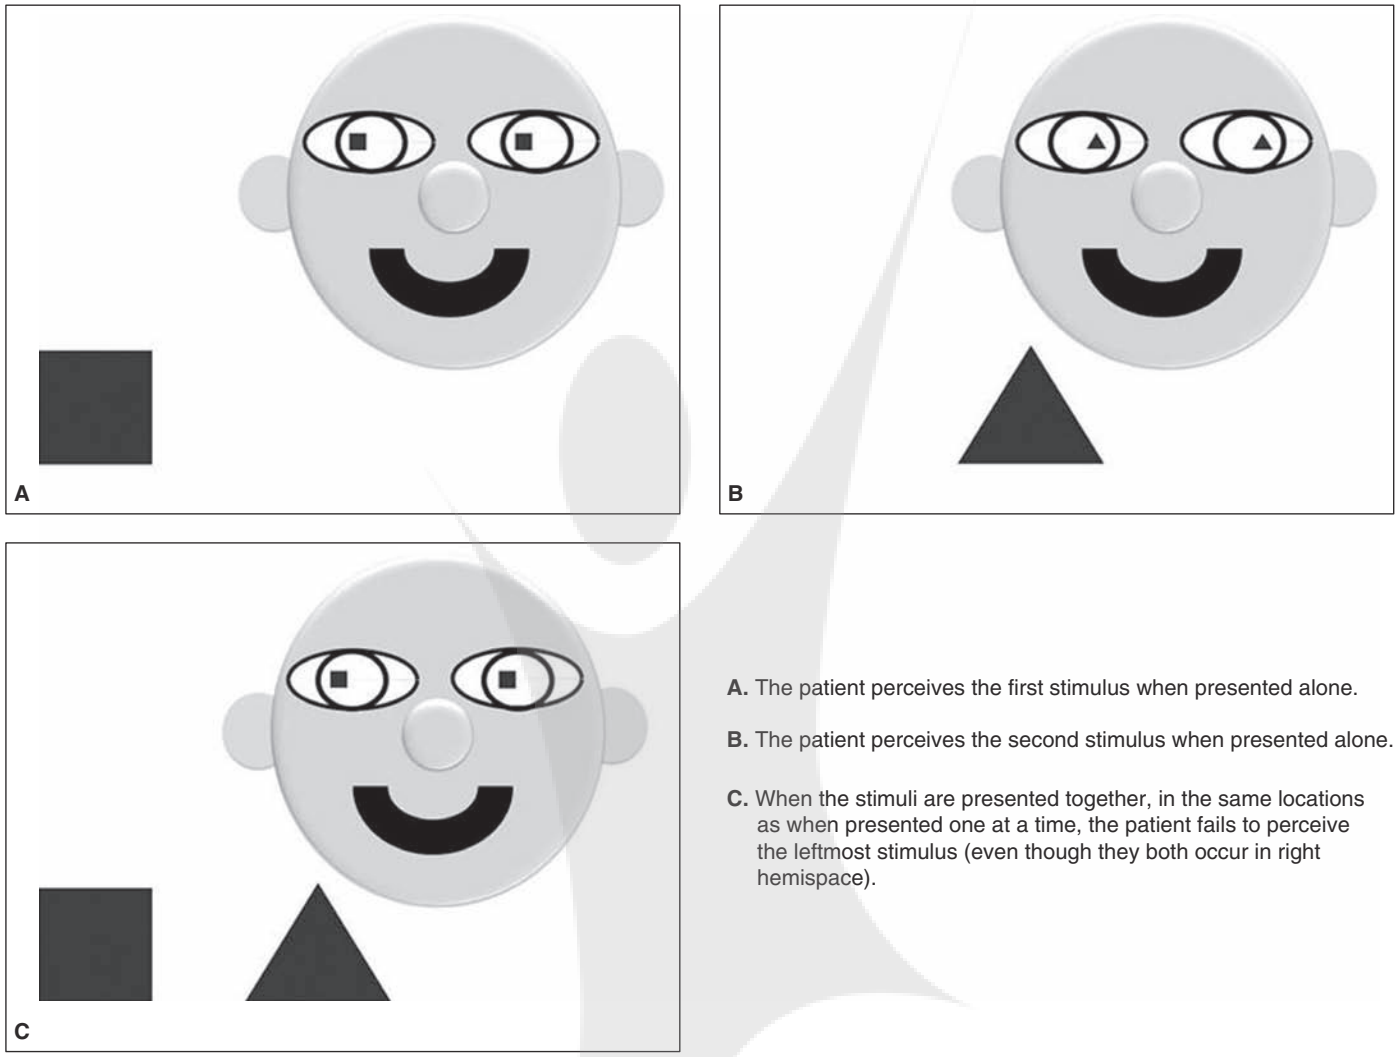
Hypometria is when a patient makes abnormally small movements with the limbs, eyes, or head (1). Premature discontinuation of movement owing to impersistence can reduce movement amplitude and thus give rise to hypometria. However, other factors such as perceptual disorders, inattention, and abnormal spatial representations can also induce hypometria.

Motor Extinction. Some patients who can move the contralesional limb alone have difficulty initiating movement of this limb simultaneously with the ipsilesional limb, a phenomenon known as *motor extinction* (1). To test for motor extinction, the examiner first establishes whether the patient can move each forelimb independently. Then the patient closes his or her eyes and puts his or her hands on his or her lap; the examiner randomly touches the right, left, or both hands, asking the patient to lift the stimulated hand. To distinguish sensory extinction from motor extinction, the examiner should also test for sensory extinction by asking the patient to tell the examiner which hand(s) the examiner touched. Patients with motor extinction will detect the bilateral stimulation but move only one hand.

Some patients may have hypokinetic extinction. Unlike those with akinetic motor extinction, these patients do move both hands when touched bilaterally but have a delay in initiating movement of their contralesional hand, which causes this hand to move slower than the ipsilesional hand and slower than when moving the contralesional hand alone.

Spatial Neglect

Contralesional Spatial Neglect. Spatial neglect, which is a failure to be aware of or interact with stimuli in a portion of space, can occur in all three dimensions of space: horizontal (right/left), vertical (up/down), and radial (near/far), as well as in combinations of these dimensions (1). Spatial neglect can also take place in near (peripersonal) or far (extrapersonal) space or both (1). Therefore, tests for spatial neglect should assess all these dimensions. However, in this discussion, we focus



A. The patient perceives the first stimulus when presented alone.

B. The patient perceives the second stimulus when presented alone.

C. When the stimuli are presented together, in the same locations as when presented one at a time, the patient fails to perceive the leftmost stimulus (even though they both occur in right hemispace).

FIGURE 15.2 Extinction with two unilateral simultaneous stimuli.

primarily on horizontal spatial neglect. Three bedside tests can screen patients for spatial neglect: line bisection, target cancellation, and drawing. Each of these tests, in part, assesses a different aspect of spatial neglect; therefore, though some patients may show impairment on all these tests, others may show impairment on only one or two of these tests.

In the line bisection task, the examiner presents the patient with a line and asks him or her to mark the midpoint of the line. Longer lines have a greater sensitivity for the detection of neglect than do shorter lines. Typically, when patients with contralesional spatial neglect attempt to bisect long lines, they deviate their bisection mark toward the injured hemisphere. However, with very short lines, patients may err by placing their mark on the portion of the line in contralesional hemispace, a phenomenon called the *crossover effect*. Placing the entire line in the portion of space on the side opposite the injured hemisphere (rather than in ipsilateral hemispace) increases the likelihood of detecting neglect.

In the cancellation test, a sheet of paper with many targets (such as randomly placed, small, line segments) is placed before the patient, and the patient is asked to mark out all the targets. Patients with neglect will often fail to cancel targets positioned in the contralesional hemispace. Increasing the number of targets, asking the patient to selectively cancel target stimuli intermixed with foils, and using foils similar to the targets (for example, target Ts in a background of Ls) can all improve the sensitivity of the task.

In addition to occurring in the three dimensions of space, spatial neglect can take place within three different reference frames: viewer-centered, object-centered, and environment-centered. To distinguish between viewer-centered and object-centered neglect, the examiner can ask the patient to copy some simple objects, such as a house with tree on one side and a bush on the other side. If a patient with neglect fails to draw the object on the contralesional side of the paper, the patient most likely has viewer-centered neglect. However, if the patient attempts to draw all three objects but only draws one side of these objects, then the patient has object-centered neglect (Figure 15.3). Asking patients to perform line bisection tasks while upright

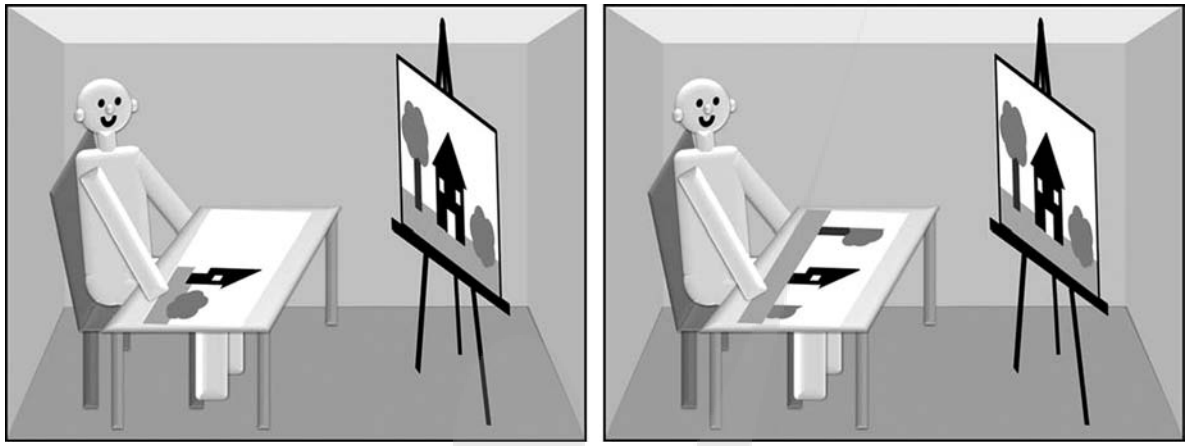


FIGURE 15.3 Horizontal neglect: viewer-centered (A) versus object-centered (B).

and lying flat on their side can evaluate for environment-centered neglect; all lines remain horizontal with respect to the environment, regardless of the patients' position (such that the lines are parallel to the patient's vertical body axis at times and parallel to the patient's horizontal body axis at others). If a patient deviates in the same direction on line bisection when lying down and sitting up and performs accurately on radial line bisection, then that individual has environment-centered neglect (Figure 15.4).

In addition to demonstrating contralesional spatial neglect with the line bisection, cancellation, and drawing tasks, patients with neglect might also show impairment when reading and writing, failing to read or write a part of a sentence or a part of a word.

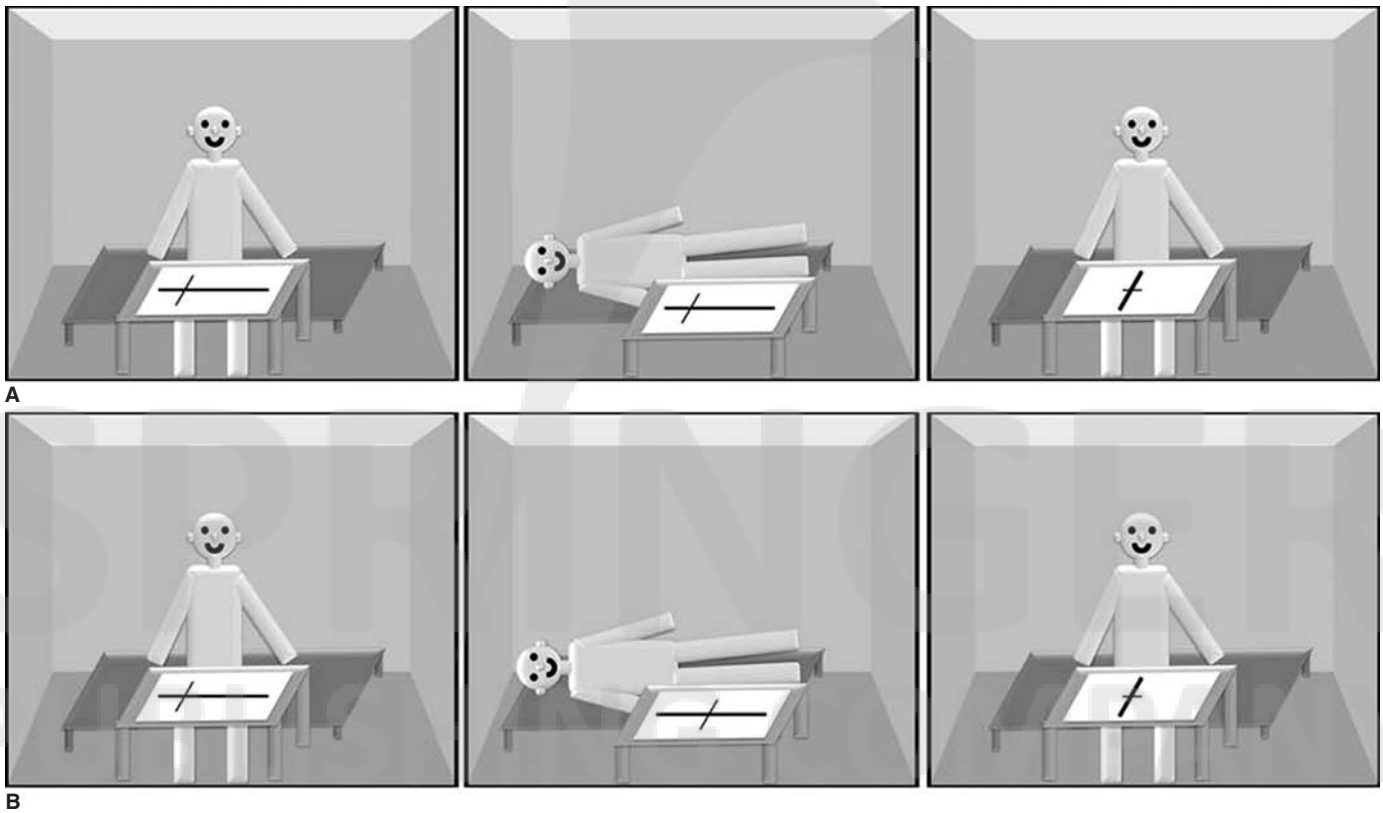

FIGURE 15.4 Horizontal neglect: environment-centered (A) versus viewer-centered (B).

Ipsilesional Neglect. When performing a task such as line bisection, patients with neglect will mostly exhibit contralesional neglect, deviating to the side of hemispheric injury (6). Some patients, however, will deviate atypically, in the opposite direction (for instance, deviating to the left following a right hemisphere lesion), a finding called *ipsile-sional neglect*. Unlike the crossover effect mentioned earlier, ipsilesional neglect can occur even when using long lines.

Attentional Versus Intentional Spatial Neglect. Disturbances of attention may account for the failure of many patients with neglect to correctly perform tasks such as line bisection or cancellation. This attentional disturbance might alter performance on these tasks by several means. Normally, awareness depends on attention: when we are inattentive to something, either that item does not reach our awareness, or we do not maintain awareness of it. If we are not aware of an item or part of an item, we do not interact with it. Patients with spatial neglect might be unaware of a segment of a line (generally the left side) and only bisect the portion of which they are aware, thus deviating to one side. Similarly, they might be unaware of cancellation targets on one side of a paper and thus fail to cancel these targets.

People can vary the degree of attention they allocate to an object or part of an object, and objects or parts of objects that receive more attention appear to have a greater magnitude than those that receive less. For example, we pay more attention when we first drive down a new road than when we return, which causes the road to appear longer when going than when returning. Thus, when patients with spatial neglect view a line, the segment of the line to which they are inattentive (typically, the contralesional side) might appear shorter than its actual size, and the segment to which they strongly attend will appear longer. This attentional asymmetry induces a misperception, and patients deviate their attempted bisection toward the segment that appears longer. To determine the size of a line or to find all the targets, a person has to be able to move his or her attention. If a person has a strong attentional bias toward an object or a part of space, he or she might have difficulty disengaging his or her attention and moving attention to other parts of space. Patients with neglect often have problems disengaging their attention from a portion of space (usually, ipsilesional space) and thus neglect the opposite portion of space (usually, contralesional space).

In addition to correctly allocating attention, to correctly bisect a line, cancel targets, or copy a picture, individuals must move their eyes and arms to different parts of space. Some patients, as mentioned earlier, might have types of motor neglect where they fail to explore with their eyes or move their arms into a part of space (e.g., the contralesional left space).

To dissociate attentional from intentional hemispatial neglect, the clinician can use a variety of techniques, including video cameras with an image reversal system and a monitor, strings and pulleys, and mirrors. All of these techniques can dissociate the direction of action (e.g., leftward) from the direction of sensory feedback (e.g., rightward). If reversed feedback causes a patient to change the side of his or her bias—for example, from a right-sided bias on the line bisection in the direct condition to a leftward bias on the reversed feedback condition—then this patient has primarily an attentional neglect. However, if the bias does not change in the reverse condition, the patient has a primarily intentional spatial neglect.

Asomatognosia and Personal Neglect

Patients with personal neglect may fail to groom or even dress one side of their bodies. Patients with asomatognosia do not recognize that parts of their body belong to them (7). To test for asomatognosia, the examiner can take a portion of the body contralateral to the hemispheric injury and bring it into ipsilateral hemispace and visual field. To make certain that the patient sees this part of his or her body, the examiner can write a number on it. The examiner then asks the patient to read the number on this body part. If the patient can recognize this number, the examiner can then ask the patient who this body part belongs to. If the patient denies that this body part belongs to him or her, the patient has asomatognosia. To test for personal neglect more formally, the examiner can perform a type of cancellation task where the examiner puts little pieces of sticky paper on different portions of the patient's body and asks the patient to remove all the pieces of paper. The examiner can also perform a type of line bisection task, placing a large horizontal line before the patient and asking the patient to point to the position on the line directly across from the middle of his or her chest, right shoulder, and left shoulder. Patients with personal neglect will often shift their midline and contralesional shoulder to the ipsilesional side. Patients with asomatognosia and personal neglect might also have lost or degraded their mental representations of their own bodies. Some of these patients will also demonstrate allesthesia and allokinesia. When touched on the contralesional side of their body, patients with allesthesia claim that they were touched on the ipsilesional side. When asked to move the contralesional side of their body, patients with allokinesia move the ipsilesional side.

Representational/Imagery Neglect

Representational or imagery neglect causes patients to neglect one side of their mental picture of a place or object (8). Imagery neglect may be spatial or personal. When patients with retrograde imagery neglect are asked to recall details of a scene with which they were familiar before the onset of their illness, they might only report those details that are ipsilateral to their lesion. This disorder can also be anterograde: for instance, a patient with a stroke may view a scene in which he or she can recognize all the objects; but when attempting to recall the scene after an interval, he or she may only report those parts of the scene ipsilateral to the hemispheric injury. Patients may also fail at performing a

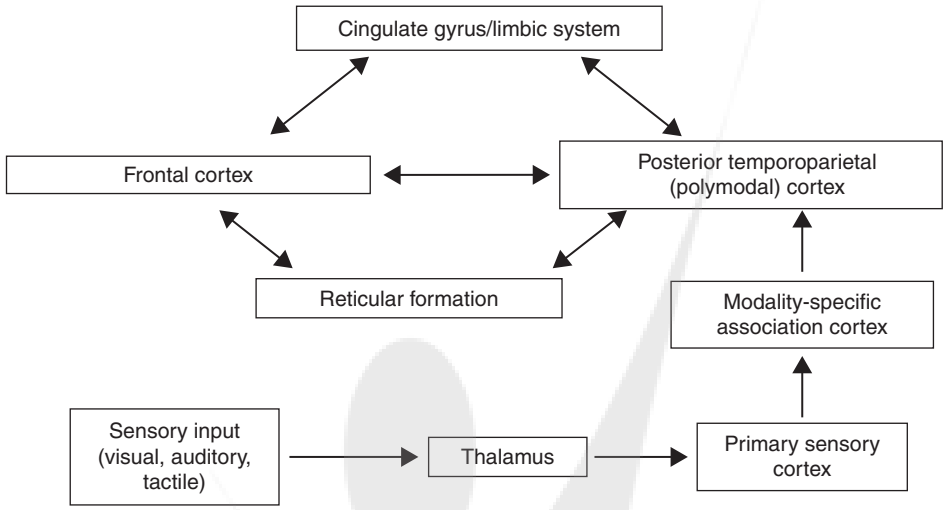

FIGURE 15.5 Simplified schematic diagram of attentional systems. Lesions interrupting these networks can produce attentional neglect.

task where they are required to imagine a contralesional part of their body (4).

Anosognosia and Anosodiaphoria

Patients with neglect can be unaware of their illness and disability (7). For example, many patients with neglect also have weakness of their contralesional arm. However, when asked about weakness, such patients may explicitly deny their hemiparesis. They might also deny sensory loss or hemianopia. Anosognosia most often presents during the acute phase of illness. After being repeatedly told that they have a disability, most patients with anosognosia will usually acknowledge their illness, but they may exhibit anosodiaphoria, appearing unconcerned or even joking about their disabilities.

Pathophysiology of Neglect

Attention

In 1949, Morrizzi and Magoun established the critical role of the reticular activating system (RAS) in mediating arousal (9). When an organism encounters a novel or significant stimulus, it becomes behaviorally and electrophysiologically aroused. An organism that cannot become aroused cannot normally attend. Therefore, arousal constitutes a critical element in the systems that mediate attention. The mesencephalic reticular formation and portions of the thalamus mediate arousal, and unilateral injury to either of these structures can produce neglect.

Attention must also be selective, and Sokolov posited that the cortex selects which stimuli to attend to (10). The human brain can only process a limited number of stimuli, and sensory input into the brain often exceeds its processing capacity. To decide where and what to attend to, the regions of the brain that make these computations must get information about long-term goals, emotions, and needs. Because each parietal lobe is a convergence area that receives input from the lateral frontal lobe (which subserves long-term, prospective, goal-oriented behavior) and the medial frontal lobe/cingulate gyrus (a region highly interconnected with other portions of the limbic system important in mediating behaviors induced by biological needs and emotions), as well as information from sensory processing systems that indicate the type of stimulus (what) and its spatial position (where), the temporoparietal cortex can compute where and to what stimuli a person's attention should be directed (1).

In humans, attentional neglect most commonly follows right hemisphere lesions that involve the posterior superior temporal lobe and the adjacent inferior parietal lobe (1). This temporoparietal region receives afferent (input) information from the cortical visual, auditory, and tactile association areas and sends projections to the RAS. However, lesions in other areas, such as the lateral frontal lobe and the medial frontal lobe, may also induce neglect in humans, presumably owing to disruption of critical attentional networks (1). Figure 15.5 illustrates the neural networks involved in attention.

Imagery

The posterior superior temporal and inferior parietal cortices share strong reciprocal relations with the hippocampus. Damasio posited that the hippocampus participates in retroactivation of sensory association areas (11). Therefore, lesions of the posterior temporal–inferior parietal region might interfere with retroactivation and induce the imagery and representational defects described by Bisiach and Luzzatti (12).

Action-Intention

As mentioned earlier, *attention* is the process by which the brain triages incoming stimuli according to its importance to a person's long-term goals as well as his or her immediate needs and drives. In addition to the limited input processing capacity, the brain also has a limited ability to prepare and control motor actions directed to the environment. "Selective intention" denotes the process by which the brain triages environmentally directed actions. A complete failure of this action-intentional system induces a total inability to initiate movements, termed *akinesia*. Milder defects in the action-intentional systems may induce hypokinesia (delay in implementing an action), abulia (reduced number of self-initiated actions), or motor impersistence (failure to continue action until successful completion of a task). All these action-intentional deficits can involve different body parts and can be directional or hemispatial.

Deciding whether to act and where to act requires knowledge of long-term goals (mediated by the prefrontal lobes), knowledge of drives, needs, and emotions (mediated by the limbic system), and cognitive knowledge of how to act (mediated by temporoparietal regions). Just as the RAS regulates the cortical arousal required for attentional processing, the basal ganglia–dopaminergic system plays a parallel role in the action-intentional system (Figure 15.5). Thus, unilateral injury to the frontal lobe–basal ganglia system or dopaminergic system will produce forms of unilateral or asymmetrical action-intentional neglect. The basal ganglia receive glutaminergic (excitatory) projections from the premotor cortices of the lateral and medial frontal lobes, so damage to any of these regions can also induce action-intentional neglect (1). Figure 15.6 illustrates the neural networks involved in action-intention.

Although both sensory-attentional and action-intentional neglect can develop from damage to either the temporal–parietal or frontal lobes (both lateral and medial), in general, injury to the frontal lobes typically induces primarily action-intentional neglect and injury to the parietal lobes induces sensory-attentional neglect (1). However, for a person to successfully interact with the environment, the intentional and attentional systems must interact, a process facilitated by strong connections between the frontal and parietal lobes.

Right–Left Asymmetries of Attentional and Intentional Neglect

Although either right or left hemisphere lesions may produce neglect, in humans neglect is more common and severe with right than left hemisphere lesions. These asymmetries of neglect appear to arise from asymmetrical attentional and intentional representations of the body and space. Electrophysiological and functional imaging studies suggest that, whereas the left hemisphere attends primarily to the right side or in a rightward direction, the right hemisphere can attend to both sides or in both directions (13). Similarly, whereas the left hemisphere can prepare for right-sided or rightward actions, the right hemisphere can help prepare for actions on both sides or in both directions.

Treatment of Neglect

Treatment of Underlying Diseases

Although ischemic and hemorrhagic stroke represent the most common causes of neglect, any disease that injures

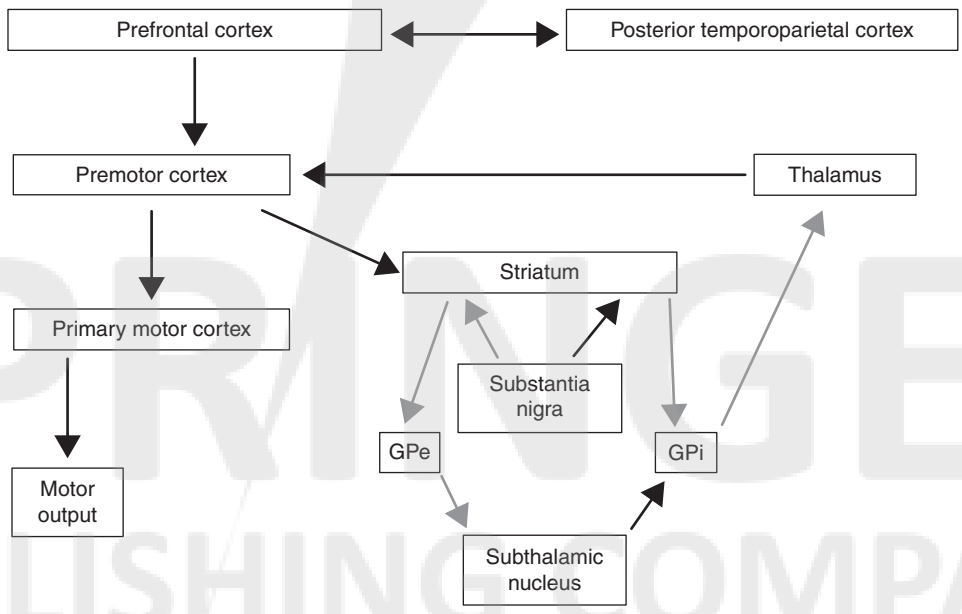

FIGURE 15.6 Simplified schematic diagram of intentional systems. Lesions interrupting these networks can produce neglect. Lesions interrupting these networks can produce intentional neglect. Black arrows: excitatory; gray arrows: inhibitory.

Abbreviations: GPe, globus pallidus externa; GPi, globus pallidus interna.

or destroys networks important in mediating attention and intention can also induce neglect. Therefore, clinicians always need to evaluate patients to learn the cause of the neglect, so that when possible, they can treat the underlying disease and attempt to prevent additional brain injury.

Pharmacologic Treatments

Experiments in animals demonstrated that unilaterally damaging the dopaminergic system by injury (such as by MPTP) or interruption (such as by hydroxydopamine) can produce neglect (14,15); based on these findings, some investigators have examined whether increasing dopaminergic tone may treat neglect. In the largest study of dopamine therapy for neglect to date, a 16-patient double-blind randomized placebo-controlled trial, the dopamine agonist rotigotine appeared to improve neglect on neuropsychological tests (16). However, case reports have described patients treated with dopaminergic agents whose neglect did not improve, or even worsened, with this treatment (17).

One open-label study of the cholinesterase inhibitor rivastigmine (given at a relatively low dose over a short period of time) suggested that this drug may potentially accelerate improvement from neglect, without necessarily affecting the final outcome, as a nontreated group showed similar—though slower—improvement (18). However, these benefits only manifested on neuropsychological tests for neglect, not in activities of daily living (ADLs).

Based on the evidence thus far, we recommend that clinicians considering the use of medications for neglect carefully assess their patients before and after the initiation of treatment to ensure that they really improve. In addition, because many patients spontaneously improve with time, clinicians should perform periodic medication withdrawal with before-and-after testing to make sure that the medication, in fact, caused the improvement.

Neurostimulation

Therapies such as repetitive transcranial magnetic stimulation (rTMS) and transcranial direct current stimulation (tDCS) can activate or inhibit cortical electrical activity; these effects may potentially persist beyond the duration of the stimulus by influencing brain plasticity (19). Recently, investigators have examined whether these therapies could help ameliorate neglect, possibly by reducing the ipsilesional attentional bias.

A double-blind placebo-controlled randomized trial found that rTMS improved both performance on neuropsychological tests for neglect and ADLs; these improvements persisted at least three weeks after finishing the rTMS treatment (20). Although no studies have examined long-term effects of tDCS, double-blind placebo-controlled randomized trials of tDCS indicate that it can reduce neglect on neuropsychological tests administered immediately after treatment (21–23). Further studies may help clarify the optimal role of neurostimulation therapies in neglect rehabilitation.

Behavioral Treatments

"Bottom–Up" Interventions. As many patients with neglect have anosognosia for their deficits, many investigators have tried to develop treatments for neglect that can train patients to automatically attend to contralesional hemispace without having to consciously remember to do so each time; these treatments constitute the "bottom–up" approach, as opposed to "top–down" strategies focusing on conscious efforts (24). These "bottom–up" interventions include prism adaptation, optokinetic stimulation, cold caloric vestibular stimulation, neck stimulation, and monocular eye patching (24)

In prism interventions, patients with left-sided neglect receive training in interacting with environmental stimuli while wearing Fresnel prism lenses that shift the environment to the right. Thus, when patients point to objects they see, they initially overshoot and point to the right of the true location; however, with feedback, they learn to shift their interactions toward their left to reach the target. After removing the prisms, patients experience an aftereffect in which they continue to overcompensate to the left. Although the exact mechanisms by which prisms may treat neglect remain incompletely understood, the leftward bias they produce may contribute to the long-term potentiation of the network directing attention and action-intention to contralesional space (25).

Two randomized controlled trials of prisms have shown that prism interventions can improve neglect not only on neuropsychological tests but also in ADLs, with benefit persisting up to three months after concluding treatment (26,27). In addition, other uncontrolled studies of patients with neglect found similar sustained improvements, lasting up to two years following prism interventions (28–31). One randomized controlled trial of prisms found no improvements, but the prism glasses used only shifted the environment by 6 degrees, whereas the studies that showed improvement used stronger prisms that shifted the visual perception of the environment by 10 degrees or more (25,32). Taken together, the evidence suggests that prisms can be an effective intervention for neglect, with gains sustained well past the conclusion of treatment; however, a dose effect may exist, requiring an adequate number of prism intervention sessions (10–20 sessions) with adequate prism strength (10 degrees) to optimize benefits (25).

Optokinetic stimulation (tracking images moving to the left) and cold caloric stimulation (cold water injected in the left ear) induce a smooth pursuit eye movement to the left (33,34). When healthy individuals attend to and watch an object moving to the left, they make leftward pursuit movements with their eyes, suggesting that perhaps these movements upregulate the systems involved in allocating attention to the contralesional hemispace (33,34). In controlled trials, optokinetic stimulation reduced both auditory and visual neglect on neuropsychological testing, with benefits lasting up to two months after the intervention (33,35–37). A controlled trial of contralesional cold caloric stimulation found that it improved neglect on neuropsychological testing as well as postural control, with effects lasting for at least one hour following treatment, a much longer benefit than the few

seconds described in prior reports (34,38). Cold calorics may reduce attentional neglect more than intentional neglect (39). Vibrating or electrically stimulating the left neck muscles or the left hand can also improve neglect on neuropsychological tests, with benefits lasting for one week in the case of electrical stimulation of the neck (37,40,41). One study found that a vestibular rehabilitation program consisting of specific head movements improved neuropsychological measures of neglect, balance, and ADLs during the period in which patients participated in the intervention (42).

Monocular eye patching derives from the work of Sprague, who produced neglect (asymmetrical exploration and orienting) in animals by ablating a posterior portion of the neocortex, then subsequently reduced this orienting asymmetry by ablating the superior colliculus on the opposite side of the animals' brains (43). In mammals, the retina (both temporal and nasal) in each eye projects more strongly to the contralateral than ipsilateral colliculus. Posner and Rafal suggested that decreasing the visual input into the colliculus of the nonlesioned hemisphere could reduce unilateral spatial neglect (44). Patching the eye ipsilateral to the lesioned hemisphere might reduce the activation of the contralateral colliculus, and this decrease in activation may achieve effects similar to collicular ablasion; the colliculus might influence posterior neocortical activation, and a reduction of cortical activation of the intact hemisphere might potentially reduce the ipsilesional attentional bias. One study did demonstrate a reduction of left-sided neglect with a right eye patch (45); however, Barrett et al. reported a patient with left-sided neglect whose problem worsened with patching the right eye, for unknown reasons (46).

"Top–Down" Training. Operant training techniques can help train patients with neglect to use self-cueing (e.g., "look left") to explore and scan contralesional hemispace (47). One randomized controlled trial found that visual scanning training improved neglect on neuropsychological tests and improved ADLs, with benefits still present, albeit diminished, three months after concluding the intervention (48). Another randomized controlled trial of strategy training found that performance on an untrained task also improved immediately after the intervention (49). However, other studies have found that training often fails to generalize to other tasks, including ADLs and instrumental activities (50–52). Many patients with neglect also have anosognosia for their deficits and may not remember to consciously deploy these training strategies, which may limit the usefulness of these techniques (53).

Salience and Arousal. Although neglect represents an involuntary phenomenon, measures that increase the salience of the neglected space may improve the performance of individuals with neglect. A randomized controlled trial found that rewarding neglect patients for detecting targets improved performance both overall and on targets in the neglected hemispace, compared to when no rewards were given (54). However, two out of the ten patients studied did not show improvement in the reward condition; lesion analysis revealed that, unlike the eight patients whose performance improved, these individuals had strokes involving the right striatum (54). These results suggest that a dopamine-mediated effect on attention and salience could potentially contribute to the efficacy of reward on improved performance (54).

Providing spatially inattentive patients with appropriate attentional cues may also encourage them to attend to contralesional hemispace. Novel stimuli command attention, and novel visual, auditory, and tactile cues presented in contralesional hemispace can help patients direct their attention toward the formerly neglected side (55,56). Self-initiated motor cues may also help: when patients with neglect from a right hemisphere lesion use their left hand to perform tests of visuospatial neglect (such as line bisection and cancellation tasks), they show less neglect than when using their right hand (57). Although many patients with neglect have hemiplegia, any attempted movement of the left arm—even movements unrelated to the task under study, or when the arm remains out of view—can improve performance (58).

Some recent studies have examined whether training to improve attention and alertness in general can help improve neglect. Trials of both visual and auditory sustained attention training improved performance on visuospatial tests of neglect, suggesting that optimization of supramodal attentional mechanisms may transiently ameliorate neglect; however, this improvement was not sustained on later retesting (59,60).

Forced Use. Interventions that force patients with neglect to use the neglected side of the body and to interact with neglected hemispace may help lessen the signs of neglect. Multiple studies have shown that poststroke hemiparesis can improve with forced use or constraint-induced therapy, a technique in which the therapist places the less affected hand in a mitt and intensively trains the paretic upper extremity using an array of behaviorally reinforced tasks (61); as patients with neglect may have limb akinesia (limb motor neglect), which resembles hemiparesis, forced use therapy may help them as well. One recent randomized controlled trial found that constraint-induced therapy of the left arm lessened neglect behaviors in ADLs (62).

Patients with neglect often demonstrate a directional akinesia of their eyes, failing to move their eyes in a contralesional direction and failing to explore contralesional visual hemispace. When patients with neglect wear glasses in which an opaque material covers the ipsilesional half of each lens, this may force them to learn to move their eyes in a contralesional direction to see. One randomized controlled trial in patients with neglect compared the effects of occupational therapy done with the right hemifield patched to standard occupational therapy; the patched group did better on neuropsychological tests for neglect when tested shortly after the intervention, but the groups did not differ on ADLs (63).

Environmental modifications that require patients with neglect to attend to the contralesional space may also act as a form of forced-use therapy. One randomized controlled trial found that for patients with neglect who used a wheelchair, placing the wheelchair control joystick on the left led to significantly more accuracy while driving the wheelchair than when the control joystick was placed on the right; putting the joystick on the left may have acted as a spatial cue, forcing patients to attend more to the contralesional side (64).

Optimization of Standard Rehabilitation Therapies

Neglect can substantially interfere with participation in physical therapy and occupational therapy targeting other neurological deficits, such as hemiparesis and difficulty in walking. However, some simple modifications of standard rehabilitation therapies may help patients with neglect participate more fully. In the acute poststroke period, having family members participate in the rehabilitation program with patients with neglect may improve outcomes on both neuropsychological measures and ADLs (65). Patients with neglect from acute stroke generally experience longer hospital stays than those without neglect; however, when patients undergo very early mobilization (beginning within the first 24 hours after stroke), length of stay does not differ between patients with and without neglect (66). It remains unknown at this point, though, whether shortening hospital stays through early mobilization improves the long-term outcome for patients with neglect.

Combinations of Interventions

The various treatments for neglect described earlier may differentially affect the various neural mechanisms believed to underlie the neglect syndrome. Thus, combinations of treatments may potentially offer synergistic benefits (24). However, not all studies combining treatments have found an additive benefit, and in some cases the combination may be less effective than the treatments in isolation, particularly if combining treatments prevents results in an inadequate amount of time with each different intervention (24,62,67).

Management of the Environment and Safety Considerations

The sensory-attentional and action-intentional disorders associated with neglect dramatically reduce a person's capacity to successfully interact with his or her environment. To reduce disability and keep the patient and others safe, patients with these disorders must have their environment altered to reduce the risk of injury and to increase the possibility for successful interaction with environmental stimuli. Patients with even the mildest forms of neglect should not drive vehicles or use machinery with the potential to injure themselves or others.

Neglect more often occurs in reference to the patients' body (egocentric neglect) rather than to the objects in the environment (allocentric neglect). Thus, many patients can be positioned and the environment arranged such that environmental stimuli take place on the ipsilesional side of the patient's body. The historical case of President Woodrow Wilson offers a dramatic example of how optimizing the spatial arrangement of a neglect patient's environment may significantly improve performance. Following Wilson's large right hemisphere stroke and left hemiparesis, many members of Congress were worried that his medical condition would make him incapable of governing the country, so they dispatched some senators to visit him. However, before they came, Wilson's wife, who was doing much of the governing, placed him so that his left side was against a wall and his right side faced the senators. After their visit, the senate delegation claimed that Wilson was fit to govern (68). In contrast, if a patient's environment never requires him or her to attend to or act in contralesional hemispace, this could possibly impede recovery.

Appropriate temporal structuring of activities may also help optimize functioning. Because patients with neglect have a reduced attentional capacity and have difficulty dealing with more than one stimulus, reducing competing or distracting stimuli may improve performance. In addition, because patients with neglect also have a reduction of sustained attention and vigilance, the most important stimuli or actions should take place first.

EMOTIONAL COMMUNICATION DISORDERS

Changes in emotional communication can result from injury to the right hemisphere and include modality-specific subtypes (visual/facial and auditory/prosody) as well as afferent (receptive) and efferent (expressive) subtypes.

Receptive Disorders

Emotional Faces

To interpret the emotional aspects of a given situation, as well as to successfully communicate with others, we must correctly perceive and comprehend visual stimuli such as facial expressions, gestures, and scenes.

When patients with right versus left hemisphere lesions were asked to name the emotion being expressed by faces, as well as to discriminate whether two faces displayed the same or different emotional expressions, right hemisphere-damaged individuals showed a specific impairment in emotion processing, not attributable to facial identity discrimination or other visuospatial disorders (69). Investigators from other laboratories have also reported that patients with right hemisphere stroke experience more impairment than their left hemisphere counterparts in recognizing or categorizing facial emotions (70–72). In general, these defects in identifying facial affect do not depend on emotional valence, as patients with right hemisphere damage have trouble recognizing both positive (happy) and negative (sad or angry) emotional expressions.

Based on stimulation studies of patients with epilepsy, Fried et al. found that inducing dysfunction of the posterior portion of the superior temporal gyrus by focal electrical

stimulation caused patients to become impaired in comprehending and discriminating emotional facial expressions (73). As patients with damage to this area fail at both naming emotional faces as well as discriminating between the same and different emotional expressions, these patients might have an iconic representational deficit. When patients with these face comprehension deficits encountered sentences that either describe emotional expressions or emotion-invoking stories, they showed deficits in comprehending the emotions associated with expressions but not stories, suggesting that they had degradation of emotional expressive representations (74). In addition, Bowers et al. demonstrated that the patients with right hemisphere damage had deficits of facial emotional imagery, but not object imagery, providing evidence that these representations are, at least in part, iconic (75). However, other studies also suggest that the discrimination of emotional faces might depend on motor-imitation or movement mirroring (76).

Affective Prosody

When people with a meaningful relationship talk to each other about a disagreement, one of the partners frequently says to the other, "It's not what you said, but how you said it." This expression indicates that speech might carry more than one message. In addition to communicating a propositional message—which requires lexical, syntactic, and phonemic encoding and decoding—speech may simultaneously communicate a message by the use of prosody. Prosody—expressed by making changes in pitch, tempo, amplitude, and rhythm—frequently conveys an emotional message, though it may also express linguistic content (e.g., in English, rising intonation often denotes a question).

Since Paul Broca's reports of right-handed patients who develop aphasia from left hemisphere strokes, numerous studies have repeatedly demonstrated that in more than 95% of right-handed people, the left hemisphere mediates propositional language. Hughlings Jackson, however, described a patient with nonfluent aphasia who remained capable of expressing emotional speech prosody and posited that the uninjured right hemisphere might mediate this skill (7,77). The first systematic studies of emotional prosody, conducted by Heilman et al. (78) and Tucker et al. (79), indicated that when compared to patients with aphasia from left hemisphere injury, those with right hemisphere injury frequently showed impairment at comprehending and expressing emotional speech prosody. Although Ross reported similar findings (80), not all investigators found differences between right and left hemisphere-damaged patients. Further evidence for the dominant role of the right hemisphere in comprehending affective intonations comes from studies that demonstrate preserved abilities in patients with left hemisphere lesions. Patients with global aphasia who have destroyed their entire left perisylvian speech cortex and patients with pure word deafness (normal speech output and reading, but impaired speech comprehension and repetition) induced by injury to the left auditory cortex, comprehend speech very poorly but may have no difficulty recognizing emotional intonations of speech (81,82). Tucker et al. attempted to determine whether patients with right hemisphere disease could discriminate between affective intonations of speech without having to verbally classify or denote these intonations and found that patients with right hemisphere disease performed more poorly on this task than patients with left hemisphere disease (79).

The defect underlying the impaired comprehension of emotional prosody remains incompletely understood; however, we suspect that the right hemisphere contains the auditory representations of the prototypical emotional prosodies, and degradation of these representations or an inability to access them could impair both comprehension and discrimination of emotional prosody.

In normal conversation and experimental tasks, emotional prosody generally exists superimposed on propositional speech, raising the possibility that after right hemisphere damage, the intact left hemisphere fails to comprehend emotional prosody as it devotes its resources to processing the propositional semantic message. When right and left hemisphere-damaged individuals underwent an emotional prosody task that varied in the degree of conflict between the emotional message conveyed by the prosody and that conveyed by the propositional content, the right hemisphere-damaged group experienced more disruption when the propositional and prosodic emotional messages conflicted strongly than when they conflicted less (83). However, in a subsequent experiment, when the propositional semantic message was deleted by filtering the speech, the patients with right hemisphere damage still showed more impairment than those with left-sided lesions; these findings suggest that, though the left hemisphere is capable of some processing of emotional prosodic information, the right hemisphere is dominant, and distraction by propositional content cannot fully account for the prosody deficits that follow right hemisphere injury (83).

Visual and Auditory Verbal Processes

The comprehension of spoken and written words by patients with aphasia from left hemisphere-damaged patients improves when emotional words or phrases are used (84), suggesting that the right hemisphere has a lexical–semantic system that can process emotional words better than non-emotional words. However, increased arousal, which typically accompanies emotional stimuli, may instead represent the critical factor. Support for a right hemisphere emotion-based lexical–semantic system comes from the work of Borod and coworkers, who tested patients on emotional and non-emotional sentence and word discrimination tests and found that right hemisphere damage produced more impairment than left hemisphere damage on the emotional discrimination tests (85). Other studies, however, suggest that lesions of the right hemisphere do not specifically disrupt lexical semantic knowledge about emotions or emotional situations (86). Patients with right hemisphere lesions appear to have intact conceptual knowledge about emotions that are communicated verbally, as long as this communication does not involve verbal descriptions of nonverbal affect signals (74).

Expressive Defects

Speech and Writing

We demonstrated that many patients with right hemisphere disease cannot express affective speech prosody (expressive affective aprosodia) (79). Typically, these patients speak in a flat monotone and often verbally denote their emotions through the propositional content of their speech. Ross and Mesulam described two patients who could not express affectively intoned speech but who could comprehend affective speech prosody (87). Ross postulated that right hemisphere lesions may disrupt the comprehension, repetition, or production of affective speech in the same manner that left hemisphere lesions disrupt propositional speech (80).

The evidence suggests that patients with right hemisphere dysfunction can still express emotions using propositional speech or writing, although Bloom et al. reported that right hemisphere-damaged patients used fewer words when denoting emotions in their spontaneous speech (88). However, this finding might be related to other factors such as the decreased arousal associated with right hemisphere injury, rather than a true lexical–semantic deficit.

Facial Expressions

Buck and Duffy reported that patients with right hemisphere damage express fewer facial emotions than patients with left hemisphere damage (89). Multiple other studies have replicated these findings, and these patients show similar deficits in more naturalistic settings outside the laboratory (86). By contrast, studies using the facial action coding system have not found differences in facial emotion expressiveness between patients with right and left hemisphere damage (90,91). The reason for this discrepancy remains unclear; however, the observation that normal people express emotions more intensely on the left side of the face supports the postulate of right hemisphere dominance (92).

Treatment

Rosenbek and associates demonstrated that both imitative treatment and cognitive–linguistic treatments might help patients with expressive aprosodia (93). However, no well-controlled studies have examined the treatment of comprehension disorders of aprosodia or of disorders of facial emotional communication.

VISUOSPATIAL FUNCTIONS

Angle and Face Matching

Based on observations of patients with discrete lesions and corpus callosum disconnection, neuropsychologists have proposed functional hemispheric asymmetries, including left hemisphere dominance for mediating speech and language and right hemisphere dominance for visuospatial functions. However, Trojano tested patients with brain lesions using many tests of visuospatial ability, including mental rotation and the copying portions of the Rey Complex Figure Test, and did not find significant differences between those with right and left hemisphere injuries (94).

Only two well-known visuospatial tests—the Judgment of Line Orientation (JOLO) and the face-matching test—clearly differentiate between right and left hemisphere damage (95). On the JOLO, patients see a series of pages displaying two line segments drawn at different angles from each other and subsequently perform a recognition test, selecting the angle on a protractor-like display (95). On the face-matching test, patients attempt to match photographs of faces of unfamiliar people; the photographs are taken from different perspectives so that patients cannot correctly perform this task by simply making same–different decisions (95). On these two tests, patients with left hemisphere injuries perform normally and those with right hemisphere injuries show significant impairments.

These findings suggest that the right hemisphere may perform some specific visuospatial functions distinct from those represented in the left hemisphere or bilaterally. With regard to intrahemispheric localization, some investigators have hypothesized that injury to the posterior portions of the right hemisphere's cerebral cortex, including the parietal lobes, induces visuospatial dysfunction (96).

Constructional Apraxia

Constructional apraxia, or an impaired ability to copy and make drawings, may occur after either left or right hemisphere injury; however, patterns of errors may differ depending on the laterality of the lesion (97). Patients with left hemisphere lesions appear to have problems with planning and organizing their drawing; therefore, their productions become simplified and impoverished. For example, when attempting to draw a three-dimensional cube, patients with left hemisphere damage might draw several attached rectangles. In contrast, patients with right hemisphere lesions have problems in correctly producing the spatial relationships between the components of the drawing. When attempting to draw a cube, patients with right hemisphere damage will have problems displaying the correct angles between the lines that form the cube. Patients with right hemisphere damage also frequently demonstrate elements of spatial neglect and thus might fail to copy or draw the left side of objects.

Topographic Disorientation and Image Rotation

Patients can have topographic disorientation for several reasons, such as impaired spatial orientation, inability to recall the spatial relationships of landmarks, or failure to recognize landmarks. These disorders most often accompany bilateral hemispheric dysfunction, but right medial temporal lobe dysfunction may produce defects in the acquisition of topographic relationships (98).

Many defects of imagery exist (see Farah and Epstein (8) for a review) and can occur with lesions of the right parietal lobe (99).

Dressing Apraxia

Dressing apraxia most commonly occurs in the setting of degenerative diseases such as corticobasal degeneration, but focal right hemisphere lesions might also induce this deficit. Many patients with right hemisphere strokes have neglect and related disorders and might be inattentive to or unaware of the left side of space and/or the left side of their body. This inattention–unawareness can induce a failure to dress the left side of the body, but some patients without neglect also have trouble with dressing. Dressing apraxia can give rise to significant disability, so clinicians should keep this disorder in mind when evaluating patients with right hemisphere lesions. To test for dressing apraxia, the examiner can provide an inside-out jacket and ask the patient to put it on.

Treatment

Unfortunately, very few studies have systematically examined the treatment of the visuospatial disorders mentioned earlier. One randomized controlled trial found that, for patients with right hemisphere lesions, a detailed assessment of the cognitive contributors to dressing problems and a rehabilitation strategy tailored to those specific deficits resulted in improvement in dressing (100). Recently, some groups have explored virtual reality training as a means for improving topographic orientation deficits and other visuospatial problems, but work remains in the preliminary stage (101).

CONCLUSIONS

For many years, physicians and surgeons believed that except for the motor and sensory systems, the right hemisphere was "silent" and did not play a critical role in controlling higher-order neurobehavioral functions. Therefore, when surgeons had to take a brain biopsy or insert a tube through the cortex into the ventricles, they would operate on the right hemisphere. Over the past several decades, however, it has become apparent that the right hemisphere mediates many of human beings' most important cognitive functions, such as attending to relevant stimuli, as well as deciding when to initiate an action, when to persist at an action, when to complete an action, and even when not to act. Emotions play a critical role in our lives, and the right hemisphere appears to be dominant for verbal–prosodic and facial–emotional communications. In addition, the right hemisphere appears to mediate spatial operations such as drawing and dressing. Developing effective and readily accessible rehabilitation strategies for right hemisphere deficits remains an important yet unfulfilled goal.

Overall, the evidence indicates that right hemisphere damage induces severe disabilities that reduce independence more frequently than does left hemisphere damage. Thus, despite its traditional designation as the "nondominant" hemisphere, the right hemisphere in many respects is the "governing" hemisphere. Health providers who deal with patients having brain injuries or neurodegenerative conditions must understand the right hemisphere's functions—and we hope that this chapter will aid this understanding.

Memory, Executive Function, and Dementia

Steven M. Greenberg and Yael D. Reijmer

POSTSTROKE COGNITIVE DYSFUNCTION: THE SCOPE OF THE PROBLEM

Cognitive impairment following symptomatic stroke is one of the most important aspects of stroke recovery, and historically also has been one of the least appreciated. Despite the self-evident importance of cognitive function to quality of life, widely used scales of stroke-related disability, such as the Barthel index (1), have typically focused on motor-dependent skills, such as ambulation, transfers, bathing, toileting, and feeding, without reference to cognition. One contributor to this tendency to exclude cognition from the stroke recovery field may have been the belief that dementia is caused primarily by Alzheimer's disease (AD) and is largely unrelated to cerebrovascular disease. With increased understanding of the key role played by vascular injury in cognitive dysfunction (2) and of possible overlaps and synergies between vascular processes and AD (3), however, has come greater appreciation of the cognitive dysfunction that follows stroke.

Stroke is a potent risk factor for cognitive impairment and dementia. Studies of hospitalized stroke patients using prospective follow-up (4) or analysis of Medicare Part A inpatient claims (5) estimated an approximately 10-fold increased risk for dementia and a prevalence of 20% to 25% (6). Prospective population-based studies (7–11) have yielded smaller—but still quite substantial (approximately two-fold)—increases in risk for dementia following stroke. As not all cognitive impairment meets the criteria for "dementia" (12,13) and not all cerebrovascular disease is diagnosed as "stroke," these figures likely underestimate the full contribution of vascular disease to cognitive dysfunction.

Once present, poststroke cognitive impairment and dementia are major independent risks for death and disability (14,15), underlining the importance of this complication from the stroke rehabilitation perspective. Poststroke dementia also causes attrition from research follow-up (16), and is another factor likely to lead to underestimates of its true prevalence.

Poststroke cognitive dysfunction, like poststroke dysfunction of any type, occurs only in subjects who survive their strokes. The improvements in stroke survival achieved over the past few decades (17) might thereby have the unintended effect of increasing the prevalence of poststroke cognitive dysfunction. At least some data have suggested such a trend. In an analysis of Medicare Part A inpatient claims from approximately 42,000 subjects age 65 and older participating in the National Long-Term Care Survey (5), a comparison of the time periods 1984 to 1990 and 1991 to 2000 demonstrated a 53% increase in the age-adjusted rate of all dementia types, with the greatest increase (87%) occurring in those subjects with symptomatic stroke. These secular trends occurred in the setting of increased one-year stroke survival from 53% to 65% over the same time interval, suggesting that gains in stroke survival indeed may be contributing to the increasing burden posed by poststroke cognitive dysfunction. Further, both cerebrovascular and AD pathologies are markedly age dependent, suggesting that the prevalence of each will rise with the aging of the population. The net effect of improved stroke survival, an aging population, and steady age-specific stroke rates thus is predicted to be a major increase in the number of patients affected by poststroke cognitive dysfunction.

THE SPECTRUM OF POSTSTROKE COGNITIVE DYSFUNCTION

Two issues have stood as barriers to a full appreciation of the role of vascular factors in cognitive impairment. One is the heterogeneity of the vascular contribution to cognitive dysfunction. The vascular role can range from relatively pure instances of cognitive devastation, caused by clinically recognized strokes with no apparent contribution from other neurologic disorders, to the more common situation where small vascular injuries combine with neurodegenerative processes like AD to produce mixed impairments. The second complicating issue has been the types of cognitive impairments that result from vascular injury. These also span a spectrum from frank dementia (defined as deficits of multiple cognitive domains, including memory, that interfere with functional activities (18)) to cognitive impairments not meeting these criteria but nonetheless causing substantial functional limitation.

Since disseminating the term "multi-infarct dementia" (19), Vladimir Hachinski has argued eloquently that

the field essentially should bypass these questions by considering vascular cognitive impairment as a spectrum of disorders with varying types of vascular contributors and varying types of cognitive deficits (20). The following discussion of poststroke cognitive impairment emulates this approach by considering first the range of factors (related to both the stroke and the patient in whom it occurs) that determine the likelihood of subsequent cognitive impairment, and then the array of cognitive deficits that can occur following stroke.

Determinants of Impairment

Stroke Factors

The effect of stroke on cognition likely represents the cumulative effects of location, number, and volume. In a subset of syndromes defined as "strategic" infarctions (21,22), location is the overriding factor allowing single discrete infarctions to cause multidomain cognitive impairment. Among these strategic locations are

1. The paramedian thalamus, typically supplied by branches from the distal basilar or proximal posterior cerebral arteries. Infarctions in this territory can give rise to widespread disturbances in memory, spatial processing, and personality as well as language (if the dominant side is included) (23).
2. The inferomedial temporal cortex, fed by the posterior cerebral arteries. If the dominant side is affected, this leads to verbal memory and verbal–visual impairments such as alexia and color anomia (24).
3. The dominant angular gyrus, fed by branches of the middle cerebral artery. This leads to impairments of memory, language, and affect (25,26).
4. The parieto–temporal association cortex in the territory of the middle cerebral arteries, leading to inattention and behavioral abnormalities.
5. The frontal lobe, fed by the anterior cerebral artery. This produces deficits in memory and initiative.

Neuropathological studies have also pointed to lacunar infarctions in regions such as the basal ganglia, thalamus, and hippocampus or the medial temporal lobe as mimicking strategic stroke syndromes (27). In practice, the preponderance of single strategic infarcts causing vascular cognitive impairments appears to occur in the posterior circulation (28).

The remainder of the spectrum of strokes causing cognitive dysfunction is comprised of multiple infarctions, clinically symptomatic or asymptomatic, that collectively impair cognition. In multivariable analyses controlling for other potential contributors to dementia (see later in this section), studies have implicated the total volume of infarcts in left and right vascular territories (29–31)—or more specifically, the volume of infarction in limbic and multimodal association cortex (32)—as predictors of stroke-related dementia. Efforts to identify specific radiographic features distinguishing patients with and without poststroke dementia, however, have proven difficult. In a study of 125 subjects with stroke, none of the radiographic characteristics proposed as supporting a diagnosis of vascular dementia (21) (such as infarction of a strategic area or extensive white-matter lesions) were overrepresented among those with dementia (33). These data suggest that the risk of poststroke dementia may depend substantially on factors other than the stroke itself, in particular the pre-existing state of the brain in which it occurs.

Patient Factors

Among demographic factors, age, low education level, and nonwhite race have been demonstrated as risks for poststroke dementia (8,29,31,34–36). The extent of pre-existing cerebrovascular disease also appears to contribute to the likelihood that a subsequent stroke will impair cognition, as suggested by positive associations with history of prior stroke, the extent of white-matter lesions or microstructural changes on neuroimaging, and vascular risk factors such as diabetes mellitus, cigarette use, or elevated low-density lipoprotein (29,31,34,35,37–39). The latter findings are consistent with broader studies of the general population, linking vascular risk factors of all types (including midlife hypertension, midlife cholesterol, diabetes/hyperinsulinemia, plasma homocysteine, tobacco use, metabolic syndrome, and a composite score of atherosclerosis) with impairments of cognition (40–56).

Presence of pre-existing AD pathology may be another key determinant of the effects of stroke on cognition, in keeping with the increasingly accepted concept that cerebrovascular disease and AD act synergistically in generating cognitive impairment (57–59). Supporting an important role for underlying AD is the observation that atrophy of the medial temporal lobe is a strong predictor of poststroke dementia (31,33,36). Similarly, prestroke cognitive impairment has been identified as a predictor of poststroke impairment (39,60). Some studies (61,62) (though not all (63)) have also identified the AD-associated apolipoprotein E (APOE) 4 allele as a genetic risk for poststroke cognitive decline and dementia. Interpretation of this finding potentially is confounded by the fact that APOE 4 also has associations with ischemic stroke (64) and cerebral amyloid angiopathy (65). With the development of noninvasive markers for senile plaques (66), assessing the interaction of stroke with AD pathology in determining poststroke cognition will be increasingly feasible (67,68).

In summary, the situation where widespread cognitive impairment can be attributed to individual strategic strokes appears to be the exception rather than the rule. Instead, poststroke cognitive impairment generally represents the cumulative effects of location, number, and size of strokes (both incident and remote) and white-matter lesions—"a matter of strokes large and small" in Fisher's widely quoted formulation (69)—and pre-existing brain pathologies, in particular, AD.

Characteristics of Impairment

Although stroke-related cognitive impairment might be expected to manifest immediately following the triggering stroke, studies have emphasized the ongoing incidence of newly diagnosed dementia months or even years after stroke. This phenomenon might be related partly to difficulties in diagnosing dementia during the medically active early poststroke period, but very likely also reflects an increased vulnerability of stroke patients to ongoing vascular and neurodegenerative events. One study of 154 stroke survivors initially free of dementia demonstrated that the incidence of new dementia remained substantially greater than that in elderly controls, with cumulative incidence of approximately 10% at 1 year after stroke, 15% at 2 years, and 22% at 3 years (70). Approximately two-thirds of the incident dementias in this study could be attributed to recurrent stroke, intercurrent medical illnesses potentially causative of brain hypoxia (such as seizure, heart failure, or pneumonia), or borderline poststroke cognitive test scores that left the patient close to meeting dementia criteria during follow-up. The remaining one-third had no clinically evident cause or event. Similarly, high rates of incident cognitive impairment during the years following stroke have been identified in other prospective studies (39,71,72), with recurrent stroke or borderline poststroke cognitive status acting again as risk factors (8,36,71,73).

Studies comparing the cognitive profile of AD and vascular dementia have often emphasized the relatively greater impairments of episodic memory in AD and increased impairments on tasks requiring executive function, information processing speed, and working memory, such as picture arrangement or object assembly, in vascular disease (74–76). Deficits in *short-term episodic memory* nonetheless are a common feature of poststroke cognitive impairment, even in those not meeting criteria for dementia (76–79). Memory impairment following stroke can be a result of infarction of medial temporal lobe structures directly involved in memory storage (27). Another possible mechanism is damage to white-matter structures involved in memory encoding and retrieval through connections with the medial temporal lobe. In a functional MRI study of older, cognitively normal subjects, T2-hyperintensities in the dorsal prefrontal cortical white matter correlated with decreased activation of the medial temporal lobe and worse performance on an episodic memory task (80). Another study used diffusion-tensor imaging of diabetic subjects to demonstrate a correlation between verbal memory impairment and microstructural damage to the inferior longitudinal fasciculus (81). These findings raise the intriguing possibility that vascular lesions may contribute to memory impairment through a kind of disconnection mechanism even without direct damage to the medial temporal brain regions.

Executive function is another prominent cognitive domain commonly affected following stroke. Executive function is a somewhat ill-defined, but nonetheless central, component of the cognitive abilities required for day-to-day functioning. It represents a constellation of higher-order skills used to manipulate available information to plan and execute complex activities. Among the elemental skills felt to comprise executive function are allocation of attention, mental flexibility, processing speed, set maintenance, set shifting, working memory, and error correction. Its importance to real-life functioning is demonstrated by strikingly high correlations in the elderly with institutionalized versus noninstitutionalized level of care (82) and with formal scales of activities of daily living (ADLs) (83,84). In a study of 337 testable stroke survivors (mean age 70.2 ± 7.6), executive dysfunction (performance at least 1.5 standard deviations below the mean for elderly control subjects on 8 tests) was present in 40.6% of subjects and was associated with more than a doubling of deficits on measurements of basic ADLs (84).

Many stroke survivors with insufficient memory loss, functional impairment, or other multidomain deficits to meet criteria for dementia (18) nonetheless demonstrate substantial cognitive impairments. These patients (sometimes designated "vascular cognitive impairment, no dementia" or CIND (85)) exhibit particular impairments in executive functioning, sequencing, attention, working memory, and cognitive processing speed (86). Analysis of 92 hospital-based subjects diagnosed with CIND found less memory impairment but essentially the same extent of executive dysfunction as in 33 similarly aged subjects diagnosed with vascular dementia (78). Another notable finding from this study was that even those stroke survivors who were considered to have *no* significant cognitive impairment demonstrated worse executive function than stroke-free controls (with no difference in memory scores), indicating that executive function may indeed be the most sensitive cognitive domain to the effects of stroke.

Other cognitive domains have been studied less extensively following stroke. A population-based study found no stroke-associated decline in *visual–spatial* or *language* performance (77), whereas the previously noted study of hospitalized stroke patients without significant cognitive impairment demonstrated subtle deficits in these areas (78). Increasing attention has focused on poststroke *depression*, *apathy*, and *anxiety* as other possible manifestations of vascular dementia (87,88), with psychomotor retardation as perhaps the most prominent neuropsychiatric feature to be seen in specific association with cognitive impairment (89).

MANAGEMENT OF POSTSTROKE COGNITIVE DYSFUNCTION

The high prevalence of cognitive impairment following stroke (even in subjects felt clinically to have no significant cognitive impairment (78)) argues that cognitive screening and follow-up should be a fundamental component of the stroke rehabilitation process. No cognitive test battery has emerged as a standard protocol for this purpose, however. Widely used instruments, such as the Mini-Mental State Examination (MMSE) (90) and the full or abbreviated

Cambridge Cognitive Examination (CAMCOG) (91,92), offer little testing of executive function and therefore are not ideal for the poststroke setting. The National Institute of Neurological Disorders and Stroke–Canadian Stroke Network's (NINDS-CSN) vascular cognitive impairment working group (93) addressed the issue of cognitive testing by proposing 3 protocols requiring approximately 60, 30, or 5 minutes for administration (Table 16.1). Tests in the full 60-minute protocol address 4 primary cognitive domains: executive/activation, language, visual–spatial, and memory, as well as items such as the Neuropsychiatric Inventory Questionnaire (NPI-Q) to capture neurobehavioral change and mood. Items addressing the executive/activation domain in the 60- and 30-minute protocols are tests of semantic and phonemic fluency, digit-symbol coding, and trailmaking (the latter being an optional supplemental task in the 30-minute battery). The five-minute protocol, based largely on the Montreal Cognitive Assessment (MoCA) and designed for ease of use, as well as potential administration by telephone, tests phonemic fluency, orientation, and immediate and delayed recall. The NINDS-CSN authors note that instructions and norms in a wide range of languages for this short battery are publicly available for noncommercial use (www.mocatest.org). Comparisons of MoCA and MMSE in stroke patients suggest that the MoCA may have greater sensitivity for detecting impairments while maintaining specificity (94,95), supporting its use in clinical practice and research.

Once the presence of cognitive impairment is established, the question turns to potential nonpharmacologic and pharmacologic approaches to treatment. Cognitive rehabilitation is a widely used nonpharmacologic treatment for poststroke impairment (96), but has had little experimental testing. A Cochrane Review, published in 2000, of cognitive therapy for poststroke memory impairment found only a single study of 12 subjects meeting criteria (97), underlining the importance of further work in this area.

Pharmacologic approaches to poststroke cognitive impairment can be divided into disease-modifying treatments to prevent future declines and symptomatic treatments aimed at improving the current level of functioning. Among disease-modifying treatments, secondary stroke prevention is of paramount importance, as longitudinal studies of patients with symptomatic (8,36,70,73) or clinically silent (9) stroke demonstrate recurrent stroke as a major contributor to subsequent cognitive decline. Current guidelines for secondary prevention of ischemic stroke (98,99) include (a) antihypertensive treatment, with specific data suggesting that diuretics alone or in combination with angiotensin-converting enzyme

inhibitors are useful; (b) glycemic control in patients with diabetes; (c) statin therapy for those with atherosclerosis and a low-density lipoprotein cholesterol (LDL-C) level greater than or equal to 100 mg/dL (aiming for reduction in LDL-C of at least 50% or to less than 70 mg/dL); (d) antiplatelet, anticoagulant, or vascular reperfusion therapy as dictated by stroke evaluation (99); and (e) lifestyle modifications, such as smoking cessation, reduction of heavy alcohol use, increased physical activity, and weight loss, particularly in the setting of metabolic syndrome. The most relevant data for prevention of poststroke cognitive decline came from the randomized controlled PROGRESS study, in which perindopril plus optional indapamide significantly reduced the risk of both cognitive decline (MMSE drop of ≥3 points in 9.1% of treated versus 11% of placebo, representing a 19% risk reduction) and progression of white-matter lesions (mean increase in white-matter hyperintensity volume of 0.4 mm^3 versus 2.0 mm^3) (100,101). These data suggest that this or similar drug combinations may be useful through a wide range of baseline blood pressures for prevention of poststroke cognitive decline.

The association between markers of AD, such as medial temporal atrophy and apolipoprotein E 4, and poststroke cognitive decline suggests that AD pathology also contributes to this process. Slowing of AD progression is therefore a rational approach for stroke patients with cognitive impairment, but has not yet been demonstrated for any available agent. Rapidly growing understanding of the pathogenesis of AD provides grounds for optimism that disease-modifying agents will ultimately emerge (102), however, and serve as promising candidates for prevention of cognitive decline following stroke.

Trials of symptomatic treatments for poststroke cognitive impairment have focused largely on medications already demonstrated to provide symptomatic benefit in AD (Table 16.2) (103). A pooled analysis (104) of two 24-week randomized, controlled trials (105,106) of the acetylcholinesterase inhibitor (AChEI) donepezil in patients diagnosed with vascular dementia found improvement of approximately two points on the Alzheimer's Disease Assessment Scale—cognitive subscale (ADAS-cog) and a significant increase in the proportion of subjects with global improvement (37% and 30% on 5 and 10 mg of donepezil versus 27% on placebo). These modest improvements, largely replicated in a more recent study (107), appear slightly smaller than those achieved using the same agent for AD (103), possibly reflecting the lesser tendency of vascular dementia subjects in the placebo arm to decline during the study period, compared to placebo-treated AD subjects. Slightly larger effects on cognitive testing and global functioning were noted in a six-month randomized controlled trial of the AChEI galantamine in subjects diagnosed with vascular dementia or AD plus cerebrovascular disease (108), while a study restricted to probable vascular dementia subjects demonstrated a small benefit on ADAS-cog testing and borderline benefit to global function (109). The one study of the AChEI rivastigmine in a sizable (n = 710) study sample found a small benefit to cognitive performance without global functioning improvement and with primarily gastrointestinal adverse effects leading to significantly more medication withdrawals (110). Finally, two 28-week randomized controlled trials of the uncompetitive NMDA antagonist memantine in subjects diagnosed with vascular dementia reported improvements relative to placebo of approximately two points on ADAS-cog, with statistically insignificant improvements in global functioning (111,112).

Practical steps that merit strong consideration in patients with cognitive impairment following stroke are screening for and treating poststroke depression (113) and reduction or withdrawal of medications contributing to cognitive slowing, such as psychotropic or anticholinergic agents. Studies in animal models of brain injury have highlighted the possibility that common classes of drugs may slow the poststroke recovery process (114), although the relevance of these data to human stroke recovery remains

TABLE 16.2 Medications With Reported Efficacy for Vascular Cognitive Impairment

AGENT (TRADE NAME)	INITIAL DOSE	TITRATION SCHEDULE/ EFFECTIVE DOSE	MOST COMMON ADVERSE EFFECTS
Donepezil (104–107) (Aricept)	5 mg/day, single dose	Increase 5 mg/day after 4 to 6 weeks 5 to 10 mg/day	Nausea, diarrhea, vomiting, sleep disturbances
Galantamine (108,109) (Razadyne or Razadyne ER)	8 mg/day, single dose (extended-release formulation) or two divided doses	Increase 8 mg/day every 4 to 6 weeks 16 to 24 mg/day	Nausea, diarrhea, vomiting, anorexia
Rivastigmine (110) (Exelon)	3 mg/day, two divided doses	Increase 3 mg/day every 4+ weeks 12 mg/day, 2 divided doses	Nausea, vomiting, diarrhea, dizziness
Memantine (111,112) (Namenda)	5 mg/day, single dose	Increase 5 mg/day every week 20 mg/day, 2 divided doses	Dizziness, confusion, fatigue

largely unknown. Other potential symptomatic approaches to poststroke cognitive impairment have not been tested by large, randomized trials and their effectiveness remains unclear. These include stimulants, such as methylphenidate or modafanil (115), and antidepressants (in the absence of diagnosed depression) (116).

In summary, the treatment approach to poststroke cognitive impairment is based on aggressive secondary stroke prevention and symptomatic treatment. Although the U.S. Food and Drug Administration has not approved agents for the specific indication of vascular dementia, the AChEIs donepezil, galantamine, and possibly rivastigmine appear to be rational choices, with the possibility of further efficacy from added memantine, as has been demonstrated in moderate to severe AD (117). Among the highest priorities for future studies will be to identify vasculoprotective or anti-AD agents with specific effects on preventing further cognitive decline in stroke patients.

Central Poststroke Pain

Anthony J. Pellicane and Richard L. Harvey

Central pain occurs commonly in disorders of the central nervous system (CNS). Although central pain affects a higher percentage of people with certain other CNS diagnoses (such as spinal cord injury and multiple sclerosis) stroke is the most common cause of central pain due to the higher prevalence of stroke. The overall incidence of pain during the first year of stroke is 14% to 43%, and more than one pain generator can be present in a patient at the same time, making diagnosis difficult (1,2). Furthermore, the diagnosis of central poststroke pain (CPSP) can be quite difficult because there are no pathognomonic features, uniform signs, or diagnostic tests, and CPSP can mimic other pain syndromes.

The purpose of this chapter is to place CPSP in its historical context and provide a clear definition and diagnostic criteria for this complex condition. We present theories on the pathophysiology of this condition and provide guidance for CPSP treatment, including pharmacologic and nonpharmacologic approaches. Our goal is to provide a framework for diagnosis and management, with a menu of treatment options. By doing so, we hope to provide the clinician with greater confidence in the care of this most difficult problem.

HISTORICAL PERSPECTIVES

The first published record of a central pain phenomenon associated with stroke was when Adolf Wallenberg described his now famous case of the lateral medullary stroke syndrome in 1895 (3). His original paper was a case study of a patient who suffered "vertigo without loss of consciousness." This patient developed hyperesthesia and spontaneous pain on the left side of his face and body. He also had hyperesthesia of his right face and loss of pain and temperature sensation in his right limbs and torso. Though not a typical description of central pain following the Wallenberg stroke syndrome, this case report represents the first case of central pain after stroke in the literature.

The classic description of central pain after stroke was that of Dejerine and Roussy in 1906 in their report of the *thalamic pain syndrome* following a thalamic infarction (4). This patient presented with persistent hemianesthesia, mild hemiataxia, severe persistent intractable pain that was unresponsive to treatment, and choreoathetoid movements (all located contralesionally). In a 1911 analysis of this and other cases of pain after stroke, Head and Holmes (incorrectly) concluded that any stroke within the cerebral hemisphere that causes pain must involve thalamic injury (5).

In a contradictory article published in 1935, Davison and Schick presented a series of clinical–pathological cases of spontaneous pain following thalamic stroke, cortical stroke, spinal cord injury, and peripheral nerve injury (6). Thus, it became clear that pain syndromes can occur following nervous system lesions outside of the thalamus. Three years later, Riddoch published a summary of the literature on central pain, describing it as a spontaneous pain associated with an overreaction to stimulation resulting from a CNS lesion (7).

In their book entitled *Central Pain* (1969), Cassinari and Pagni clarified that CPSP can result from a lesion anywhere along the spinothalamic and thalamocortical tracts, and suggesed that pain results from an alteration in the central processing of pain and temperature transmission through the CNS (8). Following this landmark publication, much work has taken place clarifying the definition, clinical presentation, and characteristics of CPSP.

DEFINITION

CPSP can be defined as a central neuropathic pain syndrome occurring after stroke in the body part(s) corresponding to a cerebrovascular lesion of the somatosensory system, characterized by pain and sensory abnormalities where other causes of obvious nociceptive, psychogenic, or peripheral pain have been excluded (9,10). It should be noted, however, that no agreed-upon definition or diagnostic criteria for CPSP currently exist. Despite this, since Hong et al. used diffusion tensor tractography to conclude that injury to the spino-thalamo-cortical pathway seems to be a requirement for the development of CPSP (11), this suggests that the aforementioned definition for CPSP is not without pathophysiologic basis.

TABLE 17.1 Diagnostic Criteria for CPSP

Mandatory Criteria

- Pain within an area of the body corresponding to the lesion of the CNS
- History suggestive of a stroke and onset of pain at or after stroke onset
- Confirmation of a CNS lesion by imaging or negative or positive sensory signs confined to the area of the body corresponding to the lesion
- Other causes of pain, such as nociceptive or peripheral neuropathic pain, are excluded or considered highly unlikely

Supportive Criteria

- No primary relation to movement, inflammation, or other local tissue damage
- Descriptors such as burning, painful cold, electric shocks, aching, pressing, stinging, and pins and needles, although all pain descriptors can apply
- Allodynia or dysaesthesia to touch or cold

Source: Adapted from Ref. (9). Klit H, Finnerup NB, Jensen TS. Central post-stroke pain: clinical characteristics, pathophysiology, and management. *Lancet Neurol*. 2009;8(9):857–868.

Despite the lack of agreed-upon terminology for CPSP, Klit et al. proposed diagnostic criteria (Table 17.1) and a grading system (Table 17.2) for this disorder (9). Although the grading system has received some criticism with regard to its utility (specifically, its ability to differentiate patients with CPSP from those with a peripheral injury causing activation of central pain mechanisms) (12), Klit et al. have provided the clinical and research communities with important initial guidelines that provide direction to those attempting to diagnose and study CPSP.

TABLE 17.2 Grading System for CPSP

Possible CPSP: Criteria 1–3 all fulfilled
Probable CPSP: Criteria 1–3 all fulfilled **PLUS** 4 **OR** 5 fulfilled
Definite CPSP: Criteria 1–5 all fulfilled

1. Exclusion of other likely causes of pain. No other obvious cause of pain
2. Pain with a distinct neuroanatomically plausible distribution. Either pain localized unilaterally in the body and/or face or unilaterally on one side of the body with contralateral involvement of the face
3. A history suggestive of stroke. Sudden onset of neurological symptoms with onset of pain at or after stroke onset
4. Indication of the distinct neuroanatomically plausible distribution by clinical neurological examination. Findings of positive or negative sensory signs in the painful area on clinical examination, pain localized within a territory of sensory abnormality, and anatomically plausible distribution of sensory abnormalities
5. Indication of the relevant vascular lesion by imaging. Visualization of a lesion that can explain the distribution of sensory findings (either CT or MRI)

Source: Adapted from Ref. (9). Klit H, Finnerup NB, Jensen TS. Central post-stroke pain: clinical characteristics, pathophysiology, and management. *Lancet Neurol*. 2009;8(9):857–868.

CLINICAL CHARACTERISTICS

The prevalence and incidence of CPSP has been reported as 7.3% and 8%, respectively (10,13). The majority of patients with CPSP develop symptoms within 3 months of their stroke. Specifically, Klit et al. (10) reported 60% of patients with symptom onset within 3 months of stroke; Andersen et al. (13) reported 63% symptom onset within 1 month and 82% within 6 months; Leijon et al. (14) reported 78% within 3 months; and Nasreddine et al. (15) reported 71% symptom onset within 3 months, in their respective samples. Importantly, it should be noted that delayed onset (>1 year or more) of CPSP can also occur; however, this is atypical (14–16). CPSP is considered to be a long-lasting (even lifelong) diagnosis; however, no prospective studies have documented its natural history (9). One study did note that 34% of the CPSP patients studied reported an increase in pain intensity or distribution since onset, 23% reported a decrease since onset, and 14% reported resolution in pain or dysesthesia within 4 years of stroke (10).

It is generally accepted that patient demographics (age, gender) or lesion characteristics (size, side) are not reliably associated with the development of CPSP (9,13,16–18). There has been a report suggesting that the right hemisphere is more susceptible to becoming a central pain generator (15); however, this report was not without criticism (19). As discussed previously, damage to the spino-thalamo-cortical pathway seems to be a necessary (but not sufficient) condition for development of the syndrome (20). There are reports that damage to the lateral medulla (21–23) or posterolateral thalamus (24–26) (key structures within spino-thalamo-cortical pathway) leads to the development of CPSP with a higher frequency than does damage to other structures.

There are no pathognomonic features or uniform signs of CPSP, and the characteristics and descriptions of CPSP vary among patients (9,14,27). CPSP has been depicted as indescribable and incomprehensible in character with a nagging, constant nature rendering patients functionless by deteriorating motivation, altering mood and intellect, leading to neurotic tendencies and depression, and even conferring suicide risk (28). Some studies describe the pain associated with this syndrome as being high in intensity, and mostly severe and incapacitating, with patients considering the pain to be a great burden (14,27). Andersen et al., however, reported only 19% of patients with severe pain, while 44% had moderate and 37% mild pain (13); Klit et al. reported that their sample generally had moderate pain that interfered little with daily activities, mood, sleep, and enjoyment of life (10). These varied reports speak to the heterogeneity of the disorder.

CPSP most commonly affects large body areas in the distribution of the stroke (13,14,16,20,27). The pain associated with CPSP is typically described as burning, aching, pricking, lacerating, or burning cold (10,13,14,16,27); however, scalding, throbbing, freezing, shooting, squeezing, stabbing, and painful pins and needles (13,14,16) have also been reported, with most patients experiencing more than one kind of pain (Table 17.3) (13,14). More specifically, paradoxical burning (like the sensation induced by immersion of the hand in ice water) has been reported as the most common descriptor of CPSP, with descriptors such as "cold" and "freezing" perhaps being unique to patients suffering from CPSP compared to those with other types of neuropathic pain (16). The pain and dysesthesias of CPSP are most

TABLE 17.3 Clinical Characteristics of CPSP

	SUBJECTIVE PAIN QUALITY	SUBJECTIVE EXACERBATING FACTORS	OBJECTIVE EXACERBATING FACTORS
Bowsher (19)[a]	Burning or scalding (47.0%) Aching or throbbing (34.5%) Shooting or stabbing (7.4%) Painful pins and needles (5.6%)	Environmental cold (48%) Stress (46%) Environmental cold and stress (28%) Orgasm (10%) Environmental warm (9%) None (9%)	Tactile (allodynia) (52%) Movement (allodynia) (22%) Thermal (allodynia) (19.5%) Both tactile and movement (allodynia) (12%) Both tactile and thermal (allodynia) (9%)
Leijon et al. (14)[b] Boivie et al. (27)[c]	Burning (59%) Aching (30%) Pricking (30%) Lacerating (26%) Shooting (11%) Squeezing (11%) Throbbing (11%)	Joint movements (70%) Cold (48%) Light touch (44%) Warmth (22%) Emotion (19%)	Touch, cold, or pinprick (hypersensitivity) (92%)[b] Touch, cold, or pinprick (dysesthesia) (41%)[c] Cold (allodynia) (23%)[c] Touch (allodynia) (5%)[c]
Andersen et al. (13)[d]	Lacerating (50%) Aching (25%) Burning (19%) Freezing (19%) Squeezing (19%)		Cold (allodynia and/or dysesthesia) (88%) Cold (dysesthesia) (75%) Touch (allodynia and/or dysesthesia) (75%) Cold (allodynia) (56%) Touch (allodynia) (56%) Touch (dysesthesia) (50%) Pinprick (increased sensibility) (19%) Warm (allodynia and/or dysesthesia) (0%)
Klit et al. (10)[e]			Cold (dysesthesia) (66%) Pinprick (hyperalgesia) (57%) Brush (dysesthesia) (51%) Cold (allodynia) (40%) Touch (dysesthesia) (40%)
Vestergaard et al. (20)[f]			Touch (allodynia) (55%) Cold (allodynia) (55%) Both touch and cold (allodynia) (36%) Pinprick (hyperesthesia) (20%)

Note: The fact that one patient may possess more than one quality or exacerbating factor explains why percentages may not add to 100% in this table.

[a] Touch defined as a low-intensity stimulus moving across the skin described in some cases as rubbing. Movement defined as isometric or isotonic muscle contraction. Thermal defined as contact with a cold object or warm stimulus. Note, cold allodynia predominated (89%) in patients with thermal allodynia.

[b] Hypersensitivity to cold and pinprick reported as "more common" than to cotton wool (touch). "A thorough and general somatic and neurological examination" was applied without reference to particulars of the stimuli.

[c] Evoked dysesthesias reported with "about [equal frequency]" by light touch, cold, and pinprick cutaneous stimulation. Touch defined as strokes of cotton wool. Cold defined as applying a round surface of a tuning fork of room temperature (area 3.9 cm^2). Pinprick defined as light prick with a pin. Allodynic patients also described as "extremely hyperaesthetic."

[d] Touch defined as cotton wool. Cold/warm stimulus applied using metal roller with temperature of 20°C/40°C. Pinprick not defined.

[e] Touch defined as a cotton swab. Cold stimulus applied using metal roller with temperature of 20°C. Pinprick stimulus applied using a monofilament. Brush stimulus applied using a brush.

[f] Touch defined as cotton wool stroking. Cold stimulus applied using a thermoroller. Pinprick defined as a sharp needle.

commonly constant and/or spontaneous; however, they can also be evoked by cutaneous stimuli (10,13,14,27).

In addition to pain, sensory impairment is present in the affected area(s). Sensory impairment in at least one, but commonly more than one, sensory modality is typical in patients with CPSP (16), and though the painful area is usually smaller than the area of sensory impairment, the two areas may also be identical in size (16,20). In the affected extremity of patients with CPSP, somatosensory dysfunction (in the form of hyperesthesia and/or hypoesthesia to stimuli) is often identified clinically. For example, one study reported 97% of patients with a deficit of pinprick and/or thermal (warm or cold) sensation (16); another reported decreased touch, cold, warm, and pinprick in 75%, 50%, 81%, and 69%, respectively (13); another reported hyperesthesia and/or hypoesthesia with touch, cold, and pinprick sensation in 85%, 93%, and 96% of patients, respectively (27); and still another reported hyperesthesia and/or hypoesthesia with touch, warm, cold, and pinprick in 100% of patients studied (20). Quantitatively, thermal and pinprick sensory deficits have been reported as more severe compared to tactile sensory impairment in CPSP patients (16). Despite the ubiquitous somatosensory deficits, it should be noted that CPSP patients typically present with mild to moderate motor deficits (14,16).

Positive and negative sensory signs and symptoms exist in CPSP just as they do in other neuropathic pain syndromes (29). The high prevalence of hyperesthesia and/or hypoesthesia to sensory stimuli described previously confirm the presence of these positive and negative sensory signs in CPSP. Additionally, the positive phenomena of allodynia, radiation of perceived sensation, and prolonged aftersensation have been reported in CPSP (10,13,16,20,27). *Allodynia* is defined as pain in response to a nonnociceptive stimulus (30,31). It has been reported as high as 72% of patients with CPSP, with nearly one in four of those patients with allodynia possessing more than one type simultaneously (tactile, thermal, movement) (16). Allodynia to cutaneous stimuli has been reported to a lesser extent in other studies (Table 17.3) (10,13,20,27). It should be noted that, in CPSP, tactile and cold allodynia are reported most commonly (16,20). The other positive phenomena of radiation and aftersensation have been reported in 29% to 50% and 34% to 45%, respectively, of patients with CPSP (10,27).

Factors reported to subjectively exacerbate pain in CPSP are listed in Table 17.3. In addition to those listed, studies also describe a small number of patients whose pain is exacerbated by walking, postural changes, showering, being rained on, micturition, physical pressure, or being exposed to bright lights or loud noises (14,16). Though documentation of alleviating factors is not common in the literature, keeping still, rest, warmth, movement, and cold have all been reported (14,16). The fact that the same stimulus may cause allodynia in some patients while improving symptoms in other patients again speaks to the heterogeneity of this disorder.

In summary, CPSP is not an uncommon occurrence after a stroke resulting from damage to the spino-thalamo-cortical pathway. Its onset is typically within the first three months after stroke, and duration is thought to be long (potentially lifelong). The painful area is typically large, and pain intensity and quality may vary from patient to patient. Patients with CPSP most commonly describe the quality of their pain as burning or aching. Sensory impairment in one or more sensory modalities within the affected area(s) should be demonstrable in all patients with CPSP, whereas allodynia or dysesthesia to one or more sensory modalities should be found frequently in patients with CPSP.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for CPSP includes, but is not limited to, **complex regional pain syndrome (CRPS), radiculopathy, plexopathy, peripheral mononeuropathy, hemiparetic shoulder pain (HSP), deep venous thrombosis (DVT), and conversion disorder**. As CPSP is considered a diagnosis of exclusion (9), understanding how to differentiate CPSP from these diagnoses is extremely important.

Poststroke **complex regional pain syndrome (CRPS)** may present similarly to CPSP with regard to subjective pain complaints and objective pain findings. For example, both poststroke CRPS and CPSP patients may experience allodynia with wearing clothes or showering; in the clinic, they may complain of pain to light touch applied by the physician. However, the patient with poststroke CRPS will also possess numerous other specific subjective complaints and physical examination findings that will allow the practitioner to differentiate between poststroke CRPS and CPSP. Known as the "Budapest Criteria," clear, validated diagnostic criteria for CRPS exist for use in both clinical and research settings (Table 17.4) (32,33). In brief, the Budapest Criteria require the presence of continuing pain in addition to a certain number of symptoms and signs from four distinct categories (sensory, vasomotor, sudomotor/edema, motor/trophic). Thus, if a patient fails to meet the Budapest Criteria, poststroke CRPS can be moved lower on the differential diagnosis list of possibilities. It should be noted that the Budapest Criteria were not developed specifically for the stroke population. Further, as sensorimotor dysfunction (including spasticity) and autonomic dysfunction (34) may exist after stroke, the Budapest Criteria should be applied cautiously in this population. Regardless, they do supply guidelines to help the practitioner differentiate between poststroke CRPS and CPSP, and it has been suggested that "utilization of [the Budapest Criteria] in the stroke literature will advance our understanding and treatment of post-stoke CRPS and is highly recommended" (35).

Because of their unilateral presentation and symptomatology, **cervical and lumbosacral radiculopathy, brachial and lumbosacral plexopathy, and upper and lower extremity peripheral mononeuropathy** all may present similarly to CPSP (36–41). Differentiation between these diagnoses and CPSP can be made with careful history and physical

TABLE 17.4 Proposed Clinical Diagnostic Criteria for CRPS

General definition of the syndrome: CRPS describes an array of painful conditions that are characterized by continuing (spontaneous and/or evoked) regional pain that is seemingly disproportionate in time or degree to the usual course of any known trauma or other lesion. The pain is regional (not in a specific nerve territory or dermatome) and usually has a distal predominance of abnormal sensory, motor, sudomotor, vasomotor, and/or trophic findings. The syndrome shows variable progression over time.

To make the clinical diagnosis, the following criteria must be met:

1. Continuing pain, which is disproportionate to any inciting event
2. Must report at least one symptom in *three of the four* following categories:
   - **Sensory:** Reports of hyperesthesia and/or allodynia
   - **Vasomotor:** Reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry
   - **Sudomotor/Edema:** Reports of edema and/or sweating changes and/or sweating asymmetry
   - **Motor/Trophic:** Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
3. Must display at least one sign at time of evaluation in *two or more* of the following categories:
   - **Sensory:** Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or temperature sensation and/or deep somatic pressure and/or joint movement)
   - **Vasomotor:** Evidence of temperature asymmetry (>1°C) and/or skin color changes and/or asymmetry
   - **Sudomotor/Edema:** Evidence of edema and/or sweating changes and/or sweating asymmetry
   - **Motor/Trophic:** Evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
4. There is no other diagnosis that better explains the signs and symptoms

For research purposes, diagnostic decision rule should be at least one symptom *in all four* symptom categories and at least one sign (observed at evaluation) in *two or more* sign categories.

examination. For example, reproduction of symptoms with femoral nerve stretch or straight leg raise test, in the presence of pain centralization with lumbar extension and in the absence of provoked allodynia and hyperalgesia, points toward the diagnosis of lumbosacral radiculopathy and away from CPSP in the stroke patient who presents with burning, unilateral leg pain (37,42). When necessary, electrodiagnosis can be utilized to confirm or refute the diagnosis of radiculopathy, plexopathy, and peripheral mononeuropathy in the stroke patient (43–46). Although there have been reports of successful identification of these diagnoses in the stroke patient (47–51), it should be noted that testing may be challenging due to the electrodiagnostic abnormalities typically found after stroke (52,53).

HSP may be caused by a number of diagnosable problems, including but not limited to rotator cuff tendonitis or injury, impingement syndrome, adhesive capsulitis, bursitis, shoulder (glenohumeral) subluxation, and spasticity (54,55). The determination of the specific cause for HSP in a particular patient can be quite challenging for a multitude of reasons. First, there is substantial plasticity of the neurologic and musculoskeletal systems after stroke. Second, more than one cause for HSP can exist simultaneously, and some causes of HSP may exist transiently and resolve spontaneously. Finally, some causes of HSP cause pain indirectly (54). With a detailed history and physical examination of the shoulder, the practitioner can narrow the differential diagnosis for HSP in the stroke patient. To complicate matters, it should be noted that, regardless of the cause of HSP, central sensitization may result from the chronically painful shoulder (55). *Central sensitization* can be defined as an amplification of neural signaling within nociceptive pathways in the CNS that elicits pain hypersensitivity (for example, dynamic tactile allodynia or pressure hyperalgesia), aftersensations, and enhanced temporal summation (56). Roosink et al. demonstrated sensitization to innocuous and noxious stimuli in the affected body side in patients with persistent poststroke shoulder pain (57,58); thus, it is clear that chronic HSP (regardless of etiology) that has resulted in central sensitization can mimic CPSP. Additionally, specific causes of HSP can also mimic CPSP. For example, shoulder subluxation has been postulated to cause traction injuries to the brachial plexus, and these injuries can present similar to CPSP, as discussed previously (50). Also, as spasticity can cause pain with range of motion, it may also mimic CPSP (59).

DVT in the upper or lower extremity most typically presents as edema, pain, and/or warmth and erythema in the affected limb (60–62). In the stroke patient, varying combinations of these presenting symptoms may mimic CPSP, poststroke CRPS, infection, lymphatic edema, musculoskeletal injury, or other pathologies. In the upper extremity, DVT can also present with headache, chest or jaw pain, cough, limb cyanosis, superficial limb vein distension, collateral shoulder girdle vein distension, jugular vein distension, neck swelling, or fever—all of which may be useful in differentiating an upper extremity DVT from CPSP (62,63). However, as an upper extremity DVT may cause arm paresthesias, this may inappropriately lead to a CPSP diagnosis (62). In the lower extremity, DVT can present with fever, which would

not be expected in CPSP (64,65). For completeness, it should be noted that in the clinical assessment of lower extremity DVT, Homan's sign (posterior calf tenderness with passive ankle dorsiflexion) is present in only 13% of cases and a palpable cord is detectable in only 6% of cases (66). As clinical diagnosis alone is inadequate, whenever upper or lower extremity DVT is suspected, the practitioner should not hesitate to utilize compression duplex ultrasound as the initial diagnostic test, given its noninvasiveness and high sensitivity and specificity (60–62).

Conversion disorder is broadly defined as the presence of neurologic symptoms in the absence of a neurologic diagnosis, and four types have been specified (motor symptoms or deficits, sensory symptoms or deficits, pseudoseizures, or a mixed presentation) (67). Symptoms are not deliberate or consciously produced and are believed to reflect the "conversion" of conflicts, stressors, or underlying emotional distress into physical (neurologic) symptoms (67). Whereas many case reports describe conversion disorder presenting like stroke with sensorimotor deficits in the absence of pain (68–70), there is one case report of conversion disorder specifically misdiagnosed as CPSP (71). Given that a survey of outpatient neurologists estimated that 30% of their new patients possessed psychological factors thought to be of etiological significance to their presenting complaint (72), recognizing nonorganic symptoms is important. After determining that no neurological disease explains the presenting symptoms and that the patient is not feigning, several factors may help the practitioner identify conversion disorder: atypical or inconsistent neurologic signs, "la belle indifference," histrionic or borderline personality disorder, a "model" for the symptoms (in the form of a relative or other), or an associated stressor (recent or historic) (67,73). It should be noted, however, that none of the aforementioned are supported with compelling or unchallenged evidence (73). For completeness, it warrants mention that the American Psychiatric Association has proposed renaming conversion disorder to "conversion disorder (functional neurological symptom disorder)" in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*), citing that the additional parenthetical term aligns with terminology currently used by neurologists and also is more acceptable to patients (74).

ANATOMY AND PATHOPHYSIOLOGY

The neuroanatomical processing of pain and temperature involves both localizing and thermoregulatory processes. Thermoregulatory processes maintain core body temperature in the presence of changes in metabolic activity and external temperature. Temperature control is comprised of both autonomic modulation and behavioral responses (for example, putting on a sweater when one is cold). Both pain localization and thermoregulatory processes are influenced by the motivational and emotional nature of the stimulus (be it pleasant, unpleasant, or damaging to the body). In 1906, Sir Charles Sherrington divided sensory input into categories: vision and hearing (teloreception), smell and taste (chemoreception), limb position (proprioception), touch (exteroception), and visceral (interoception) (75,76). Although Sherrington considered pain and temperature sensation to be exteroceptive processes, the thermoregulatory aspect of sensation is clearly interoceptive. Regarding the neuroanatomical basis of central pain, both exteroceptive and interoceptive processes are likely involved at multiple levels in the CNS (77).

The *exteroceptive pathway* involves the spino-thalamocortical pathway. Small unmyelinated and lightly myelinated fibers enter the spinal cord via the dorsal root, ascend or descend several levels via Lissauer's tract, and synapse in the substantia gelatinosa. From there, afferent nuclei send fibers that decussate in the spinal cord to the contralateral side and ascend in the lateral spinothalamic tract to the ventroposterior lateral (VPL) nucleus of the thalamus. The thalamus sends fibers superiorly that terminate in both the primary (S1) and secondary (S2) sensory cortex in the anterior parietal lobe. Additional fibers ascend from VPL to the motor cortex (M1) in the precentral gyrus.

The *interoceptive pathway* involves the lamina 1 spinothalamic tracts, which transmit afferent information about the state of body tissues (see Figure 17.1). The lamina 1 system therefore participates in the modulation of homeostasis, including that of visceral pain and thermoregulation (77). These fibers also decussate in the spinal cord and ascend in the lateral spinothalamic tract to the posterior ventromedial (VPM) nucleus of the thalamus. The thalamus then provides a rich supply of afferents to the insular cortex. The lamina 1 system also has direct input to the ventrocaudal mediodorsal (VMD) nucleus of the thalamus, as well as indirect input via the periaqueductal grey and parabrachial nucleus of the midbrain. The VMD then sends afferent fibers to the cingulate cortex, which influences the emotional state of the individual in response to these internal stimuli. The insular cortex can downregulate this latter pathway by providing inhibitory feedback to the periaqueductal grey and parabrachial nucleus (see Figure 17.1). Thus, the level of distress within the individual is modulated within the CNS via this lamina 1 system. Damage along the spino-thalamocortical pathway or within the lamina 1 system would disrupt the normal pain and thermoregulatory processing that can result in central pain, causing an alteration of sensory, emotional, and behavioral responses to stimuli, which in the clinical setting are often maladaptive.

However, it has also been proposed that central pain might be caused by disruption of the lemniscal pathway via dorsal columns in the spinal cord and medial lemniscus of the brainstem. Loss of lemniscal tracts that carry nonpainful sensory information (e.g., proprioception) might result in a kind of "release phenomenon," where central sensory processing is unbalanced toward pain perception (78). However, cases of central pain frequently lack neuroanatomical evidence of lesions within the lemniscal system, so injury within these tracks is not necessary for central pain (79,80). A more plausible release phenomenon might occur with injury to the descending inhibitory fibers from insula to periaqueductal

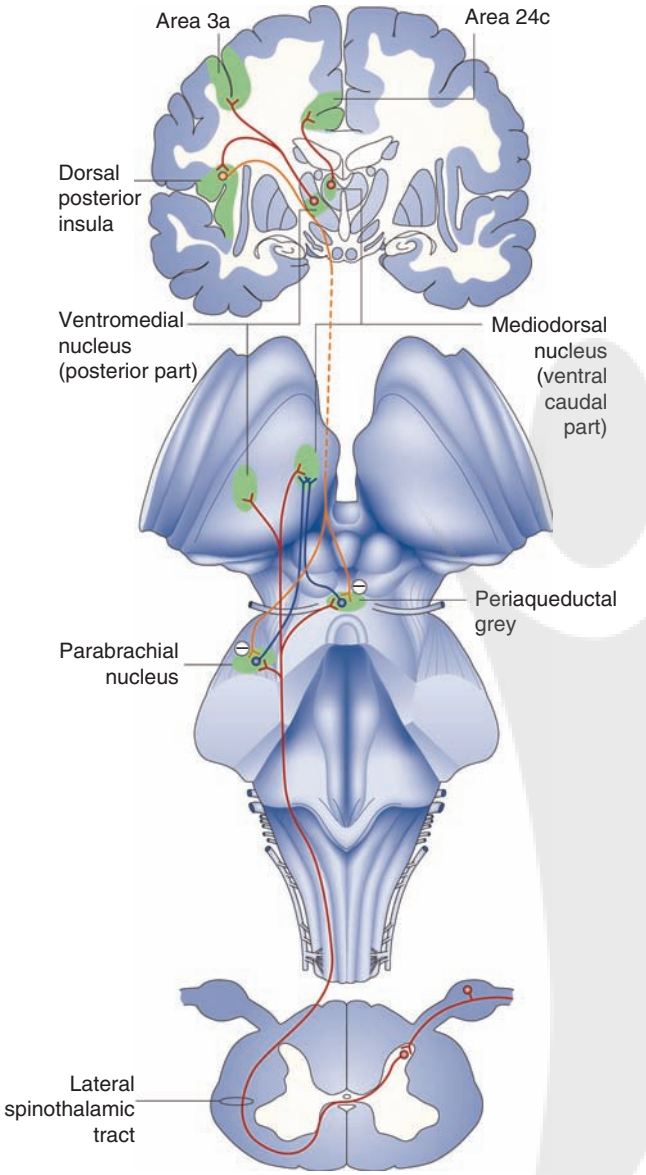

FIGURE 17.1 Central pain can result from damage to the lamina 1 spinothalamic anywhere along its ascending and descending tracts. Ascending tracts from the spinal cord (shown in red) have excitatory input to the periaqueductal grey and the parabrachial nucleus and within the thalamus to the ventromedial and mediodorsal nuclei. Periaqueductal grey and parabrachial nucleus also provide excitatory input to the ventromedial thalamus (shown in blue). The thalamic nuclei send fibers to area 3a of the primary sensory cortex as well as to the insula and cingulated gyrus (shown in red). The insula is capable of downregulating sensory input through descending inihibitory feedback to periaqueductal grey and parabrachial nucleus (shown in orange).

grey and parabrachial nucleus (see Figure 17.1). This would reduce one's ability to downregulate interoceptive input, which could increase perceived pain and associated behavioral responses.

Based on current understanding regarding the anatomy and physiology of pain and thermoregulation and on our understanding of the pharmacology of central pain management, there are several theories on the cause of central pain after CNS damage.

Loss of Aminergic Modulation

Because medications that increase adrenergic and serotonergic stimulation have some effect on central pain, it is theorized that a reduction in adrenergic and serotonergic modulation within the CNS may alter the function of the afferent pathways and result in a greater perception of pain.

Alteration of the *N*-Methyl-d-Aspartate-Glutamate System

Inhibitors of *N*-methyl-d-aspartate (NMDA) activity also have been used therapeutically for central pain. This suggests that central pain may result from enhanced thalamocortical activity due to an increase in glutaminergic NMDA stimulation. In this theory, NMDA stimiulation leads to long-term potentiation and, subsequently, maladaptive neuroplastic changes that enhance pain perception.

Abnormal Central Modulation

CNS damage resulting in a loss of central nonnoxious temperature fibers along the lamina 1 spino-thalamo-cortical pathway above the motor decussation might cause central pain. This is proposed as affecting the capability of the CNS to modulate temperature perception, leading to symptoms of allodynia.

Thermosensory Inhibition

Loss of descending inhibitory control of the brainstem homeostatic structures, including the periaqueductal grey and peribrachial nucleus via cortical interoceptive regions such as the dorsal posterior insula, will result in unabated thermoregulatory drive to the medial thalamus and anterior cingulate cortex (see Figure 17.1). The excitatory drive to the cingulate cortex will cause emotional distress and, perhaps, associated pain perception.

Central Excitation

The central excitation theory proposes that pain is due to abnormal burst activity within the lateral and medial thalamic nuclei.

In any particular case of central pain following stroke, the pathophysiology involved could be one or more of the processes described in the preceding sections. Because different pathophysiological processes are involved in the generation of CPSP, it is no surprise that patients do not necessarily respond to a single medical treatment. Instead, the treatment of CPSP typically requires a combination of multiple pharmacologic and nonpharmacologic interventions that must be individualized to each patient.

TREATMENT

Introduction to Treatment

As pain relief in CPSP is often incomplete, patient expectations must be managed appropriately. After diagnosis and at the onset of treatment, it is vital to educate the patient that complete elimination of the pain is likely an unrealistic goal. Goals of treatment should focus on pain reduction and functional restoration. The diagnosis and treatment of any preexisting pain conditions or psychiatric disorders should occur simultaneously with the treatment of CPSP.

The management of chronic pain conditions like CPSP should follow an interdisciplinary model. Interdisciplinary pain rehabilitation programs with a greater appreciation for a biopsychosocial approach to pain management (as opposed to a biomedical approach) remain a growing area in the evolution of modern comprehensive pain management (81). These programs have shown that concomitant pharmacologic and nonpharmacologic pain management (including but not limited to physical therapy, occupational therapy, and pain psychology), in addition to adjunctive components like vocational rehabilitation, employed by a team familiar with the patient and each other represents the most likely paradigm for success in the treatment of chronic pain. For example, pain psychology can employ cognitive behavioral therapy, relaxation techniques (with or without biofeedback), autogenic training, meditation, and guided imagery, all in an attempt to help the patient self-manage pain and stress. In addition, pain psychologists help to educate patients with regard to the principles of goal setting and pacing. The involvement of a psychologist is also important to prepare the patient and family for the possibility of a life with pain (28). Further, the psychologist's ability to identify depression may also help with CPSP diagnosis, as one study demonstrated that patients with CPSP were significantly less likely to report depression compared to stroke patients with chronic pain not considered to be secondary to CPSP (10). Thus, the presence of depression may lower CPSP on the list of differential diagnoses in a patient with stroke. Clearly, many practitioners with varied backgrounds and expertise all must contribute to the care of the patient with CPSP to achieve a positive outcome. The following sections discuss pharmacologic and nonpharmacologic management of CPSP in greater detail.

Pharmacologic Management

Many review articles exist describing the pharmacologic management of CPSP (9,17,28,82–86). These reviews typically organize management options based on drug class or mechanism of action; however, some also attempt to organize based on efficacy (Table 17.5) (9,82–84). We have organized pharmacologic management of CPSP based on efficacy to generate a reasonable treatment algorithm for practitioners who encounter this diagnosis.

First-Line

There is consensus that **amitriptyline** (tricyclic antidepressant) is the most appropriate first choice in the treatment of CPSP (9,82–84). A randomized, blinded, crossover, placebo-controlled trial demonstrated that 75 mg daily of amitriptyline yielded significantly lower mean daily pain ratings on a 10-step verbal scale compared to placebo (4.2 ± 1.6 versus 5.3 ± 2.0 by week 4 of the treatment period). Perhaps more importantly, 67% of the amitriptyline patients reported improvement in pain on global assessment, compared to only 7% of the placebo group (87). It should be noted that there was a correlation between the pain-relieving effect and total plasma concentration of amitriptyline, with concentrations of more than 300 nmol/L being associated more consistently with positive outcomes. This may suggest that nonresponders to amitriptyline may benefit from a trial of dose escalation beyond 75 mg per day, barring untoward side effects (typically related to the anticholinergic side effects of this medication).

Most agree that **lamotrigine** (anticonvulsant) is also a first-line drug for the treatment of CPSP (9,82–84). A randomized, blinded, crossover, placebo-controlled trial demonstrated that a 200 mg daily dose of lamotrigine resulted in a significantly lower median daily pain ratings on an 11-point Likert scale compared to placebo (5 versus 7) after 8 weeks

TABLE 17.5 Hierarchy of the Pharmacologic Management of CPSP

DRUG	KLIT ET AL. (9)	KUMAR ET AL. (82)	FRESE ET AL. (83)	HARVEY (84)	RECOMMENDATION
Amitriptyline	1st line	1st line	1st line	1st line	1st line
Lamotrigine	2nd line	1st line	1st line	1st line	1st line
Pregabalin	1st line	Not ranked	Not ranked	1st line	2nd line
Gabapentin	1st line	2nd line	2nd line	1st line	2nd line
Fluvoxamine	Not ranked	2nd line	2nd line	2nd line	3nd line
Opioids	2nd line	Not ranked	Not ranked	Not ranked	3rd line
Mexiletine	Not ranked	2nd line	2nd line	Not ranked	3rd line

of medication titration (note that the lamotrigine dose was titrated up every two weeks per manufacturer recommendations to minimize risk of rash, and no effect was found at lower doses) (88). There was also significant improvement in evoked pain to cold stimulus in the lamotrigine group compared to placebo; however, there was no superiority with regard to improvement in tactile allodynia or change in size of painful body area, and only 44% were deemed clinical responders (defined by a lamotrigine pain score greater than or equal to 2 points lower than the corresponding placebo value). The authors suggested that higher doses of lamotrigine may improve efficacy in CPSP as required in other diagnoses.

Second-Line

Pregabalin (anticonvulsant) is considered by some to be a first-line agent in the treatment of CPSP (9,84); however, based on current data, use as a second-line agent seems more appropriate. A randomized, blinded, parallel group, placebo-controlled trial assessed the efficacy of 150 to 600 mg per day of pregabalin in 219 patients with CPSP (89). Mean pain score on the Daily Pain Rating Scale decreased in both groups, but there was no significant difference between the two groups at baseline or endpoint (6.5 to 4.9 in the pregabalin group; 6.3 to 5.0 in the placebo group). Additionally, the majority of patients treated with pregabalin did not achieve a 30% or 50% reduction in mean pain score compared with baseline. However, the pregabalin group did improve significantly over the placebo group in some of the secondary outcome measures, including those regarding sleep and anxiety, and on the Clinician Global Impression of Change rating scale. Also, it should be noted that a statistically significant difference in mean pain scores existed between the two groups at weeks 3, 5, 6, and 8 of the study. The authors attributed the disappearance of statistically different scores in weeks 9 through 12 to the continued improvement in pain scores in the placebo group, which has been described elsewhere as a problem inherent in neuropathic pain trials (90). As a result, the authors commented that the lack of statistical significance at the end of the study might represent a study limitation rather than drug failure. A randomized, blinded, placebo-controlled trial studied 40 patients with central neuropathic pain (48% of whom carried the diagnosis of stroke) and found that 150 to 600 mg per day of pregabalin led to significant differences in mean pain scores (7.6 ± 0.8 to 5.1 ± 2.9 in the pregabalin group; 7.4 ± 1.0 to 7.3 ± 2.0 in the placebo group), EQ-5D scores, and the pain domain of the Short Form-36 after 4 weeks of treatment (91). Notably, the authors reported no difference in pain relief following pregabalin treatment between the stroke patients and the remainder of the study participants; however, the data were not reported. Despite the improvement in secondary outcome measures in both trials, pregabalin was not superior to placebo with regard to decrease in pain in the trial that studied CPSP exclusively. For this reason, pregabalin should be considered second-line treatment for this diagnosis.

There is debate regarding the utility of **gabapentin** (anticonvulsant) in the management of CPSP (9,82–84). Whereas there are case reports of individual patients with CPSP who had failed with other pharmacologic interventions being treated successfully with gabapentin 300 mg three times daily (92,93), there are no controlled clinical trials testing gabapentin's efficacy specifically in CPSP. For example, one randomized, blinded, placebo-controlled trial demonstrated significant improvements in a group of 308 patients with neuropathic pain resulting from a variety of diagnoses who were given up to 2400 mg of gabapentin per day (94). However, because only 2.9% of the study population carried the diagnosis of CPSP, extrapolation to this population is difficult. The authors stated, however, that there were no differences in treatment effect among the various pain syndromes. Importantly, many of the clinical improvements demonstrated in this study were slight, even when statistically significant. Key findings include the small but significant decrease in mean pain diary score comparing the gabapentin group (1.5) to placebo (1.0), the lack of a significant difference in the percentage of responders between the groups (defined as a >50% pain reduction), and the fact that only two of the components of the short-form McGill Pain Questionnaire were significantly improved in the gabapentin group over placebo. That being said, the gabapentin group did perform significantly better on several of the components of the Short Form-36, and significantly higher percentages of "very much" or "much improved" responses were noted in the gabapentin group in the Patient and Clinician Global Impression of Change rating scales. Another study (open-label design) of 18 patients with neuropathic pain resulting from a variety of diagnoses who received up to 2400 mg of gabapentin per day demonstrated significant improvements in pain intensity on a visual analog scale (VAS) (74 ± 23 at baseline to 59 ± 25 at 6 weeks), number of daily pain attacks, and brush- and cold-induced allodynia (95). As in the prior study, only two of the patients studied here carried the diagnosis of CPSP, and the authors again reported no significant difference between patients with central and peripheral pain with regard to their findings. Given that no study dedicated specifically to patients with CPSP exists, we consider gabapentin a second-line treatment for this diagnosis.

Third-Line

Fluvoxamine (selective serotonin reuptake inhibitor) has been proposed as a second-line treatment for CPSP (82,83). In patients less than 1 year poststroke with CPSP, an open-label study demonstrated a significant decrease in VAS pain score (7.3 ± 2.2 to 4.7 ± 1.9) in patients given 25 to 125 mg daily of fluvoxamine (96). There was also a significant improvement in Zung's Self-rating Depression Scale (SDS) in this study; although the authors demonstrated no correlation between the changes in VAS and SDS, they state that the improvement in depression may have played a role in the relief of central pain. Given this, plus the lack of a placebo group in this study, fluvoxamine should be considered

a third-line treatment for CPSP. However, if a CPSP patient presents with concomitant signs and symptoms of depression, this medication should be considered earlier in the treatment algorithm. Note: Fluvoxamine should not be confused with fluoxetine.

In a small, randomized, blinded, crossover, placebo-controlled trial of 15 patients with central pain (5 with CPSP), intravenous **morphine** (opioid) was administered, and patients were monitored for 120 minutes after infusion (97). The mean dosage of intravenous morphine was 16 mg and intravenous saline was used for placebo. Additionally, after the infusion portion of the study, patients were trialed on various doses of oral morphine. There was no significant difference in VAS for ongoing pain intensity at any point after the two different infusions. However, it should be noted that 46% of patients receiving intravenous morphine gained more than 50% pain relief, compared to only 13% of patients receiving saline; also, 80% of the intravenous morphine patients compared to only 40% of the saline patients reported moderate or excellent pain relief after infusion. Additionally, although there was no significant effect on other types of evoked pain, intravenous morphine significantly reduced the intensity of brush-induced allodynia compared to placebo in this study population. In the oral morphine component of the study, the patients were titrated to 60 to 140 mg per day and the authors reported a significant decrease in VAS for ongoing pain intensity at 4 weeks compared to baseline (44 ± 20 versus 64 ± 13, respectively). A correlation between the analgesic effects of IV morphine and oral morphine was also noted. Limited efficacy, side effects, or both resulted in only 20% of patients continuing treatment with oral morphine at 1 year. The authors concluded that while opioids may represent a therapeutic alternative for central neuropathic pain, only a small group of patients seem to be able to continue long-term treatment because of an unfavorable balance between efficacy and side effects. Relatedly, in a randomized, blinded trial, 81 patients with central and peripheral pain were given high- or low-dose capsules of **levorphanol** (opioid) and were instructed to self-titrate their dose within predefined parameters (98). For the entire study population, the high-dose group demonstrated a significant decrease in pain intensity over the low-dose group (36% versus 21% reduction). However, only 3 of the 10 study patients with CPSP completed this study, and the small CPSP cohort did not demonstrate as robust pain reduction as the other diagnoses that made up the study population. Interestingly, a case report of a patient with chronic, treatment-resistant CPSP described complete resolution of symptoms after one intravenous infusion of 50 mg **tramadol** (opioid and serotonin/norepinephrine reuptake inhibitor) followed by 20 mg daily of oral **codeine phosphate** (opioid) combined with 25 g twice daily of **milnacipran** (serotonin/norepinephrine reuptake inhibitor) (99). The authors reported continued complete relief with the oral regimen for six days of treatment followed by symptom recurrence after cessation of the oral regimen. The authors selected the codeine phosphate and milnacipran combination to best replicate tramadol's mechanism of action. The effects of oral tramadol on CPSP have not been assessed. Given that **tapentadol** (opioid and norepinephrine reuptake inhibitor) has a similar mechanism of action to tramadol, perhaps these two medications warrant investigation as maintenance or abortive medications in the treatment of CPSP. The evidence described in this section, coupled with the fact that supraspinal central neuropathic pain (like CPSP) is considered the least responsive to opioids (100), indicates that this class of medications should be considered after other agents have been deemed ineffective. **Oxycodone** (opioid), **methadone** (opioid, NMDA antagonist, norepinephrine/5-hydroxytryptamine reuptake inhibitor), **buprenorphine** (opioid), tramadol, and tapentadol have been reported, conceivably, as effective agents in the treatment of neuropathic pain (100). As a result, if opioids are to be considered, these agents should be preferentially used when treating CPSP.

Three small studies with varying designs—two with a mixed population (101,102), one studying CPSP exclusively (103)—demonstrated some efficacy in the treatment of central neuropathic pain using intravenous **lidocaine** (antiarrhythmic, local anesthetic). More specifically, while improvements in spontaneous pain and some types of evoked pain were noted, these changes typically did not last much beyond cessation of the infusion (101,102). As a result of these studies, intravenous lidocaine has been reported as potentially having utility for short-term pain relief in patients with intractable CPSP (82,83). As a result of the positive effects of intravenous lidocaine, its oral analog **mexiletine** (antiarrhythmic) has also been studied. For example, in a small, open-label study, improvement in 7 of 8 patients with CPSP resistant to other treatments was noted using 10 mg/kg per day of mexiletine titrated over a 4-week period (104). Patients were titrated beginning with 150 mg daily and 300 mg daily for 3 days each prior to starting the 10 mg/kg per day dose. Additionally, two of the intravenous lidocaine studies described previously administered oral mexiletine after the intravenous portion of the treatment protocol. In one of these studies, 25% of the patients reported moderate pain relief (defined by a decrease in visual analog pain scale score of 30% to 50%); however, no patient was willing to be treated long term with mexiletine because of side effects (101). Similarly, in the other study, two of the four patients discontinued mexiletine due to side effects (103). Although mexiletine is often considered a second-line drug for CPSP (82,83), the lack of a placebo-controlled study coupled with patient intolerance and the need to monitor for QT interval prolongation suggests that mexiletine is more appropriate as a third-line agent.

Other Options

In the same study described earlier that demonstrated the efficacy of amitriptyline in the treatment of CPSP, there was some evidence that **carbamazepine** (anticonvulsant) might have some efficacy as well (87). Both amitriptyline and carbamazepine were compared to placebo in a blinded,

crossover trial and, by week 4 of treatment, the amitriptyline, carbamazepine, and placebo groups possessed daily mean pain ratings of 4.2 ± 1.6, 4.2 ± 1.7, and 5.3 ± 2.0. Despite having the same scores, the amitriptyline, but not the carbamazepine, group differed significantly from the placebo group; and only 36% of the carbamazepine group reported improvement in pain on global assessment. Despite this, the authors concluded that some CPSP patients may benefit from carbamazepine.

In a small, open-label trial, **phenytoin** (anticonvulsant) was given to eight patients with CPSP in escalating doses until either a clinical response or side effect was noted (105). Three of the eight patients reported a worthwhile reduction in pain (defined as a reduction of one to two levels of intensity on at least one pain scale) with concomitant family and clinician comments reporting decreased pain behaviors. Pain levels and behaviors returned in these three patients following withdrawal of phenytoin. The reported median phenytoin serum level for the population was 12.8 mcg/mL.

In two case reports, **zonisamide** (anticonvulsant) at 200 mg daily successfully treated CPSP refractory to other medications (106). Given that zonisamide has shown promise in the treatment of other neuropathic pain conditions, (107–110), it is not unreasonable to include this medication as a potential option for the treatment of CPSP, particularly if other medications have been tried unsuccessfully.

Ketamine (NMDA antagonist) has also been studied in the treatment of central pain. In a randomized, blinded, placebo-controlled trial of topical ketamine administered via iontophoresis to 33 patients (24% with CPSP), no difference was noted compared to placebo in the 50 mg daily dose; however, the 75 mg daily dose significantly improved components of the Pain Disability Index, EQ-5D, and Short Form-36 (111). There was no improvement in pain intensity visual analog scores with either dose compared to placebo, but because of the improvement in secondary outcomes with the 75 mg daily dose, the authors concluded that iontophoretic administration of ketamine can be therapeutic in central neuropathic pain refractory to typical interventions. In a single case report of a patient with CPSP, oral ketamine titrated to 50 mg three times daily (after an intravenous ketamine trial) was deemed beneficial in decreasing pain, allodynia, and hyperalgesia (112). Due to the patient's response to oral ketamine, gabapentin and opioids were discontinued. In this case, thrice daily diazepam was required to combat ketamine's side effects. Finally, in a study attempting to establish an intervention to predict successful motor cortex stimulation in patients with CPSP, 47.8% of patients demonstrated 40% or better pain reduction with 5 mg intravenous ketamine given every 5 minutes up to a total dose of 25 mg; however, these effects lasted less than 1 hour after completion of the infusion (113). With further investigation, ketamine may play a more significant role in the treatment of CPSP.

Several boluses of intrathecal **baclofen** (gamma-aminobutyric acid agonist) were given to five patients with CPSP over a week's time (doses ranged from 50 to 150 mcg) (114). Four of the five patients reported relief with these interventions that lasted for 12 to 24 hours after the procedure. In all patients, a bolus of intrathecal saline was administered at some point during the study period, with no patients reporting symptom relief with this intervention. All patients were given oral baclofen after the intrathecal portion of the case series, with no patients reporting relief with the oral formulation. In a study referenced previously that sought an intervention to predict successful motor cortex stimulation in patients with CPSP, 56.4% of patients demonstrated 40% or better pain reduction with a subanesthetic infusion of up to 250 mg of **thiamylal/thiopental** (gamma-aminobutyric acid agonists) (113). Effects, however, lasted less than one hour after discontinuation of the infusion. Another study showed that an intravenous bolus of subhypnotic **propofol** (gamma-aminobutyric acid agonist) at 0.2 mg/kg led to reductions in spontaneous ongoing pain and allodynia superior to placebo in a randomized, blinded, crossover trial of 44 patients with central pain (50% with CPSP) (115). Again, pain relief did not last beyond one hour in any of the patients studied. Given the findings in these three studies, gamma-aminobutyric acid agonists show some promise in the treatment of CPSP. Intravenous propofol, like intravenous lidocaine, has been suggested as a viable treatment option for short-term pain relief in patients with intractable CPSP (82,83).

A retrospective study of 12 patients with CPSP revealed significant differences in mean numerical rating scale for pain scores after treatment onset comparing seven patients treated with an oral **methylprednisolone** taper (1.7 ± 2.1) to five patients who had received varying combinations of typical medications used to treat CPSP (5.0 ± 1.9). This significant difference remained between the two groups at discharge from acute inpatient rehabilitation (0.3 ± 0.9 versus 4.1 ± 3.2) (116). Given the clinical and pathophysiological similarities between CPSP and post-stroke CRPS (9,35), coupled with the existence of studies demonstrating the successful treatment of poststroke CRPS with steroids (117,118), further study of the effect of steroids on CPSP is warranted.

Ineffective Treatments

In small studies, **reboxetine** (selective norepinephrine reuptake inhibitor) and **citalopram** (selective serotonin reuptake inhibitor) were deemed ineffective treatments of CPSP (119,120). In the reboxetine trial, the authors concluded that perhaps the combined action of serotonin and norepinephrine is needed to activate the endogenous brainstem pain-inhibiting system, thus explaining the selective norepinephrine reuptake inhibitor's lack of efficacy (119).

In a small study, seven patients with central pain (three due to stroke) received **topiramate** (anticonvulsant) without meaningful relief (121). The small size and mixed population of this study may result in an inability to completely exclude topiramate's utility in CPSP; however, the lack of value in the treatment of other neuropathic pain disorders (122) suggests a lack of efficacy in CPSP as well.

Levetiracetam (anticonvulsant) was studied in a randomized, blinded, placebo-controlled study consisting of 42 patients who received a maximum dose of 3000 mg per day (123). There were no improvement in primary or secondary outcome measures comparing drug to placebo, and the authors concluded that levetiracetam is not effective in the treatment of CPSP.

Dextromethorphan (NMDA antagonist) was given at 40.5 mg and 81.5 mg per day in a randomized, blinded, crossover, placebo-controlled trial of 21 patients (9 with CPSP) (124). No effect compared to placebo was noted for the entire population or the CPSP subgroup. Of note, this study used much lower doses of dextromethorphan compared to other studies, where efficacy was established in various types of neuropathic pain (125).

A blinded, crossover, placebo-controlled study of 20 patients with CPSP who received 8 mg intravenous **naloxone** (opioid antagonist) or saline reported equal numbers of patients reporting improvement in the treatment and placebo groups and four patients improving with both the naloxone and saline administrations (126). Additionally, no patients reporting improvement (irrespective of intervention) remained improved beyond the day of infusion. There was also no difference in percent change in visual analog pain scale score between the groups. The authors concluded that intravenous naloxone is of no value in alleviating the pain of CPSP.

The pharmacologic treatment of CPSP is often based on trial and error until pain relief is found, and the best results are usually achieved with a combination of several drugs (9). Furthermore, pharmacologic treatment typically results in only a subtle improvement in pain intensity. One review adds that enthusiasm for pharmacologic management in CPSP should be tempered, as only a fraction of patients benefit from drugs and those that do benefit will achieve only partial relief (84). Despite this, the utility of these agents should not be called into question as a clinically meaningful reduction in pain extends beyond numerical values to include the patient's subjective experience and the percent reduction in pain (which varies depending on the patient's baseline pain level) (127).

Nonpharmacologic Management

Historically, the use of simple desensitization techniques, such as rubbing painful areas or applying materials of different textures (cotton, wool, light sandpaper), has been recommended to treat neuropathic pain symptoms including CPSP. There are no clinical trials using these techniques. However, in complex regional pain syndrome, a diagnosis where maladaptive central processes are implicated, "pain exposure" physical therapy has been trialed sucessfully in a small number of patients (128). Application of this strategy to CPSP has not been attempted. In theory, exercise therapy might reduce pain-related symptoms by improving strength, flexibility, and functional use of the impaired body areas or limbs. Whether exercise therapy improves function and the emotional response to pain or directly reduces pain perception is not clear. Further, the overall efficacy of exercise therapy for the treatment of CPSP is unknown. Nevertheless, exercise therapy remains a key component of a comprehensive approach to the management of central pain.

Mirror therapy has been used to treat pain after stroke. In this therapy, the patient practices bilateral functional movements with the painful limb behind a mirror, so that only the reflected image of the unaffected limb is seen by the patient. This approach has shown efficacy in CRPS type 1 following stroke (129,130), but there are no trials assessing the efficacy of mirror therapy in CPSP (131).

Transcutaneous Electrical Nerve Stimulation (TENS)

In a single, unblinded cohort trial of patients with CPSP, application of either high-frequency (70 Hz) or low-frequency (2 Hz) TENS had positive clinical effect in only 4 of 15 patients (pain reduction 20% to 57%); only 3 of these patients reported long-term improvement. Other patients either did not respond or had a transient *increase* in pain of 20% or more.

Motor Cortex Stimulation

There has been a growing interest in the use of invasive and noninvasive methods of neuromodulation to treat chronic pain. Neuromodulation involves the therapeutic alteration of neurological activity either through stimulation or medication, both of which are introduced by implanted devices. The use of implanted cortical stimulators to treat CPSP has been explored for years. Tsubokawa and others have shown that pain relief can be achieved best when the stimulating epidural electrode is placed overlying the primary motor cortex (M1) rather than over the sensory cortex (132). Because of this finding, these researchers suggested that central pain is a result of aberrant plastic changes in the inhibitory receptive fields of the sensory cortex such that nonnoxious input can stimulate nociceptive neurons, centrally. It is theorized that motor cortex stimulation might block these aberrant connections through either orthodromic stimulation via motor neuron pathways to S1 cortex or through antidromic stimulation of sensory fibers that project transcortically from S1 cortex (133). However, positron emission tomography (PET) imaging during motor cortex stimulation does not demonstrate any increase in regional blood flow in either M1 or S1 cortex. Rather, there is an increase in blood flow within the ventrolateral thalamus, which has rich connections with both precentral and postcentral cortical regions (134). Goto and colleagues used diffusion tensor imaging to evaluate white-matter fiber tract integrity in patients with CPSP and noted that, when thalamocortical tracts were intact, pain reduction with motor cortex stimulation was more likely effective (135). PET imaging also demonstrates that during motor cortex stimulation, there is increased regional blood flow in the medial thalamus, anterior cingulate gyrus, upper brainstem, and contralateral insular cortex. These structures make up portions of the lamina 1 spino-thalamo-cortical (interoceptive) pathway and are critical in pain processing (see Figure 17.1). Thus, stimulation of the motor cortex might reduce CPSP-related pain through orthodromic or antidromic stimulation of the thalamus along thalamocortical pathways; this could

then modify pain processing activity within the anterior cingulate, brainstem structures, and insular cortex (135,136). Such cortical changes may be gamma-aminobutyric acid-mediated because patients who respond to an intravenous propofol infusion (gamma-aminobutyric acid A agonist) also respond well to motor cortex stimulation. It has also been proposed that motor cortex stimulation modulates pain through descending cortical spinal pathways that connect to dorsal horn structures (135).

Motor cortex stimulation is delivered by an electrode implanted on the dura overlying the precentral gyrus contralateral to the painful side of the body or directly on the M1 cortex (136,137). The electrode lead is tunneled subcutaneously to the chest region, where it is attached to a pacemaker-like pulse generator (137). Tsubokawa and associates achieved a 67% to 73% rate of clinically important reduction in CPSP symptoms with motor cortex stimulation, defined as at least a 50% reduction on the VAS (132,133). Most patients had effective pain relief for more than a year, though some had pain recurrence. In another study, motor cortex stimulation produced an average pain reduction of 83% in a small cohort of 32 central pain patients of which 11 had CPSP (138). Katayama and colleagues achieved a 60% reduction in pain for more than 2 years in nearly half the patients they implanted with a motor cortex stimulator (139). In a review of the existing literature, Fontaine and others noted several complications with cortical stimulator implantion, including infection (5.7%), hardware failure (5.1%), and postoperative seizures without long-term epilepsy (12%) (140). They concluded that, although motor cortex stimulation is not without risk, 54% of patients implanted will report a positive response to therapy, with the best responders being patients carrying the diagnoses of CPSP and trigeminal neuralgia (140).

The decision to implant a cortical stimulator should be reserved for patients whose clinical presentation suggests that they will respond positively to this treatment. For example, CPSP patients with little or no motor impairment respond best to motor cortex stimulation (139). Additionally, CPSP patients with a normal temperature sensory threshold within the affected cutaneous regions also respond better to motor cortex stimulation (141). Finally, as mentioned previously, pain relief with intravenous infusion of propofol, a gabaergic medication, is predictive of a positive response to motor cortex stimulation (137,142,143). Pain relief with intravenous ketamine has a similar predictive value to propofol; however, those who have favorable pain relief from intravenous morphine do not respond well to motor cortex stimulation (144).

Deep Brain Stimulation

Deep brain stimulation for CPSP has also been explored, but there is conflicting evidence with regard to efficacy. Owen and associates implanted 15 patients with CPSP that resulted from either cortical or subcortial stroke. They targeted both the periventricular grey (PVG) and the VPL thalamus and initially tested efficacy postoperatively with an external pulse generator. If pain relief was achieved, the pulse generator was internalized and either PVG or VPL was stimulated, depending on clinical response. In this study, 70% of implanted patients responded with a 43% to 54% reduction in visual analog score (145). Conversely, Rasche and colleagues found only an 18% response rate to deep brain stimulation of the PVG or VPL (2 patients out of 11 with CPSP); some nonresponders reported an increase in pain with the intervention (146). PVG, rather than VPL, may be the preferred implantation site for deep brain stimulation. This has been suggested because stimulation in the PVG reduces low-frequency field potentials in the thalamus to a higher degree than stimulation in the VPL, which corresponded to more robust pain relief (147). In a single case study of PVG deep brain stimulation for CPSP, the patient reported significant pain reduction along with improved sensory function, including resolution of allodynia and better sensory discrimination (148). It has also been suggested that the centromedian thalamus may be an appropriate site for deep brain stimulation, as it is involved with the motivational aspects of pain, but this has yet to be tested clinically (149).

Noninvasive Neuromodulation

The invasive nature of motor cortex stimulation and deep brain stimulation limits their clinical application due to the risks associated with surgical implantation. An alternative is to use noninvasive techniques to stimulate the motor cortex for CPSP management. Repetitive transcranial magnetic stimulation (rTMS) uses a magnetic coil to deliver electromagnetic pulses over the cranial surface that induce local currents in the underlying cortex and can induce a peripheral motor evoked response. In patients with CPSP, rTMS can provide transient pain relief when delivered over the motor cortex contralateral to the painful region. rTMS over the motor cortex is superior to stimulation over the sensory cortex, premotor cortex, or supplementary motor cortex in patients with CPSP (141). Both high-frequency and low-frequency rTMS have shown efficacy, and provision of several daily sessions of rTMS can result in a longer duration of pain relief (142,150–153). Given that pain relief in CPSP after rTMS typically only lasts a few hours, its utility is limited. Further research is needed to explore the best stimulation frequency, intensity, and location to improve duration of pain relief. Additionally, the investigation of pharmacologic agents to be used in conjunction with rTMS to enhance efficacy is warranted (154).

Transcranial direct current stimulation (tDCS) is another method that can be used to provide noninvasive motor cortex stimulation. This simple method involves the delivery of 1 to 2 mA of direct electrical current, with one electrode over the motor cortex and the other typically placed on the forehead just above the opposite orbit. Using this device, Fregni and colleagues have effectively reduced pain in patients with fibromyalgia and with central pain after spinal cord injury (155,156). tDCS has not been studied for the treatment of CPSP, but it would be appropriate to trial the application of anodal stimulation over the motor cortex contralateral to

CPSP symptoms. If effective, tDCS might have more utility than rTMS, because tDCS is relatively safe and easy to use. With proper education, patients could use tDCS at home.

Clinical Correlation in Treatment

A careful history and physical examination are extremely important in monitoring response to treatment in patients with CPSP. The documentation of specific subjective and objective exacerbating and alleviating phenomena is vital from encounter to encounter. For example, detailed documentation of a patient's subjective complaints of an inability to wear a bra and shower due to allodynia, coupled with objective demonstration of light touch and cold allodynia in the affected upper and lower extremities, serves as an excellent clinical baseline. After treatment initiation, this patient returns and reports no subjective improvement in symptomatology, and the practitioner sees no improvement in visual analog pain scale score. During this return visit, however, the practitioner recognizes that the patient now presents to the clinic tolerating a bra, inquires and learns about her newfound ability to tolerate showering, and demonstrates the alleviation of light-touch allodynia in the arm and leg while noting persistence of only the cold allodynia in the upper extremity alone. Referring back to prior documentation, the practitioner realizes the significant improvements achieved based on these new clinical findings despite the patient's poor insight into these improvements and the lack of change on conventional pain measures. Without the specific baseline clinical documentation, the efficacy of the treatment may have been missed and led to an alteration in management. Instead, in this clinical scenario, the practitioner would obviously continue treatment, consider dose escalation, and/or add adjunctive therapies. In addition to a detailed history and physical specific to each patient, the use of detailed pain measures like the short-form McGill Pain Questionnaire (157) to monitor change relative to treatment has utility in the clinical as well as the research settings.

CONCLUSION

CPSP continues to be a poorly understood potential consequence of stroke. To improve our understanding of this diagnosis, reliable, valid, user-friendly diagnostic criteria that can be applied in clinical and research settings must be developed. Here, we propose new diagnostic criteria for CPSP (Table 17.6). These new criteria seamlessly meld the existing diagnostic criteria and grading system proposed by Klit et al., as displayed in Tables 17.1 and 17.2 (9), while also altering and adding some important components. The melding of the scheme proposed by Klit et al. leads to easier diagnosis of CPSP, as it creates a more straightforward set of diagnostic criteria. The proposed criteria alter the existing criteria in that they separate the **objective negative** and **objective positive sensory signs** into *different* components. The rationale for this is based on the information discussed in the "Clinical Characteristics" section of this chapter. According to the studies described earlier, some form of sensory deficit (**objective negative sign**) can be demonstrated in all patients with CPSP, whereas allodynia or hyperalgesia (**objective positive signs**) are not necessarily demonstrated in all patients with CPSP. Hence, the criteria were altered accordingly, making the demonstration of somatosensory deficits fundamental to the diagnosis of CPSP while making the demonstration of allodynia or hyperalgesia on physical examination more confirmatory. Finally, existing criteria do not include **subjective** reports of allodynia; thus, this component was added to the proposed criteria. As discussed in the "Clinical Characteristics" section, a patient with CPSP will complain of pain, but might not report allodynia (**subjective positive symptom**). Again, the subjective report of allodynia was added as a confirmatory component of the proposed diagnostic criteria. Of course, this new set of criteria must be validated before being utilized in clinical or research settings.

The establishment of universally agreed-upon, validated diagnostic criteria will add much-needed reliability to the study of CPSP. This will ultimately help with the determination of pathophysiologic mechanisms and, subsequently, the development of pharmacologic and nonpharmacologic treatments. For example, there are reports that lesion location actually affects pain quality in patients with CPSP (158–160). Exploring such a concept may lead to further elucidation of the pathophysiology that underlies CPSP and, potentially, other central pain processes. Additionally, the exploration of such a concept may lead to changes in treatment planning, as lesion location might guide a clinician to trial one

TABLE 17.6 New Proposed Diagnostic Criteria for Central Poststroke Pain

Probable CPSP: Criteria 1–3 all fulfilled

Definite CPSP: Criteria 1–3 all fulfilled **PLUS** 4 **OR** 5 fulfilled

1. Pain in a body area(s) corresponding to and beginning after a radiographically confirmed stroke damaging the spino-thalamo-cortical pathway
2. Objective demonstration of somatosensory deficits (touch, cold, warm, and/or pinprick) surrounding or within the painful body area(s)
3. Elimination of other diagnoses that may better explain symptoms (nociceptive, peripheral neuropathic, psychogenic)
4. Subjective report of allodynia to touch and/or thermal (cold or warm)
5. Objective demonstration of allodynia to touch and/or thermal (cold or warm) **OR** hyperalgesia to pinprick

therapeutic option over another. This level of exploration, however, requires consistency among trials in the form of patient identification and accurate diagnosis in the form of clear, universal diagnostic criteria. Regarding treatment, much remains to be discovered in CPSP. The study of promising pharmacologic and nonpharmacologic treatments is warranted. These include, but are not limited to, serotonin/norepinephrine reuptake inhibitors, zonisamide, tramadol, tapentadol, methylprednisolone, intrathecal baclofen, "pain exposure" physical therapy, rTMS, and tDCS.

Visual, Ocular Motor, and Vestibular Deficits

Judith E. Goldstein, Nicole C. Ross, Daniel R. Gold, and Amir Kheradmand

Stroke commonly impacts the visual and vestibular systems. These sensory systems play critical roles in mobility, communication, and daily activities, and deficits in either (or both) systems can be quite disabling. Rehabilitation of these impairments can substantially improve quality of life, yet these areas are often less emphasized in stroke rehabilitation than other sequelae of stroke. In this chapter, we review the anatomic and physiological basis of these systems, the impact of stroke on vestibular and visual function, and rehabilitation approaches.

VISUAL SYSTEM

Estimates of the proportion of stroke survivors with visual manifestations range from 30% to 50% (1,2). The variability of effects on the visual system alone is remarkable, including, visual field loss, oculomotor deficits, visual perceptual problems, and reduction in visual acuity (VA). In isolation or together, these deficits can cause problems with mobility, reading, driving, socialization, and depression. It is the impact on the visual processing system that causes loss of *visual ability*—the ability to perform vision-mediated tasks, comfortably and independently. In the absence of spontaneous resolution of deficits, a carefully tailored rehabilitative plan of low vision therapy can be instrumental in regaining visual ability, and a safe, more independent life state (3,4). Despite the potential devastating impact on visual ability function, there is often a delay in identification of visual deficits and referral for low vision rehabilitation (LVR). This is in part because of a lack of awareness of LVR services and systematized treatment approaches as are present in language, speech, and motor rehabilitation (5).

In reviewing visual and oculomotor deficits, we will describe the epidemiology, natural history, impairments, and the impact on visual ability, and rehabilitative and/or restorative therapies in stroke-related vision loss. Like most other aspects of the neurologic system, the location and etiology of the lesion generally assists in identifying the type and magnitude of the deficit. For the purposes of this chapter, we will restrict the discussion to postchiasmal loss, which typically involves interruption to the middle or posterior cerebral arteries or vertebral basilar circulation. Most notable, and familiar to readers, is infarct or hemorrhage affecting the posterior cerebral artery that nourishes the occipital lobe, also known as the visual cortex. Stroke causing damage to the occipital lobe is the most common cause of homonymous hemianopia-visual field loss in both eyes to the same side. Approximately 30% of stroke admissions are found to have homonymous hemianopia, hemi-inattention, or visual neglect (6–8), and 70% of all hemianopias result from stroke. Hemianopia is likely the most debilitating and common visual complication of stroke that must be addressed during rehabilitation.

Although therapies for speech, language, motor disorders, and cognitive dysfunction are universally accepted and implemented as part of stroke rehabilitation, vision–sensory and oculomotor disorders are still widely neglected. The most likely reason is that rehabilitation strategies in vision have shown limited success (5). They require lengthy therapy of a typically unmotivated cohort and, when successful, often entail a specialized clinical skill set and rehabilitation team that is readily accessible in only a handful of hospitals and facilities.

KEY AREAS OF VISUAL IMPACT

Homonymous Visual Field Disorder (HVFD)

HVFDs represent a loss of vision in both eyes on the same side; because of the decussation of fibers occurring at the chiasm, the effective visual field loss is contralateral to the side of the lesion (Figure 18.1). The term "hemianopia" is typically included in the description of visual field loss secondary to cortical stroke and implies loss to one-half of the vision; however, loss may not necessarily be complete, but rather quadranopic, partial, or even relative (see Figure 18.2) (9). Depending on the location of the stroke, the symmetry of the loss between the eyes will vary. Typically, more anterior lesions result in incongruity, whereas posterior damage to the radiations result in more congruous loss. Although HVFDs are not solely vascular in origin, 70% of all occurrences are a result of arterial infarctions (10). The remaining nonstroke causes include head trauma, brain tumor, neurosurgical procedures, and multiple sclerosis (11).

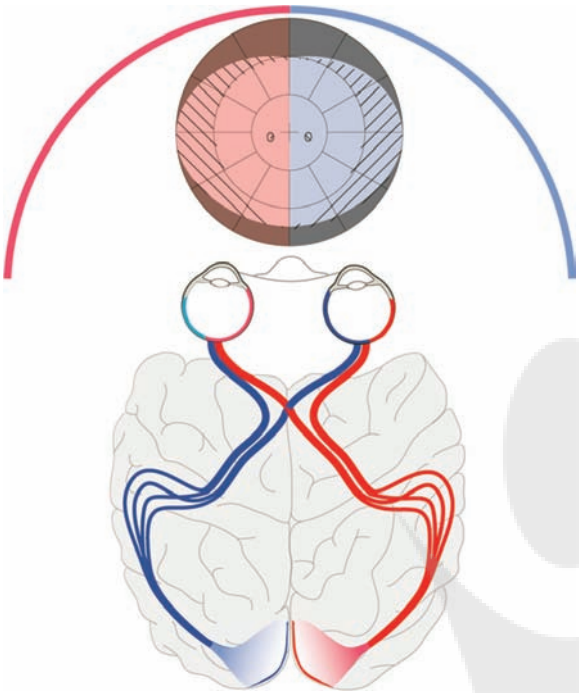

FIGURE 18.1 The visual pathway and corresponding visual fields. The red color highlights the left visual field, which is projecting on the temporal retina of the right eye and the nasal retina of the left eye. Those areas highlighted in blue represent information from the right visual field. Hatched areas represent the portions of the visual field, which are only viewed by the nasal retina of one eye, known as the temporal crescents. At the optic chiasm, right and left visual space is segregated with fibers from each nasal hemiretina passing into a single corresponding optic tract (left and right, respectively). Fibers in each tract connect through the lateral geniculate nucleus and continue through the optic radiations to terminate at the striate cortex in the occipital lobe. Any lesion to the right post chiasmic optic tract, or any of its terminal projections, will result in an homonymous left visual field defect.

HVFD typically manifests itself as a lack of response to visual stimuli presented on the affected side. It is essential for patients, families, and caregivers to understand that in HVFD, the vision loss is in both eyes on the same side as opposed to loss in one eye. Approximately 70% of all HVFD cases are thought to have central visual field sparing of five degrees or less (see Figure 18.3) (5). This is commonly referred to as macular or foveal sparing and provides for what is typically considered normal VA or 20/20. Some controversy exists as to whether macular sparing is real, the relevance of it, and whether it represents scanning during VF testing (i.e., perimetry) and rather is an artifact of testing (12,13). Macular sparing does not help predict the location of the lesion within the retrochiasmal visual pathway; however, it does provide significant benefit in tasks where VA is a strong predictor of visual ability such as reading (12–15).

When a stroke impacts both the parietal and occipital lobe (especially on the right side), an important distinction must be made in the continuum between HVFD with and without unilateral spatial inattention (USI) (see Visuospatial Perception Deficits below). The complicating factor of inattention may change the prognosis and rehabilitation training in such activities as reading, mobility, safety, and driving.

Reading

Reading is the most common complaint in patients seeking LVR services (16) and is a common concern among patients with HVFD. Paracentral visual field or, more appropriately, preview area, along with VA has been correlated with impaired reading (17). For efficient reading, it is necessary to scan ahead using the preview area to assist with planning for rightward reading saccades (18,19). During reading from left to right, the necessary window for fluent reading extends three to four characters to the left of fixation and seven to eleven letter spaces to the right of it (this can also be translated to 5 degrees to the right of fixation) (20). Right-sided loss will typically cause greater reading impairment than left-sided loss in the absence of inattention or neglect, as the former forces reading into the scotoma or blind area and eliminates the possibility of anticipatory scanning. This may result in reading errors and reduced reading speed (5). Right-sided loss and problems in reading are also known as hemianopic alexia (21). This disorder is evident through disrupted eye movement scanpaths, prolonged fixations, inappropriate small amplitude saccades to the right, and saccadic regressions (19). Left-sided loss primarily accounts for deficits in omissions in the first letter or word on a line and is often responsible for difficulty with return eye movements to the beginning of a new line of text.

Other Functional Domains

Effects on mobility and navigation are evident early after stroke when HVFD is present. Several recent studies evaluating detection during mobility and visual–motor-related tasks in real and virtual environments have demonstrated significant impairments in object detection on the side of the field loss (22–25) such that individuals frequently bump into people, trip over unseen obstacles, spill when pouring liquids, and experience reading difficulty (26). Visual–motor skills (such as reaching and grabbing) are often impaired because of visual exploratory deficits in the blind and intact hemifield caused by inaccurate saccades and disorganized visual search patterns (27–29). In addition, impaired walking (bumping into obstacles) and impaired detection of potential hazards when driving may occur depending on the extent of the visual field deficit, presence of inattention, or other comorbidities. In the majority of U.S. states, motor vehicle laws prohibit individuals with HVFD from driving; however, there are states without visual field requirements and states with special programs that enable patients to drive with HVFD (30,31). Vision-related quality-of-life studies indicate that patients with HVFD have a significantly

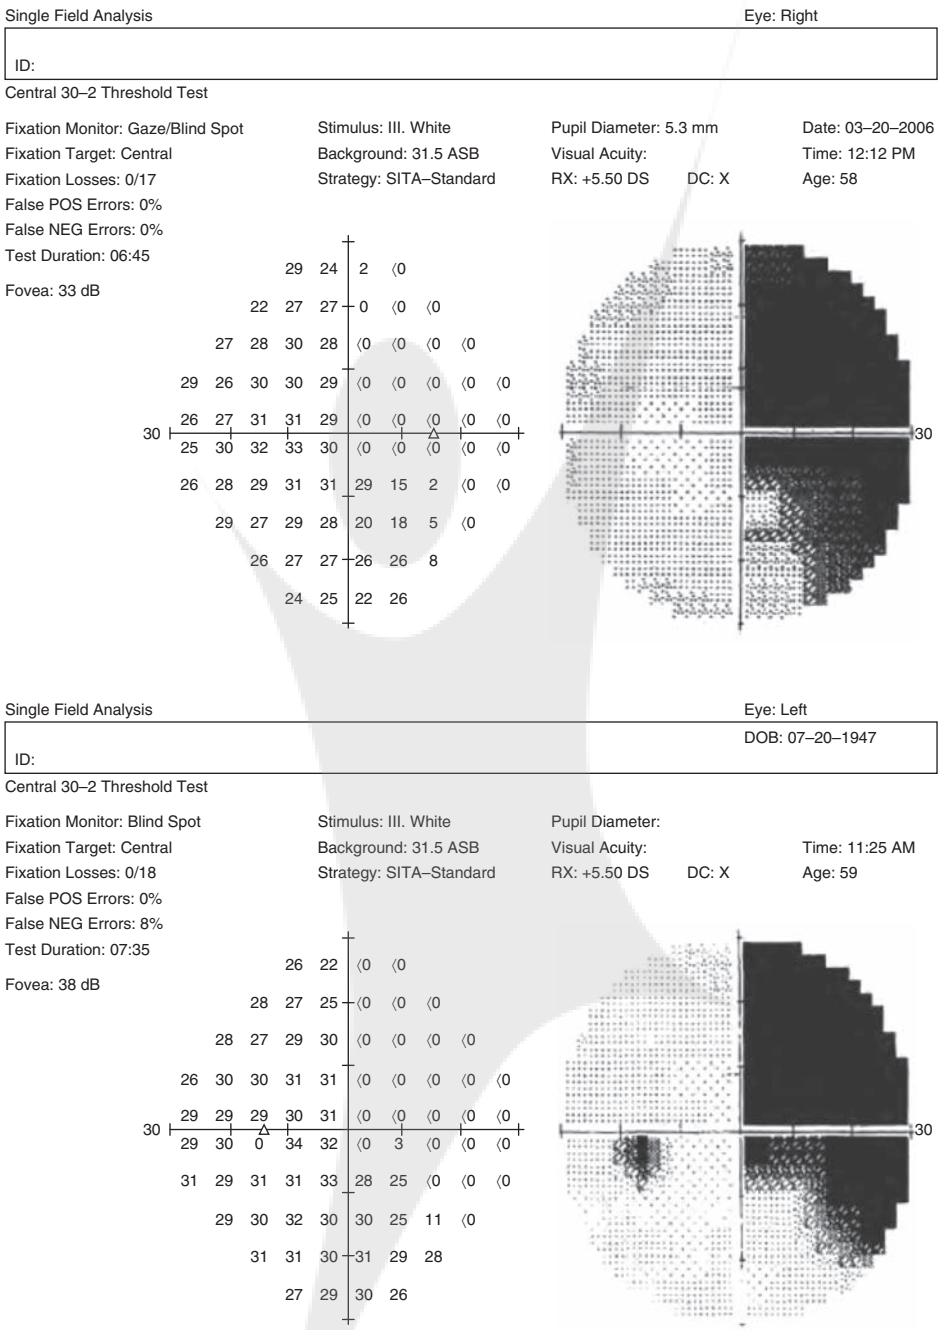

FIGURE 18.2 Incomplete right homonymous hemianopia with sparing inferiorly on the right side evaluated by Humphrey visual field.

reduced quality of life specifically with respect to social functioning, role difficulties, mental health, driving, and increased dependency on others (32,33). The consequence of driving cessation alone has significant impacts on the ability to work and maintain social networks (34). In addition, up to 48% of patients report significantly increased stress and anxiety levels when moving in crowded community environments (35). Overall, the presence of HVFD has been associated with significantly lower likelihood and increased time in achieving independence with walking and with instrumental activities of daily living (6).

VISUOSPATIAL PERCEPTION DEFICITS

In the case of stroke involving the occipital and parietal lobes, visual function may be compromised by the loss of visual field and/or the loss of visual attention because the parietal lobe is responsible for the brain's representation of personal space, or body image, and external space (36). When the secondary pathway fibers from the occipital lobe to the parietal lobe (known as "dorsal stream") are disrupted, disorders of perception, spanning the continuum from USI to visuospatial neglect may occur (37–39). This occurs most frequently

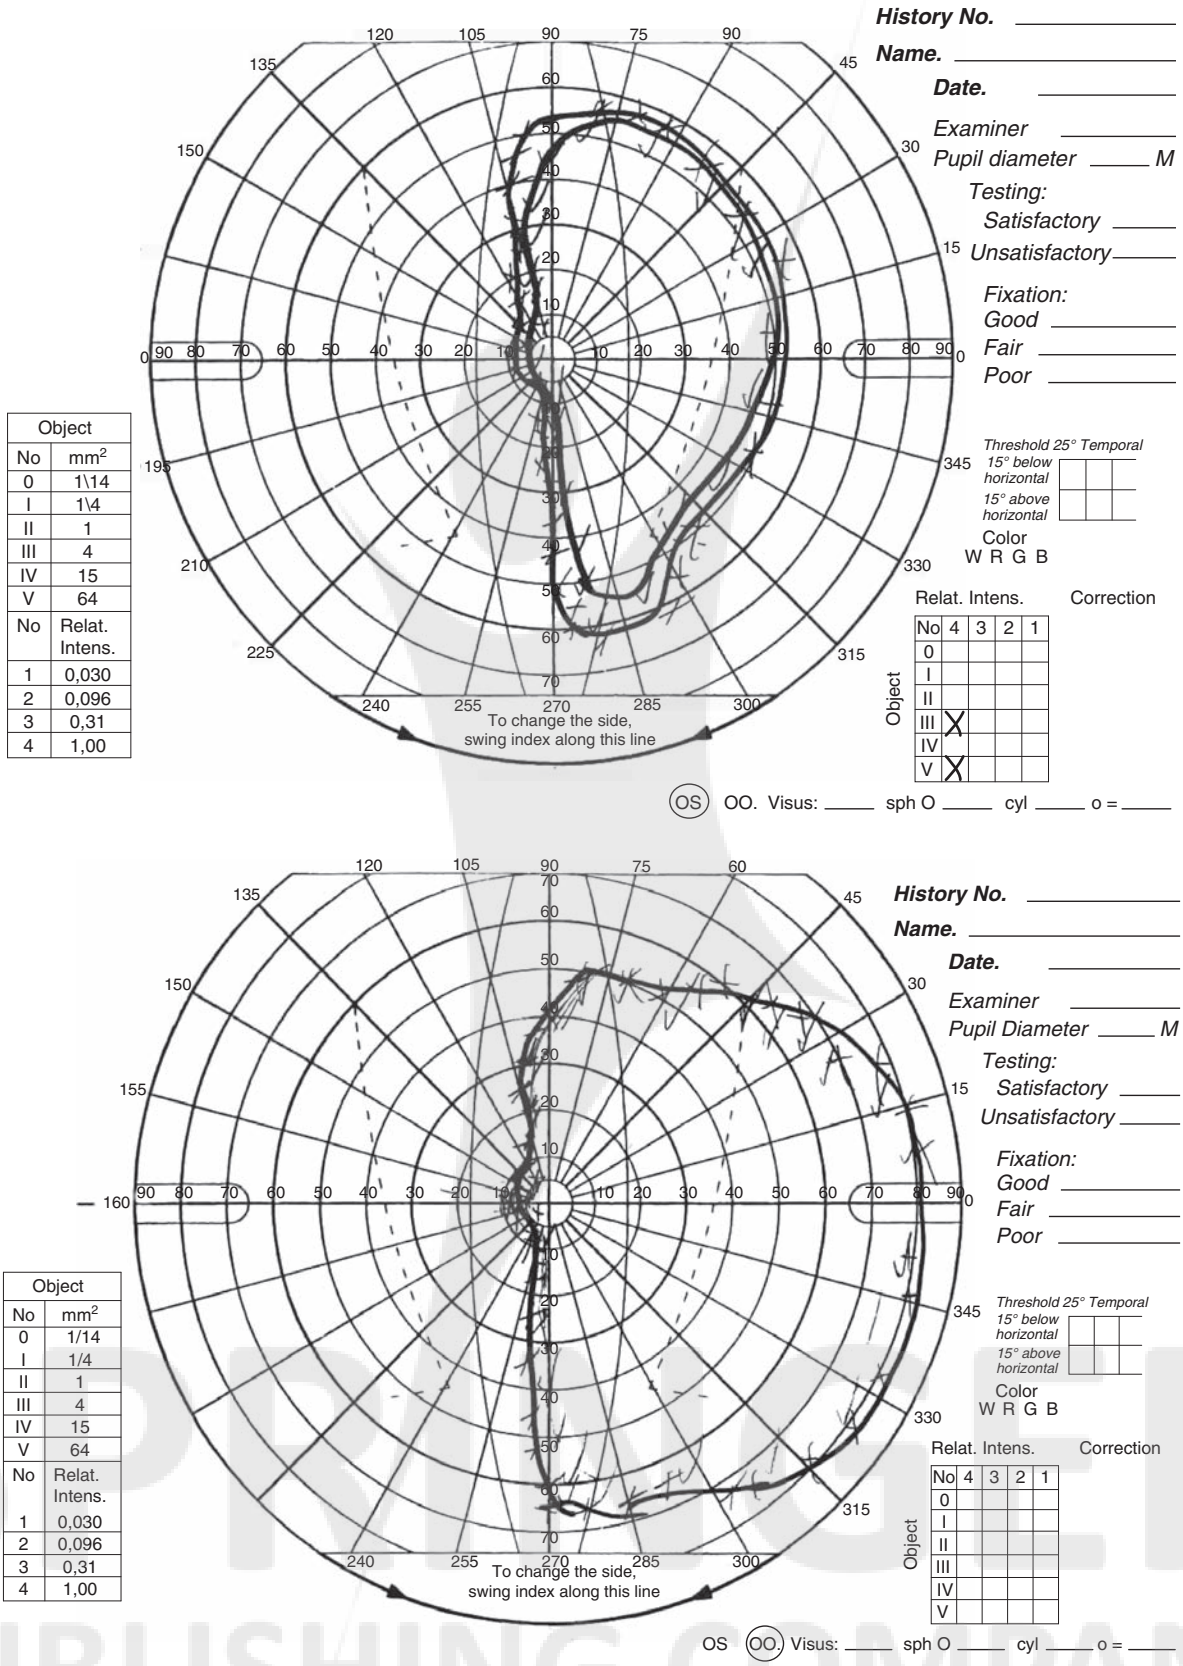

FIGURE 18.3 Left homonymous hemianopia with macular sparing evaluated on Goldman visual field for the right and left eyes respectively, to the size V4e and III4e isopters.

when there are right hemispheric lesions involving the right inferior parietal lobe. The result is reduced awareness or inattention on one's left side of the body, extending out into left visual space (40,41). A practical distinction to assist in the management of visual ability loss in these patients is to detect whether the inattention occurs in peripersonal space, which primarily tends to affect near-oriented activities (e.g., missing food on plate or failure to perform personal care on the affected side), and/or extra-personal space that causes more orientation and mobility problems (e.g., bumping into objects on the affected side when walking).

The visual evaluation after stroke requires differentially diagnosing HVFD from inattention or in some cases, the presence or absence of both. Typically, when solely postchiasmal nerve fibers extending from the retina to the lateral geniculate to the occipital lobe are compromised, the result is an HVFD that can be diagnosed by perimetry. In everyday function, these patients often retain good awareness and a self-intentioned effort at compensating for the loss (e.g., head turning or scanning to the affected side). In contrast, if the lesion occurs when fibers are traveling along the secondary pathway, occipital to parietal cortex, the result is more likely USI without evidence of HVFD on perimetry. When both pathways are involved, HVFD and spatial inattention can coexist, resulting in a bleak outlook, as disorders of perception are a poor prognostic factor for rehabilitation of stroke outcomes (41,42). The presence of inattention creates barriers in reading and mobility rehabilitation as the loss of awareness reduces responsiveness to new learning.

Diagnosing the continuum of USI to visual neglect as part of the LVR evaluation involves patient observation, testing of VA, visual fields with assessment of visual extinction, ocular pursuits, saccadic testing, and standardized paper and pencil tasks. The extinction phenomenon occurs when a patient shows awareness to a singular stimulus in the affected visual field; however, when two of the same stimuli are presented simultaneously (one in the affected and one in the intact visual field), the patient becomes unaware of the contralesional stimulus. Extinction exemplifies the variable presentation in performance shown by patients with mild inattention deficits, such that these individuals may show functional deficits when over-stimulated such as navigating in crowded unfamiliar environments but appear completely intact when walking in very familiar environments. Paper and pencil tests incorporated in the LVR assessment are consistent with the standardized battery including the line bisect test (43), Bell's test (44), and other cancellation tests. In prior reviews, the most sensitive clinical measure of neglect was a rightward orientation bias, whereas others have shown the best sensitivity from an assessment involving observation of behavior in ten everyday life situations (45).

VISUAL ACUITY

After stroke, the ultimate, best-corrected acuity, or clarity, will impact an individual's reading and mobility ability, including risk for falls (46). The level of VA loss is an important consideration in the rehabilitation plan and prognosis for improved visual function. After bilateral postchiasmatic lesions, VA declines with great variability (47). Generally, the more posterior the lesion, the more symmetrical the acuity and visual field loss. With that said, many patients retain good VA after stroke. One cross-sectional study indicated that only 13% of patients following stroke exhibit reduced VA at distance and near, and in one third of these cases, the low vision was attributable to prior ocular pathology not as a result of the stroke (48).

Measuring VA in a stroke patient can be challenging, especially in the presence of aphasia and cognitive impairment, and at times it is necessary to deviate from standard Snellen acuity testing. Portable charts with numbers can work well, as there are fewer optotypes, and verbalization of numbers in aphasic patients often provides better success than letters. Matching characters and tracing can be an effective testing method when detailed explanation can be repeated and reinforced. With severe aphasia, alternatives such as tumbling E, Landolt C, Cardiff, or even Teller VA cards (preferential looking test that takes advantage of one's natural preference to look at a bold pattern as opposed to a blank homogeneous area) can be helpful in obtaining measurable responses, although correlation to Snellen visual acuities can be poor (49). Line and letter isolation during VA measurement can also help to enhance attention during testing and limit confusion.

VA testing can be useful in distinguishing hemianopia from USI. In absolute terms, patients with hemianopia without USI may miss letters on the side of the eye chart contralateral to the lesion (e.g., letters on the left with a right-sided occipital stroke); however, when made aware that they are doing so, the HFVD patient will typically initiate looking to the left and pick up letters on the left, a behavior often applied during therapeutic activities. When assessing VA in patients with USI, reminders regarding omissions rarely result in a consistent performance in scanning into the affected area. VA measurement can also be of diagnostic assistance in spatially locating inattention effects (e.g., peri-personal vs. extra-personal space). Patients with extra-personal involvement may miss letters more so on the distance VA chart whereas personal and peri-personal impact may show greater loss when testing VA at near. Carefully evaluating patients VA at distance and near becomes that much more important for patients with USI and their caregivers, as they will often deny or be unaware of the differential effects of loss at different locations and when different level of stimuli are present.

When there is VA loss, it is helpful to understand whether VA and visual ability were intact prior to stroke, both for the purposes of understanding the presence of ocular comorbidities and expectations of refraction testing to determine the appropriate spectacle correction. In one series, 14% of patients had visual impairment that benefited from refractive correction alone (50). Improved spectacle correction, whenever possible, can assist with training of

visual processing skills, speech and language therapy, and improved safety in activities of daily living. In cases where visual field cuts are also present, it is necessary to educate the patient and family members that spectacles do not eliminate field loss; therefore, many of the problems with mobility and reading will persist even with new glasses.

EYE MOVEMENT DISORDERS

The rate of ocular misalignment and symptoms of double vision (diplopia) vary between 28% (51) and 54% (52), with higher incidence occurring with brainstem involvement. In both the studies, the majority of the cases were diagnosed with cranial nerve III palsy. In these cases, many patients experience diplopia (i.e., double vision) as the eyes maybe pointed in differing directions in primary or alternate gaze. Diplopia was reported in 38% of consecutive patients with posterior circulation stroke admitted to a rehabilitation service (53). Although up to 15% of stroke rehabilitation patients have had brain stem involvement, there is a relative lack of research in rehabilitating these cases (54). More detailed descriptions of posterior circulation oculomotor deficits are provided in Chapter 6 (Infratentorial Stroke Syndromes). When internuclear ophthalmoplegia is the predominant or only manifestation of a dorsal brainstem stroke, the prognosis is very good (55).

Reading

Double vision, that is, diplopia, secondary to ocular motor paresis causes significant reading impairments secondary to the inability to following a line of text as a consequence of disrupted eye movements. Examples of disrupted eye movements include: prolonged fixations and inability to make appropriate saccades to the next word (or next line). As a result, many diplopic patients clinically report they have discontinued or are completely unable to read without either complete or partial occlusion of the paretic eye.

Mobility and Safety

Symptomatic and constant diplopia can be disruptive to mobility safety and distressing during everyday viewing. A patient may not be able to discern the real location of the object from the two images he or she is seeing. Falls and misjudgments in reach and grasp tasks are obvious consequences of this problem. Therefore solutions to ameliorate diplopia should be a significant priority in a patient's stroke rehabilitation plan.

RECOVERY FROM VISUAL SEQUELAE

Even prior to rehabilitation, however, some individuals experience spontaneous visual recovery depending on the underlying pathology (11). In less than 10% of cases, individuals with HVFD caused by ischemia fully recover their visual field (56–58). This recovery is largely complete within the first 10 days from the time of stoke. Recovery of a partial defect occurs within the first 48 hours and is typically complete within 10 to 12 weeks (56–58). The extent of visual recovery negatively correlates with age and other comorbidities. The documented course of recovery shows that vision returns to the affected field in definite stages, starting with perception of light, motion, form, color, and lastly, stereognosis (59,60). In addition to spontaneous visual improvement, we see improvement from natural compensatory strategies that occur within the visual system; these are likely associated with some degree of cortical reorganization and individual adaptation. Possible evidence for this is in HVFD patients where fixation is directed into the blind hemifield perhaps to increase the effective size of the "seeing visual field" or scanning that occurs to minimize bumping into objects.

There is evidence that loss within damaged cortical areas is not absolute and areas that appear to be nonfunctional do in fact retain certain visual function through subcortical mechanisms (61). Given this, much effort has been placed in exploring methods to enhance adult neurogenesis and neuroplasticity (4) by stimulating and/or regenerating areas that appear deficient to enhance current rehabilitation strategies. Potential therapies, such as stem cell therapy, hyperbaric oxygen treatment, exogenous tissue engineering and brain–computer interface technologies, could hold promise and are currently being explored with respect to enhancing motor control in postischemic stroke (62,63). Additional investigations exploring potential to restore the penumbra—tissue that has been damaged by the stroke event but has not yet undergone apotoptosis—offers some promise for recovery (64). As efforts at restorative therapies continue to develop, the lack of an effective treatment has emphasized the role of rehabilitation strategies to maximize visual ability function.

REHABILITATION STRATEGIES

Visual rehabilitative strategies can be divided into compensatory optical and training approaches. As each case is unique, it is necessary to tailor therapy for the individual because of the complexity and variety of effects from stroke. To be maximally successful, these therapies should be implemented in a task-oriented approach—for example, reading, writing, navigation, etc. In coordination with other therapies, the ultimate objective of vision rehabilitation is to improve visual ability at the goal level (e.g., managing finances, shopping, personal care, etc.). Once the visual effects of stroke are diagnosed, vision rehabilitation services should be initiated. Of utmost importance is education of the patient, family, caregivers, etc. on the visual deficit, how that impairment affects function, and the type and extent of support needed at discharge. Education on driving resumption is critical for stroke patients with vision impairment, assuming that they were driving prior to admission. Regardless of state law, patients with new onset visual field loss, spatial inattention or diplopia should defer any driving until they have been further evaluated and cleared. Vision rehabilitation can be provided in a continuum starting with inpatient moving to outpatient, with success often dependent on the degree of

nonocular comorbidities. Early intervention can be considered for enhancing safety (e.g., walking with compensatory strategies) and visual comfort (e.g., prism or occlusion for double vision).

Optical Approaches for Acuity Loss and Diplopia

The Role of Maximal Spectacle Correction

Decreased VA may exacerbate the impact of other impairments on overall disability (65). Although VA often remains intact after stroke, every effort should be made by the inpatient team to ensure that stroke patients have and wear their glasses as they would have habitually prior to the stroke (e.g., most patients over the age of 40 require reading correction and thus would need to use their reading spectacles for all near tasks during their therapies). Careful refraction with a trial frame should be performed to ensure that best-lens correction is obtained for both distance and near. Although refraction will not address postchiasmal HVFD loss, it is possible that patients were not maximally optically refracted in their distance or near correction prior to the stroke. To assist with clarity and comfort and enhance function at near, a stronger or weaker power in the bifocal along with a directed, well-placed light source and appropriate material positioning will be beneficial. Prescribing distance only glasses should be considered when navigation is impaired from visual field and gait effects. When walking down steps or off curbs, a bifocal can have the effect of altering perception of depth, which may further impair safe mobility. Separate spectacles for mobility and reading may be the most advantageous solution with regard to safety, although patient cognition, memory and tolerance may dictate the most effective strategies.

Optical-Based Solutions for Diplopia Resolution

The presence of diplopia, or double vision, because of ocular misalignment can be visually disturbing to the patient and can interfere with their progress in other aspects of their safety and care during their inpatient and outpatient clinical care. Partial or complete occlusion of the paretic eye may improve reading ability and/or comfort. Alternating patching is a quick, simple solution that can minimize visual discomfort without risk of sensory deprivation in an adult patient. This approach may also be appropriate for mobility tasks; however, this is often a less than acceptable solution, as patients lose stereoscopic/depth cues when functioning with one eye only.

Alternatively, in some cases, the diplopia can be resolved in primary gaze with the use of a prism. In this manner, a prism is used to shift the location of the image to account for any deviation in the position of the eyes. In this case, careful measures of ocular deviation, prism type, and prism placement must be carefully considered. Depending on the nature of the oculomotor impairment, the ocular deviation may improve either partially or completely. Given that the ocular deviation may change over time, Fresnel press-on temporary prisms are often prescribed, such that the prism amount can be changed throughout the course of recovery and limit the added expense of frequent spectacle changing. Use of Fresnels creates optical aberrations, which unfortunately do degrade VA and contrast sensitivity through the prism, which is proportional to the amount of prism power prescribed (66,67). In lieu of patching, limited use of prisms can be prescribed early on after stroke depending on the individual patient needs.

Optical and Rehabilitation Aids for Those With Reduced Visual Acuity

The use of low vision aids incorporating magnification can be of some assistance when VA is not spared or if VA loss was present prior to stroke. Moderate-powered reading lenses and magnifiers may be of use for spot-reading purposes (e.g., mail, bills, and medicine bottles), understanding that, if an HVFD is present, tracking and fixation may complicate continuous reading. Video magnifiers, or closed-circuit television (CCTV) provides magnification, enhanced contrast, and scrolling of the printed material to improve visibility and, in the case of eye movement disorders, improve one's ability to accurately follow a line of text (68). Video magnification is also now manufactured in a portable fashion, providing greater flexibility for affected individuals, especially those returning to work.

Technology has advanced to the degree that visual and auditory support through screen reading can further enhance a person's overall function. Several e-book readers offer text-to-speech conversion. Specialized software applications, such as Zoom Text Kurzweil 1000, now provide magnification of computer screen information, including both icons and text. The speech output component can read documents at varying speeds, like e-mail and Web pages. These approaches can be most effective in cases where the visual ability function benefits from augmentation with auditory processing. In a vocational environment, this can reduce fatigue and increase work efficiency in a visually impaired individual.

Focused lighting and proper illumination is another treatment strategy that is often overlooked in the performance of activities of daily living, especially reading. Several types of lighting are now available, including full-spectrum, high-intensity, and halogen. Careful selection and positioning of appropriate lighting can be useful in the overall improvement of daily functioning, including reading in patients with reduced vision secondary to ocular pathology.

Optical Treatments in HVFD and USI

Optical approaches aim to improve mobility function in patients with HFVD by improving detection performance of potential obstacles located on the blind side. As of now, few optical approaches have been developed to improve reading function in these patients. These differing spectacle designs attempt to either relocate the field of view of the visual image or to expand field of view (69). Prismatic glasses have most commonly been employed as a rehabilitative device for HVFD. Prisms, in this approach, are used to

shift the image of objects located within the blind hemifield to the seeing field. This differs from the approach of using prisms to ameliorate diplopia. Different configurations of prismatic glasses can provide either visual field relocation or visual field expansion. Visual field relocation results in exchanging visibility of parts of the blind field for parts of the seeing field whereas visual field expansion is a perimetrically measurable widening of the visual field (70). Both approaches are aimed at improving mobility, navigation, and awareness rather than reading. Visual field relocation is typically achieved with bilateral sector prisms (discussed further below) and reflecting mirrors. If the prisms cover the entire field of view (as in full-field bilateral yoked prisms) neither expansion nor relocation occurs.

Visual field expansion can be created by inducing binocular visual confusion—the placement of different images in the same position in visual space. Confusion is achieved by taking an image from the blind hemifield in one eye and superimposing it onto the seeing hemifield in the other, this is typically created with many unilateral prism designs, or partially reflecting or dichroic mirrors. As the use of mirrors is relatively uncommon in clinical practice, we will limit our discussion to prismatic spectacle designs.

Yoked Prism Spectacles

Full-diameter binocular prisms, or yoked prisms, were among the first prismatic spectacle designs to be developed (71,72). Typically, a prism of approximately 10 to 20 diopters with the base toward the defect can be placed in training goggles or ground into spectacles, causing shifting of the image by 5 to 10 degrees respectively into the seeing field (Figure 18.4). This technique assumes that patients do not neutralize the effect by making compensatory eye movements of 5 to 10 degrees. The effect of yoked prisms on normal individuals is a displacement of an image or space toward the apex of the prism causing an initial disagreement between the visual and motor systems, which, for example, causes errors when trying to reach for an object. Within just a few attempts of making errors, conscious correction occurs and the accuracy of motor judgment is restored, this is often termed prism adaptation. When prisms are removed from normal subjects, reaching inaccuracies of the same magnitude that occurred initially results, however, to the opposite side. Again, after a few attempts, spatial realignment occurs. Much work has been done with yoked prism placement in patients with USI with the underlying theory that these patients' perception of "straight ahead" has been shifted to the right (73). Using base-left yoked prism spectacles shifts the image to the right, thus potentially alleviating the disconnect between the objective and perceived "straight ahead" in the patient with visual spatial inattention or neglect. In some cases, the perceptual effects of yoked prism placement persisted up to 2 hours after removal of prism goggles, though the results are quite variable (74). Although several reports emphasize the usefulness of this technique as part of rehabilitation training in practice, the beneficial effect on activities of daily living from yoked prisms is individual, uncertain, and unsustainable in many.

Optical Visual Field Relocation Strategies

Yoked bilateral prisms have also been fitted for patients with HVFD in the form of sector prism segments (covering only part of the spectacle lens) (Figure 18.5). Prismatic powers of up to 30Δ (75–77), but usually under 20Δ (6), have been prescribed. In this design, each prism segment covers nearly one half of the spectacle lens and is offset by 1 to 6 mm from pupil center into the blind hemifield (75–79). For a patient with left HVFD, one prism segment is placed base-left (base out) into the temporal half of the left lens, and the other prism segment is placed base-left (base in) on the nasal half of the right lens.

The patient is instructed to look into the prism segments to detect obstacles on the blind side. It has been suggested that the primary intent of the bilateral segment prism spectacle is to reduce the amplitude of scanning movements

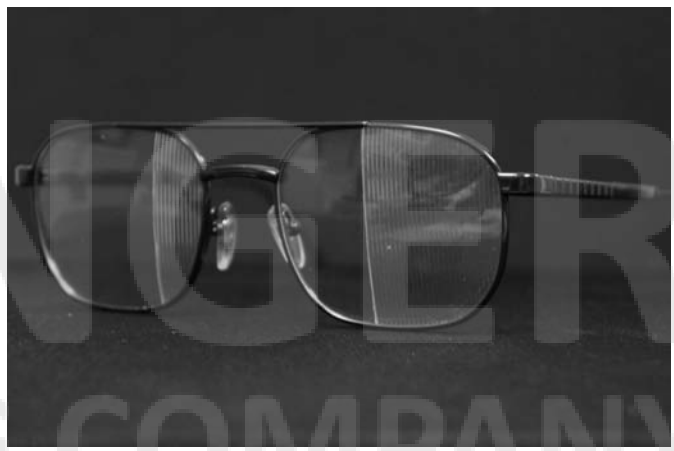

FIGURE 18.5 Bilateral sector prism spectacles utilizing a 20-prism diopter Fresnel prism, placed on the left portion of each spectacle lens. Bases are also oriented to the left for a patient with left homonymous hemianopia.

necessary to detect objects in the blind field (79). This design is only helpful if the patient actively looks into the prism (as the prisms are mounted on the side of the blind hemifield). There is no effect in primary gaze or when a gaze is shifted to the seeing side. The other shortcoming to the use of bilateral segment prism designs is the optical scotoma induced (in the binocular visual field) when looking into the prism. Images from the prism obscure those within the central area of the seeing hemifield creating a scotoma in the physical space. This optical scotoma is referred to as a prism apical scotoma (70) or "Jack-in-the-Box" scotoma and occurs at the apex of any prism (80).

It is important to emphasize that one of the limitations in this treatment strategy is that it requires intentional, self-directed scanning into the affected field/prism, which can be difficult in patients with inattention and cognitive impairment. In addition, the scotoma induced by the prism jump at the transition of lens into prism, causing the jack-in-the-box phenomenon, can be disconcerting to the patient (70). In one clinical trial using Fresnel prisms binocularly in stroke patients with HVFD or unilateral visual neglect, improvement of visual perceptual test scores were evident; however, they did not generalize to improvement in activities of daily living (6).

Optical Visual Field Expansion Strategies

Monocular sector prisms expand the field of view as scanning occurs into the blind field. The Fresnel prisms are placed in a very similar fashion to the binocular prisms, except that only one lens is fitted (76,81). Unlike bilateral sector prisms that only provide visual field relocation, unilateral sector prisms may provide visual field expansion through binocular visual confusion when looking into the prism. However, the patient will also likely experience central diplopia (82), which may deter the patient from looking into the prism. It is both the confusion and diplopia that make this treatment strategy less than desirable and should be avoided in cognitively impaired individuals. However, Gottlieb et al. (83) suggest that implementing the prism in this way can train and encourage a patient to scan toward the blind hemifield, although no formal study or evidence has been published in this regard.

A more promising approach to field expansion is through the use of monocular peripheral prism segments (see Figure 18.6) that are restricted to the peripheral field (superior, inferior, or both) of the lens (69). Therefore, obstacles within the blind hemifield can be detected using the patient's peripheral vision without the bothersome central diplopia present in other unilateral designs. However, although the peripheral prisms expand the accessible visual field immediately on first application, the perceived direction of objects detected through the prism is incorrect, as in all prism designs. When a patient detects an obstacle through the prism, he or she is instructed to turn his or her head and look at the object directly using the clear interprism area of the spectacle lens. The peripheral prism of 40 or 57 prism diopters is placed monocularly with base in the direction of the HVFD across the vertical midline of the spectacle lens, above and below the visual axis. The prism expands the field 22 to 30 degrees, depending upon the power utilized.

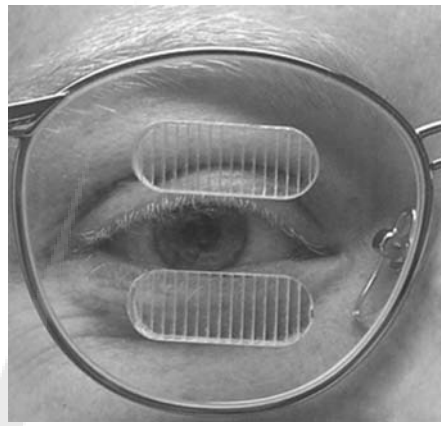

FIGURE 18.6 Monocular peripheral prism correction for visual field expansion, placed on the right spectacle lens for a patient with a right homonymous hemianopia.

Practically, the prisms enable individuals increased detection of obstacles above and below the line of sight, such as open cabinets or a trash can on the floor. The ability to detect objects in areas of visual field expansion provided by peripheral prisms has been assessed using conventional kinetic perimetric techniques (69,84–86), and in more complex viewing environments (87). In addition, improvements in mobility, especially in unfamiliar situations (88) and improvements in activities of daily living (86) have been reported. Like all optical relocation and expansion strategies, this approach requires good cognition as well as patient motivation and training.

Saccadic Training for Homonymous Hemianopia

Saccadic Training Treatment for Visual Exploration

Eye movement and scanning training strategies arose from exploratory work analyzing the eye fixations of patients, using computer-based apparatus, looking at simple patterns (89) and natural images (90). Patients concentrated gaze toward their blind side in both cases. This behavior potentially represents a compensatory strategy in HVFD; by deviating fixation into the blind field, more of the visual scene is brought into the seeing hemifield. In addition, the saccadic eye movements and visual search techniques were found to be slow, less regular, and inaccurate in patients with HVFD when asked to find a target within their blind field (27). Various fixation and saccade parameters seem to correlate with increasing lesion age but not its location or size. This may reflect the evolution of a compensatory eye movement strategy (90,91). Forty percent of hemianopic patients show dysfunction in saccadic activity, number of fixations, and, ultimately, scanpaths found in both the blind field and unaffected field, leading to longer search times (92). Scanpaths are

series of saccades and fixations undertaken when viewing a structured scene. Functionally, this translates to reduced efficiency with navigation and visual exploration tasks, such as driving, crossing the street, bumping into objects, and finding objects on a table. This suggests that patients with HVFD do not naturally or adequately compensate for their visual field loss with eye movements or eye scanning behaviors. These investigations inspired efforts and attempts to "train" patients to adopt different oculomotor strategies that may improve performance of visual search tasks and visual search area (i.e. visual search field size) to ultimately improve visual function.

Systematic training of saccadic eye movement strategies does seem to provide valuable compensatory techniques, which transfers to improvement in ADLs (28). Treatment often includes a series of steps to improve the oculomotor function:

1. Training first with quick, large amplitude (30–40 degree) saccades into the scotoma
2. Systematic training on visual search tasks (i.e., row by row or column by column)
3. Transfer of strategies into natural situations

The magnitude of improvement in visual search gain is measured by decreases in search time, number of fixations, and lengths of scanpaths in both the intact and blind fields. These eye-scanning training strategies have shown training task-specific improvements in efficiency of scan paths and a shortened response time after training (18), significant expansion of visual search field and increased effectiveness in searching for specific objects on a table (28). Many studies have also utilized patient-reported outcome measures, through use of questionnaires, and report modest improvements in activities of daily living after rehabilitation (3,28,93). Of interest, head movements during eye movement training do not appear to be of any benefit and perhaps delay rehabilitative progress (94). No differences in visual search effects have been found between the deliveries of early or late visual training, as has been shown for aphasia rehabilitation (28). Saccadic training was found to be a more effective training strategy in a recent comparative study of saccadic and flicker training therapy (95).

Saccadic Training Treatment for Reading

Reading difficulty in patients with HVFD is proportional to the extent of visual field loss and seems to correlate with the side of loss. In left-to-right reading, right homonymous hemianopes typically have more difficulty reading than individuals with left-sided loss, presuming there is no spatial inattention. Individuals with right-sided loss are reading into their scotoma or blind area and do not have the anticipatory preview area necessary for efficient reading. This preview ability of seeing the shape and location of ensuing words allows for planning of reading saccades. Whereas reading accuracy in a number of patients with HVFD may remain excellent, reading endurance is often compromised with complaints of frustration caused by frequent loss of place during reading, or potentially because of other stroke-related comorbidities (e.g., inattention, loss of comprehension, upper body weakness). Once maximal spectacle correction, low-vision aids, and lighting have been addressed, treatment involves compensatory training of eye movements with the objective of improving saccadic accuracy and decreasing reading errors:

- Reading of short, high-frequency words requiring few fixations
- Reading of increased word length and complexity
- Reading of numbers
- Reading material of importance to individual (books, magazines, computer, and so forth)

Approaches to incorporating optokinetic therapy, which offers the use of scrolling or moving text (right to left) in patients with hemianopic alexia, are another training strategy to improve saccadic activity and reading speed (96). Theoretically, the scrolling text encourages small-field involuntary eye movements (optokinetic nystagmus reflex), inducing the patient to saccade into the blind field. Sufficient practice with this technique is thought to improve patient's rightward eye movements and overall reading speed when they return to reading standard static (nonscrolling) text (96,97). This approach has been incorporated into an at-home computerized training suite, "read-right" (98). Though the software does not adequately screen for the various configurations of visual field loss (presenting targets only at the horizontal midline in a short screening test), it can be a helpful prescribed adjunct therapy. Early trials with this program have recorded improvements in reading rate with continued training, up to 20 hours at which point a plateau is observed (98). Though considerable individual variability was noted, greater improvement was noted for patients with right-sided visual field loss.

Other strategies to improve reading endurance include using an L-shaped ruler in left-sided hemianopes to maintain place during reading and assist with appropriately returning eye movements to the next line of text. This can be also be accomplished by using finger placement on the left and right side of a column to limit omissions and loss of place. Typoscopes (a black card with a cutout for a line of text) can also facilitate tracking when glare or contrast is a complicating factor. Turning a book or document 45 to 90 degrees can be effective in moving the print into the unaffected field. In these cases, patients may read up or down, avoiding the scotoma. It is important to note that in most cases, patients with HFVD frequently do not return to their prehemianopic reading ability.

Computerized Flicker Therapy

Flicker therapy involves repeatedly presenting light stimuli at the visual field border between the seeing and nonseeing

zones. It is hypothesized that training reactivates surviving neurons of the partially damaged brain structure, particularly within the "border zone" (99). It has been suggested that a minimum number of surviving neurons, of the order of 10%, may provide a sufficient substrate for visual recovery (99). A number of studies have claimed "*restored vision*" or "a modest improvement in visual fields following 3 months of visual restoration therapy," one type of flicker therapy (100–103). Intense controversy, however exists regarding the proposed benefit of flicker therapy and whether any training can be effective in creating clinically meaningful visual field expansion.

A computerized software company, Nova Vision, offers VRT for treatment of visual field defects caused by optic nerve diseases and postchiasmal brain lesions (99). Once patients are determined appropriate for therapy through diagnostic testing, revealing HVFDs, in-home computer therapy can be initiated. According to Nova-Vision, in postchiasmal disorders, VRT improved perimetric performance in 30% of patients and scotoma border shift of 4.9 degrees. VRT has significant limitations in its reliability data of fixation controls, false positives, and false negatives. During an independent study using scanning laser ophthalmoscopy combined with microperimetry, no improvement in the absolute visual field border could be detected after VRT (104). It is still unclear whether it is the frequent saccades toward the blind field or a raised level of attention that may account for the reported expansion in visual field by Nova Vision studies (104). Cross-over trial studies have indicated no significant differences in visual field diameter between flicker therapies and saccadic/exploratory eye movement training (95,105). Importantly, the minimal five degrees of "restored" visual field found in these studies represents a very small improvement of questionable value for functional performance in activities of daily living.

Sensory Substitution Strategies in Patient's With Stroke-Related Vision Loss

In cases where resolution of visual deficits does not occur, and visual ability function remains impaired despite optical approaches and saccadic training, the use of sensory substitution techniques remains an essential component of the rehabilitation plan. Sensory substitution includes environmental modifications incorporating tactile support, auditory approaches (e.g., tactile markings, braille, conversion of text to speech and talking devices), and orientation and mobility instruction. In many cases of HVFD, mobility function appears to improve over time, although it remains unclear how much of this is natural adaptation, a result of therapy or simply a reduction in life space minimizing independent activity in unfamiliar areas. When there are intractable mobility problems as a result of visual field loss or inattention, and saccadic and scanning strategies are ineffective, support cane, long white cane, and sighted guide techniques should be considered. In addition, wall-trailing techniques, holding a partner's elbow or hand, cane tapping, and receiving verbal cues can be effective in reducing the incidence of mishaps and falls caused by the visual impairment. Equally important to consider is that many patients who are impacted by stroke are older and already have the physical impairments that put them at risk for falls, irrespective of vision loss, and therefore, the use of a cane or other ambulatory aid may be the safest strategy.

VESTIBULAR REHABILITATION AFTER STROKE

In this section, we will highlight the principles underlying recovery from vestibular injury and the impact that changes in vestibular function have on patients. First, we describe the types of symptoms and deficits that occur with lesions of the vestibular apparatus and their central connections. We will then discuss mechanisms of central compensation, including changes in neuronal firing that rebalances static activity in the vestibular nuclei and mechanisms that restore dynamic vestibular function. We will also provide an outline of rehabilitation techniques for central vestibular deficits. Finally, discussion of diagnosis and treatment of benign paroxysmal positional vertigo (BPPV) is included because of the prevalence of this condition in the stroke population. It should be noted that the general principles of vestibular rehabilitation also apply to strokes involving the vestibular system, with the caveat that central vestibular lesions are more difficult to rehabilitate given the complexity of the underlying dysfunction and recovery mechanisms.

The vestibular system is a multimodal sensory network with pathways extending from the labyrinths to the cerebral cortex. Aside from maintaining images stable on the fovea via the vestibulo–ocular reflex (VOR), sensory information from the vestibular system allows us to orient to our position in space relative to the environment and gravity. Vestibular inputs to the cerebral cortex, unlike those from other sensory systems, do not cause an isolated conscious sensation. They are incorporated to self and spatial perception via multimodal sensory integration with visual and proprioceptive systems. This multimodal sensory integration is vital to generate an accurate percept of one's relationship to the environment, and subsequently, make accurate movements or maintain balance while standing, walking, or running. It is therefore important to emphasize that (a) vestibular function is not synonymous with activity in the labyrinth of the inner ear and (b) the perception of motion is unique for being multimodal as visual stimuli can cause feelings of motion indistinguishable from actual head acceleration. A common example is the feeling of one's automobile moving in reverse when a nearby vehicle begins moving forward. The auditory and somatosensory signals can similarly induce a sense of motion, which is known as vection. This multimodal property of the vestibular system has been used to alleviate symptoms in patients with syndromes of hemineglect. In these patients, vestibular stimulation (e.g., caloric irrigation) can transiently improve hemineglect as well as associated somatosensory and motor deficits (106,107).

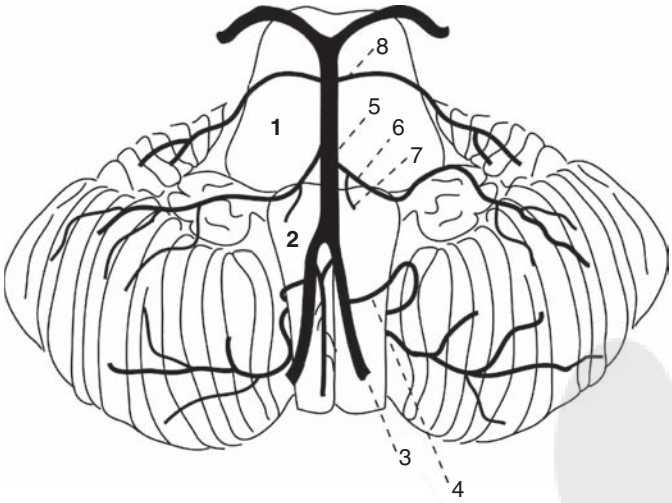

FIGURE 18.7 Schematic view showing major arteries that supply the brainstem and cerebellum. The posterior inferior cerebellar artery (PICA) is the largest branch of vertebral artery that also supplies the lateral medulla. The anterior inferior cerebellar artery (AICA) arises from the basilar artery. It supplies lateral pons and also gives off the labyrinthine artery. 1: pons, 2: medulla, 3: vertebral artery, 4: PICA, 5: basilar artery, 6: AICA, 7: labyrenthine artery, 8: superior cerebellar artery.

Although the term *stroke* is generally reserved for infarction of central nervous system structures, similar mechanisms and blood vessels are involved when ischemia occurs in the vestibular labyrinth (108). The entire blood supply to the inner ear comes from the internal auditory artery, a branch of the anterior inferior cerebellar artery (AICA) (Figure 18.7). The syndrome of AICA stroke (also known as pseudo-labyrinthitis) often includes ipsilateral loss of hearing and vestibular function, facial numbness or weakness, or cerebellar ataxia owing to ischemia of lateral pontine and midcerebellar structures (109). Vertigo and hearing loss can be the sole manifestation of AICA stroke, and ischemic lesions of the labyrinth or lateral pons at the root entry zone can mimic peripheral vestibular or auditory lesions (110). Thus, it's important to recognize that audiovestibular deficits in the AICA syndrome may result from ischemia of peripheral or central (or both) vestibular structures. Lateral medullary syndrome (also called Wallenberg syndrome) is another brainstem ischemic syndrome that commonly causes vertigo because of involvement of the vestibular nucleus in the posterolateral medulla. Other associated signs and symptoms may include ipsilateral perception of visual tilt relative to earth (true) vertical or diplopia or skew deviation (both owing to involvement of graviceptive pathways, which are connections between the utricles and those ocular motor nuclei responsible for vertical eye movements), ipsilateral ataxia, dysphagia, dysarthria, dysphonia (hoarseness, hiccups), and ipsilateral facial or contralateral body paresthesias. This syndrome is generally caused by vertebral artery or posterior inferior cerebellar artery (PICA) ischemia (Figure 18.7). A PICA stroke affecting the caudal cerebellum can likewise cause isolated vertigo that may closely resemble vestibular neuritis (also known as pseudovestibular neuritis). The absence of a positive head impulse test (HIT) (which is generally a sign of peripheral vestibular dysfunction—discussed later) may be the only sign to differentiate the two. The perception of visual tilt, or less commonly vertigo, can also arise from stroke in the anterior circulation, for instance, in the dorsal insula (111–113). Hemispheric stroke may affect the VOR and the degree of involvement correlates with disequilibrium (114,115).

BASIC PATHOPHYSIOLOGIC MECHANISMS

Vertigo is best understood as arising from an asymmetry in vestibular function. Unilateral vestibular loss, caused by the VIIIth nerve or labyrinthine lesion, can account for a range of acute signs and symptoms, including nystagmus, vertigo, and imbalance. Central nervous system compensatory mechanisms must operate to balance and recalibrate the system after unilateral injury. A lesion that results in an imbalance between vestibular information from each side presents unique challenges to the central nervous system. In some ways, this may be analogous to the idea that hemineglect syndromes may arise because of a competition in directing attention to one or the other side. When the head of a healthy individual is still, both vestibular nerves and the vestibular nuclei have equal resting discharge rates (vestibular tone), so there is no perception of linear or translational motion. Movement of the head toward one side excites that labyrinth and inhibits the other—for example, rightward head turning stimulates the right horizontal canal and simultaneously inhibits the left horizontal canal. This initiates the VOR, causing equal and conjugate eye movements opposite to the head movement. If there is a loss of tone on the left side, the brain perceives a rightward head rotation because of the relative hyperactivity of the right (opposite) side, and the eyes would drift slowly to the left because of the VOR (slow phase of nystagmus toward the pathologic side). A position reset mechanism brings the eyes back to midline (fast phase for which nystagmus is named after), and therefore spontaneous nystagmus ensues. With peripheral vestibular lesions, the nystagmus is unidirectional in that it beats in the same direction on lateral gaze to either side. It is usually more intense when the gaze is pointed in the direction of the quick phase (Alexander's law). With central lesions in the cerebellum or brainstem, however, the nystagmus can be bidirectional or direction-changing and may not follow Alexander's law.

An injury can also lead to a dynamic vestibular imbalance based on Ewald's second law: excitatory stimuli produce a relatively greater vestibular response than inhibitory stimuli. Thus, in the case of a unilateral loss of vestibular function, a greater response is elicited with rotation toward the intact side than toward the lesioned side. This is best appreciated with high-acceleration, high-velocity, and high-frequency stimuli through the "head impulse" maneuver, which is used to examine the VOR or track recovery after vestibular deficits (discussed later in this chapter). With complete bilateral vestibular loss, tasks such as reading street signs

or labels in the grocery store while walking become nearly impossible—where the VOR constantly adjusts eye position to compensate for head movements induced by each step.

Following a vestibular injury, for postural and oculomotor balance to be restored, a neuronal balance must be achieved within the vestibular nuclei. The repair mechanisms may occur within hours of the lesion without requiring any external inputs or stimuli, whereas recovery of paretic limb motor function involves recruitment of alternative pathways (115). This spontaneous recovery may be inhibited to some degree if vestibular suppressants are used for too long to treat symptoms. Such medications artificially lead to more symmetric vestibular inputs by dampening the relatively hyperactive side, thus alleviating symptoms, but normal compensatory processes may be forestalled and recovery delayed. The ultimate recovery from acute vestibular lesions is driven by interactions between the adaptive and repair mechanisms to restore function. In this process, if the tone from the paretic side is suddenly restored because of the partial repair of function, a new level of excessive spontaneous activity may arise on the paretic side relative to the central state of compensation. This mechanism may lead to ''recovery'' nystagmus, in which, owing to the new imbalance, slow phases are directed toward the intact ear (i.e., opposite to the paretic nystagmus with slow phases toward the lesioned side). Very early after a unilateral lesion, transcription events occur, leading to a restoration of spontaneous firing on the damaged side. In rodent models, evidence of immediate early gene expression (Fos-like immunoreactivity) peaks as early as 2 hours after a lesion and is differentially expressed predominantly in the ipsilateral vestibular nuclei and contralateral inferior olive (116,117). Symmetric activity is increased in locus coeruleus, autonomic nuclei, and other reticular-related nuclei (118). Some pontine and medullary nuclei also show a second peak in Fos expression between 1 and 7 days after-lesion. These two phases of transcription in animal models correspond temporally with the early restoration of static balance and later adaptive mechanisms underlying dynamic recovery. Central compensation is more efficient in unilateral loss of vestibular function and most patients recover from the initial deficits. Patients with bilateral vestibular loss also undergo central compensation, but they are usually left with residual deficits.

The cerebellum is also very important in modulation of vestibular function, and when the cerebellum is affected by a stroke, vestibular rehabilitation is less effective (119). For example, an important property of the vestibular nuclei, which are modulated by the vestibulocerebellum, mainly nodulus and uvula, is to improve the ability of the brain to sense head movement when it is prolonged at a relatively unchanging speed (i.e., low-frequency motion which is not an ideal condition for normal VOR responses). This central amplification phenomenon, called "velocity storage," extends the range of patterns of head motion that are accurately sensed by the brain beyond the mechanical properties of the cupula and endolymph, thereby supplementing the normal VOR. Lesions of the cerebellum can alter or disinhibit this normal velocity storage mechanism and lead to an increase in the duration of vestibular responses to head movements (i.e., cause uncalibrated responses or an excess of velocity storage). The vestibulo–ocular response to rapid head rotations can also be hyperactive in cerebellar lesions—for example, head impulse to the right would result in an overshoot of the examiner's nose (point of fixation) to the left (120). Moreover, "cross-coupling" of the VOR may occur with cerebellar lesions causing inappropriately directed vestibulo–ocular responses—for example, horizontal head shaking may result in vertical nystagmus (121).

Graviceptive Pathways

The otolith organs in the vestibular labyrinth detect linear head acceleration: utricle for horizontal translation or head tilt, and saccule for vertical translation. If the head is not moving, these inner ear structures are stimulated only by gravity and therefore provide information about how the head is oriented relative to the earth vertical (tilt position) (122). When the head is tilted toward one side, the ipsilateral vestibular labyrinth is excited. The calcium carbonate crystals embedded in the otoconial membrane serve as the mass upon which gravity acts, resulting in deflection of hair cells and change in firing of primary afferents in the VIIIth nerve (These crystals are the culprits in BPPV, described later). Damage to the otoliths (mainly utricle) or their central projections results in the ocular tilt reaction (OTR) that constitutes of skew deviation (vertical misalignment of the eyes not caused by muscle palsy), head tilt, and ocular torsion or counterroll (conjugate rotation of the eyes about the line of sight) (123,124). Vestibulospinal pathways originating in the lateral vestibular nucleus facilitate ipsilateral extensor motor neurons, constituting the righting reflex. Following a unilateral loss, asymmetry in spinal reflexes results in decreased ipsilesional recruitment and relatively increased extensor activity on the opposite side (125). This contributes to patients' tendency to fall or lean toward the damaged side.

Brainstem strokes can cause a sensation of being pulled toward the side of a lateral medullary stroke or away from the side of a paramedian pontine infarction (i.e., lateropulsion) (126–128). Similarly, there is often deviation of the eyes under closed lids toward the side of the lesion in lateral medullary stroke (ocular lateropulsion). In hemispheric stroke involving the posterolateral thalamus, a different phenomenon termed contraversive pushing may occur (129). This is the tendency for patients to use their nonparetic limbs to force their body away from the side of the stroke toward the paretic side. This has been found acutely in up to 10% of strokes, without a predilection for right- or left-sided lesions, and its presence is associated with a longer period of time required for functional recovery (130). Patients with acute unilateral peripheral vestibular lesions misperceive the true (earth) vertical as being tilted toward the side of the labyrinthine loss. When asked to align their bodies with the true upright, however, they perform as well as control subjects (131). By contrast, patients with contraversive pushing consider themselves

upright when they are actually tilted 18 degrees toward their unaffected side, while their perception of true vertical and head orientation are normal (132,133). The altered perception of upright can be accompanied by the OTR, which constitutes head tilt, skew deviation, and ocular counterroll toward the lesioned side. The emergence of OTR is analogous to spontaneous nystagmus that occurs because of tone imbalance with the loss of semicircular canal function. If, for instance, the right vestibular nerve or vestibular nucleus (as in a Wallenberg) is damaged, this results in relative hypofunction of the right utricle-ocular pathway, and relative hyperfunction of the left side. The brain perceives the asymmetry as a leftward head tilt (though none is actually occurring) and attempts to compensate with a rightward head tilt, ocular counterroll, and adjustment of the vertical eye position so that the right (lower eye) is on the side of the lesion (124). In the brainstem, the direction of OTR and tilt of upright perception can be toward or away from the side of the lesions, determined by where along the vestibular pathway a lesion occurs (134). In addition, perception of upright may be altered following hemispheric stroke, suggesting that its presence may influence balance recovery after stroke (135,136).

Vestibular Effects on Cortical Processes

The vestibular system is important in navigation and spatial memory, domains that also have been localized to the hippocampus. Distinct areas of the cerebral cortex mostly within the temporoparietal region (also known as the vestibular cortex) receive and integrate information from vestibular, visual, and somatosensory systems to generate a unified spatial orientation (137). Lesions involving these cortical regions can also produce pathological tilt of upright perception (112,136,138). The link between vestibular information and cognitive mechanisms underlying spatial memory and processing has been demonstrated using quantitative volumetric MRI imaging (139,140). The vestibular-related activity is stronger in the nondominant hemisphere (i.e., right hemisphere in right-handers and left hemisphere in left-handers) (141). The results from functional imaging studies also show a reciprocal inhibitory interaction between the visual and vestibular cortical regions (142,143). The cortical activity pattern is modified in patients with unilateral peripheral vestibular lesions, reflecting compensation within the central vestibular system of the unaffected side (144). Patients who have chronic bilateral peripheral vestibular loss were found to have a significant 16.9% decrease in hippocampal volume compared to controls. In addition to this selective atrophy of the hippocampus, these individuals also showed a deficit in performing a virtual navigation and spatial memory task, though general memory function was unaffected. A remarkable aspect of this study was that an intact vestibular system was required for performing a virtual task that did not involve any actual head or body motion (145). Moreover, caloric stimulation of the labyrinth has been demonstrated to transiently ameliorate left-sided visual neglect after right hemispheric stroke (108,146). A patient with left brain damage also showed a transient remission in right-sided hemianesthesia after caloric stimulation (147).

In recent decades, new technologies have emerged to promote neuromodulation through their effect on various neuronal networks. These techniques such as transcranial magnetic stimulation (TMS) or transcranial direct current stimulation (tDCS), although still in their early stage for clinical use, may open new doors in rehabilitation of patients with stroke. TMS is a noninvasive method based on the principle of electromagnetic induction of an electric field in the brain. As a brief pulse of electric current passes through a coil held over the scalp, a magnetic field is generated that can penetrate through the skull and depolarize neurons and axons. The effect of TMS has behavioral consequences and therapeutic potential. For example, a two-week course of TMS stimulation over the left parietal cortex can accelerate recovery from visuospatial neglect in patients with subacute stroke in the right hemisphere (148). tDCS modifies ongoing neuronal activities through weak direct currents up to 2 milliamperes. It can promote tonic depolarization of the resting membrane potentials in the underlying cortical brain regions by inducing excitatory effects (anodal tDCS) or lead into inhibitory effects by increasing the hyperpolarization (cathodal tDCS) (149).

ASSESSMENT OF VESTIBULAR FUNCTION

Damage to peripheral and central vestibular structures can result in vertigo, postural imbalance, oscillopsia (perceived movement of the stationary visual scene), tilt of the visual scene, or spatial disorientation. Oscillopsia or visual blur that only occurs with head movement is usually caused by bilateral vestibular loss as the underactive VOR is unable to maintain fixation during activities such as walking. When oscillopsia is present without head movement, it is generally caused by spontaneous nystagmus or other types of ocular oscillations. With lesions of the central vestibular pathways, several factors can impact the extent of recovery and central compensation such as location of the lesion, scale of the neural injury, or involvement of other sensory or motor pathways. For example, a perceptual tilt of the visual upright can occur with injuries to the pathways carrying graviceptive information at the level of brainstem or higher up within the temporoparietal cortex. The central compensations following these lesions are not similar, as brainstem injuries are generally associated with oculomotor sequelae such as skew deviation or torsional misalignment of the eyes (owing to disruption of graviceptive pathways), whereas lesions of the cerebral cortex would mainly affect integration of vestibular information into a coherent spatial perception. It is therefore important to consider pathophysiology of the underlying injury and related central compensation to individualize rehabilitation strategies in patients with vestibular deficits. The key initial step in this process is a comprehensive vestibular examination, which helps to assess the current level of physiologic and functional compensation and determine appropriate candidates for vestibular rehabilitation.

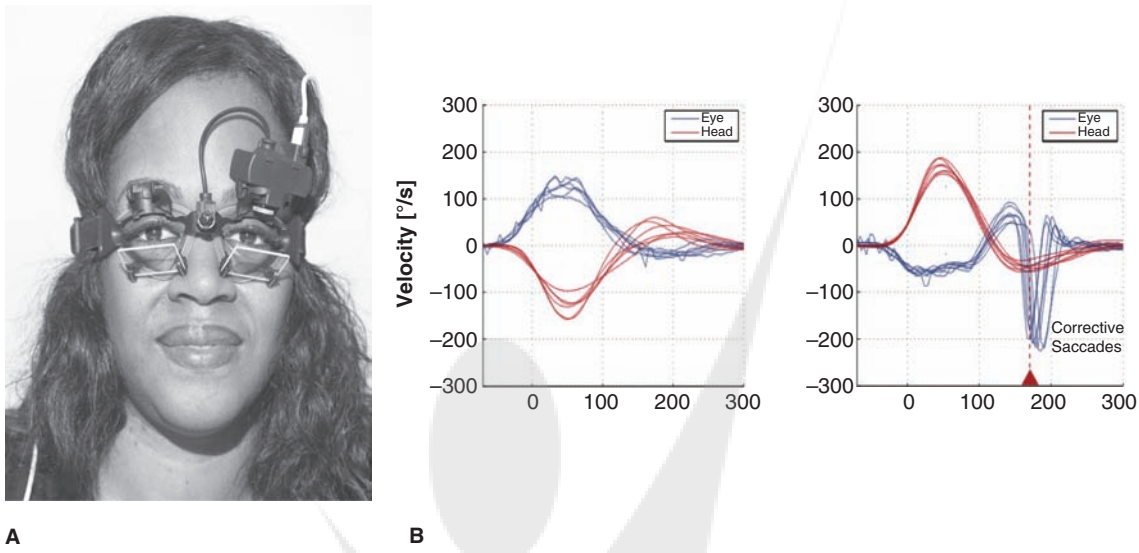

FIGURE 18.8 A video-oculography goggle (VOG) system with lightweight glasses frame, mounted high-speed digital cameras that track the pupils and sensors that quantify head movements (A). Head and eye velocity samples recorded by the VOG system showing normal (left) and abnormal (right) VOR response during head impulse test (B).

Usually, clinical findings such as spontaneous nystagmus provide evidence for failure of physiologic compensation after a vestibular injury. As discussed earlier, spontaneous jerk nystagmus is the characteristic sign of a static tone imbalance between the inputs from both labyrinths to the vestibular nuclei. The nystagmus of peripheral origin typically increases or only becomes apparent when visual fixation is eliminated. This can be appreciated by observing nystagmus under the Frenzel goggles, which, besides eliminating fixation, allow the examiner to get an illuminated, magnified view of the eyes. In patients with unilateral loss of vestibular function, the asymmetry of peripheral inputs during high-velocity head rotations leads to an unequal accumulation of activity in the central "velocity storage" mechanism within the vestibular nuclei. This can be detected by looking for head-shaking induced nystagmus (HSN) under the Frenzel goggles (150–152). For example, a patient with a chronic right peripheral vestibulopathy may no longer have spontaneous nystagmus. However, with horizontal head shaking, asymmetry is induced by the mechanisms above, and the slow (pathologic) phase of nystagmus drifts toward the weak side. The presence of HSN in such cases is associated with a greater level of disability. A reversal phase of HSN may also develop during recovery from vestibular injuries with the slow phases directed toward the intact ear (i.e., a biphasic nystagmus). This reversal phase reflects the presence of an adaptive mechanism that balances out the initial phase of HSN. The vestibular tone imbalance can be also detected by a significant directional preponderance in the caloric test (greater than 30%). The directional preponderance is a numerical expression of the overall amount of nystagmus in the right or left direction after bithermic caloric stimulations. With rotational chair testing, a persistent asymmetry in the eye velocity responses (slow phase of the nystagmus) between the rightward and leftward rotations suggests uncompensated, asymmetric loss of vestibular function.

A brief, high-acceleration head rotation or head "impulse" test is a key bedside evaluation for dynamic vestibular imbalance (153). The head impulse maneuver is performed while the patient is fixating on a target, usually the nose of the examiner. The head is quickly rotated by the examiner in a short excursion from one position to another (e.g., horizontal in the plane of the horizontal semicircular canal). With a "negative" (normal) HIT, the eyes stay perfectly on the fixation point (usually the examiner's nose). With a "positive" HIT, the eyes and head initially move together, and then there is a corrective or "catch-up" saccade opposite to the rotation of the head, which is the signature of an underactive VOR response toward the direction of the head rotation (Figure 18.8B) (154). Following the recovery, the head impulses in well-adapted patients may trigger preprogrammed "covert" saccades, which are generated so early that they become embedded in the response during the head rotation. These covert saccades are hard to discern, as opposed to the "overt" catch up saccades during the early phase of the vestibular injury, which can be easily detected by the naked eye. In recent years, the advent of 2D video-oculography (VOG) systems has provided quantitative testing of the VOR at the bedside, which helps to track recovery in patients with loss of vestibular function and assess the efficacy of rehabilitation techniques (155–157). These portable VOG goggle systems consist of a lightweight frame with mounted high-speed digital cameras that track the pupils and sensors that quantify head movements (Figure 18.8A).

In patients with acute vestibular symptoms, a normal (negative) head impulse response strongly suggests a central etiology, whereas an abnormal (positive) head impulse most

TABLE 18.1 Differentiation Between Central and Peripheral Vestibular Disorders

SIGN	PERIPHERAL	CENTRAL
HIT	Positive	Usually negative Positive HIT may be seen with lesions of vestibular nucleus, root entry zone of CN VIII, caudal cerebellum
Skew	Absent Can see a small skew and OTR with peripheral lesion if utricle is involved, but rarely causes diplopia	May be present
SVV tilt (OTR)	Ipsilesional	Ipsilesional or contralesional
Nystagmus	Unidirectional, increases in direction of fast phase (Alexander's law)	Unidirectional or bidirectional (direction-changing/gaze-evoked)

Abbreviations: HIT, head impulse test; OTR, ocular tilt reaction; SVV, subjective visual vertical.

often occurs with peripheral lesions and occasionally with a stroke (central lesion) (e.g., labyrinthine ischemia in an AICA stroke, vestibular nucleus ischemia in a Wallenberg stroke, or lesions of the caudal cerebellum) (158–160). In such cases, besides neurologic symptoms or signs of the brainstem or cerebellar involvement, a three-step ocular motor examination can specifically help to tease out a central or peripheral etiology (where up to 20% of presentations are likely caused by a stroke) (Table 18.1): A stroke should be strongly suspected when (a) head impulse testing is negative, (b) there is bidirectional nystagmus (i.e., direction changing with gaze), and (c) skew deviation is present (161). As mentioned previously, skew deviation is a vertical misalignment of the eyes because of imbalance in the graviceptive pathways, which is often seen with other features of the OTR (head tilt and ocular counterroll) (124). The disturbance in the utricle-ocular pathway can also lead to perceptual tilt of true (earth) vertical or upright (162,163). This can be assessed by a simple test of subjective visual vertical (SVV), during which a visual line is adjusted to a perceived upright orientation while the environmental visual vertical cues are eliminated (e.g., by conducting the test in darkness). The tilt of SVV is a sensitive sign that can be used to track recovery from central vestibular lesions that usually produce larger and more enduring tilts of the SVV.

The balance examination is also essential to track recovery in patients with vestibular deficits and assess the risk of falls. Patients with vestibular loss frequently restrict their head movements to avoid conflicting sensory information (i.e., vestibular and visual or vestibular and proprioceptive mismatch). They also have difficulty maintaining posture in case of sensory conflict because of the inability to suppress inaccurate inputs (164). The balance evaluation is done under static or dynamic conditions. Some of the static tests include the Romberg (standing with heels together), tandem Romberg (standing heel to toe), and single-leg stance tests. The best static measures of imbalance are those that isolate the contribution of different sensory modalities. For example, a quick and efficient way to measure static balance is the modified clinical test for the sensory integration and balance (CTSIB-M). This test is a battery of four separate, progressively difficult tasks in which the patient stands on a firm and then a foam surface (i.e., proprioceptive challenge), both with eyes open and closed: (a) eyes open standing on the firm surface (normal vision/normal proprioception), (b) eyes closed standing on a firm surface (absent vision/normal proprioception), (c) eyes open standing on a foam surface (normal vision/altered proprioception), and (d) eyes closed standing on a foam surface (absent vision/altered proprioception). For all these tasks, each attempt is considered normal when balance is maintained for 30 seconds. The dynamic balance evaluation can be done by simply observing the gait or while the patient is repeatedly moving the head in the horizontal or vertical planes while walking at normal speed. Postural sway under dynamic or static conditions can be measured by posturography in which displacement of the center of foot pressure is recorded on a force platform. This method is particularly helpful when comparing effects of treatment in different subject groups or following recovery in individual patients.

Recovery Symptoms

The vestibular system operates by comparing information from both sides to make a determination of how the head is oriented or moving through space. This push–pull arrangement has certain advantages. If labyrinthine function is completely lost on one side, the intact ear is still able to signal rotation in both directions because each side is capable of both inhibition and excitation (e.g., with a right head turn, the right horizontal canal is stimulated as endolymph flows in an excitatory direction, whereas the left horizontal canal is simultaneously inhibited as the endolymph flows in the opposite direction). An acute loss of function on one side is interpreted by the brain as rotation toward the intact side, accounting for the symptoms of vertigo and vestibulospinal manifestations of falling and veering toward the lesioned side. Early on, compensatory mechanisms alter firing in the brainstem vestibular nuclei so that neuronal activity is more symmetric and the nystagmus and vertigo are decreased. Inhibition of the normal firing rates on the intact side occurs first, which is also

the effect of various medications used appropriately during the acute phase of the illness (165). As mentioned previously, the use of vestibular suppressant should be limited to a few days because, ultimately, the goal would be to maximize utilization of the remaining function rather than inhibiting it.

Once the nervous system has responded to the initial loss of vestibular function, a second phase of compensation requires an error signal to recalibrate the system under the new postinjury conditions. Two aspects of this compensation process are worth discussing. The first is adaptation, in which an overall decreased sensory signal can be used to drive a normal motor response. A common example of this process occurs when one is prescribed a new spectacle correction; there is a brief period of disorientation before the VOR can be appropriately recalibrated for the new degree of lens-induced magnification or reduction of the size of visual field. The second aspect of compensation is habituation. By this, we mean the reduction of symptoms resulting from a mismatch between the expected sensory input from a given movement and the deficient postinjury response.

Why Some Patients Do Not Improve Following Vestibular Damage

Several factors that may delay or prevent recovery after vestibular loss include age, activity, medications, mood, fluctuating symptoms, or maladaptive strategies. Patients with vestibular deficits do not like to move their heads. In the case of dynamic symptoms, however, the brain only solves problems with which it is confronted. Several studies point to the importance of early intervention in treating a unilateral vestibular loss. Primates given a peripheral vestibular lesion regained postural and locomotor control much sooner if they were allowed to perform early active motor exploration (166). Cats subjected to motor restriction had a delayed recovery. If a 7-day interval of sensorimotor restriction was applied within the first 3 weeks of a unilateral vestibular loss, there was a delayed and limited recovery with incomplete restoration of postural abilities (167).

A unique aspect of vestibular injury is that symptoms occur even during the recovery of function. In other words, the central vestibular compensation although reliable can be somewhat fragile. This means there may be occasional periods of symptomatic relapse because of decomposition after an apparent full recovery. The common triggers are periods of inactivity, extreme fatigue, or change in medications. A relapse of vestibular symptoms in this setting should not be confused with ongoing or progressive dysfunction.

VESTIBULAR REHABILITATION THERAPY

The use of vestibular exercises dates back to the 1940s when first used by Cawthorne and Cooksey to rehabilitate patients with vestibular symptoms (168). Improvement after vestibular rehabilitation has been shown regardless of the patient's age and gender or even etiology of the vestibular dysfunction, as patients with deficits caused by stroke may show improvement without the need to increase the number of vestibular therapy sessions (169–173). Patients with cerebellar lesions, however, improve the least (119). Even one course of physical therapy has shown to reduce the risk of falling in vestibular patients from 98% to 67% (174). In most cases, there is no one-size-fits-all approach and individualized therapy has been found to be the most effective rehabilitation method (175–178). During the recovery period, each patient may have a predisposition toward relying upon one or another sensory modality (vision or somatosensation), or may adapt a different motor strategy (walking slower, widening the base of support, etc.). These early strategies used to cope with aberrant vestibular information may result in sensorimotor reorganization that is maladaptive in the chronic phase. For example, even though individuals with asymmetric vestibular inputs deviate from their intended path more when walking slowly, fear of instability (i.e., poor falls efficacy) can lead to a slowing of gait and an overreliance on visual and somatosensory cues, which can amplify symptoms and discourage participation in rehabilitation (179). Hence, attention to vestibular symptoms and awareness of their impact on basic mobility function are critical for rehabilitation planning.

The aim of vestibular rehabilitation is to promote neural plasticity and accelerate central compensatory mechanisms to recover from vestibular lesions. The initial central compensation following a vestibular injury is enhanced by head movement and delayed by physical inactivity (180,181). Again, during the rehabilitation period it is essential to avoid traditionally used vestibular suppressants such as meclizine, as these medications can impede central compensation (182). The standard vestibular therapy consists of exercises based on a set of principles focused on postural stability, gait, and gaze stabilization (183–185). These principles include (Table 18.2): (a) adaptation exercises that assist the brain to compensate for a loss of function, (b) habituation exercises that involve repeated exposure to a provoking stimuli to reduce the pathologic response, and (c) substitution exercises that promote the use of other intact sensory modalities to compensate for a deficit (e.g., use of vision or proprioception to compensate for a vestibular deficit). With all these mechanisms, the adaptation is the most effective principle in vestibular rehabilitation (185). Adaptation exercises are aimed at recalibrating the relationship between labyrinthine signals as well as vestibulo–ocular and vestibulo–spinal motor commands. It should be noted that vestibular adaptation is context-dependent, meaning that the greatest change will occur at the adapting frequencies and less significantly at other frequencies (186). In addition, there are multiple time scales of learning during the adaptation period (seconds to days), during which different rates of learning, forgetting, and relearning (i.e., recall) may occur. The pattern of training can influence these time scales, and also the retention of learning (consolidation). These complexities are important to consider when designing vestibular exercises, especially to determine whether the effect of a rehabilitation paradigm can be transferred to other daily activities (187).

TABLE 18.2 Key Rehabilitative Principles for Disorders of the Vestibular System

REHABILITATIVE STRATEGIES	DEFINITION AND EXAMPLE
Adaptation	Assist the brain in adapting to or compensating for a loss of function; e.g., unilateral loss of vestibular function on the right, and through therapy, optimizing the response of the left side to excitatory and inhibitory vestibular stimuli
Habituation	Repeated exposure to a provoked stimuli to reduce a pathologic response; e.g., repeated head movements to desensitize a patient with head motion intolerance
Substitution	Using intact sensory modalities to compensate for a deficit; e.g., promoting use of vision and/or proprioception in a patient with bilateral vestibular loss

The adaptation exercises with eye and head movements specifically improve the VOR function and enhance stabilization of the image on the retina during head movements. The improvement in gaze stability is more apparent with active than passive head movements (188,189). The VOR exercises are all variations of one principle: the patient is required to focus on a target while repeatedly moving the head in the horizontal or vertical planes (Figure 18.9). The duration recommended for each exercise is based on the difficulty level of the task and the required exposure time to error signals to see recovery. The mechanism of adaptation with VOR exercises is similar to adaptive changes with spectacle magnifiers (190). When magnifying or minifying lenses are placed in front of the eyes, because of the rotational magnification induced by spectacles, visual images will no longer be stable on the retina during head movements. The positive diopter lenses cause images to move faster than normal on the retina during head movements, whereas negative lenses cause an opposite effect. After wearing spectacles, the VOR response can adaptively change within a few hours to stabilize the visual images on the retina during head movements (191). The cervico–ocular reflex (COR) can also be adapted in some patients by using exercises that move the body under the stationary head (192,193). The COR interacts with the VOR and drives eye movements based on the cervical proprioceptive inputs. The balance training and gait exercises mainly target vestibular adaptation through postural vestibulo–colic reflex (VCR) and vestibulo–spinal reflex (VSR). These are the key reflexes that stabilize position of the neck and body according to the head movements. In patients with vestibular deficits, the postural control exercises can specifically correct asymmetries in weight bearing, improve mobility about the center of gravity, or help with sensory input selection (178).

The habituation exercises consist of provocative visual and vestibular stimuli or balance tasks with a gradual increase in difficulty. These exercises can facilitate tolerance of conflicting or novel sensory stimuli associated with head motion (194). The vestibular system may not fully recover after injuries, especially when there is severe loss of function with central lesions. The recovery is usually limited to low frequencies of head movements and a marked and permanent vestibular deficit can be demonstrated with rapid, unpredictable head movements. Under these circumstances, the brain can substitute other mechanisms to stabilize gaze or improve postural control. On this basis, substitution exercises are focused on sensory reweighting between three major sensory modalities: vision, vestibular, and somatosensory inputs. For example, if the patient is dependent on somatosensory input despite the availability of accurate visual cues, the rehabilitation program may involve exercises that require balancing on thick foam with eyes open to reduce reliance on proprioception cues. Substitution exercises are especially indicated in patients with bilateral loss of vestibular function to promote the use of

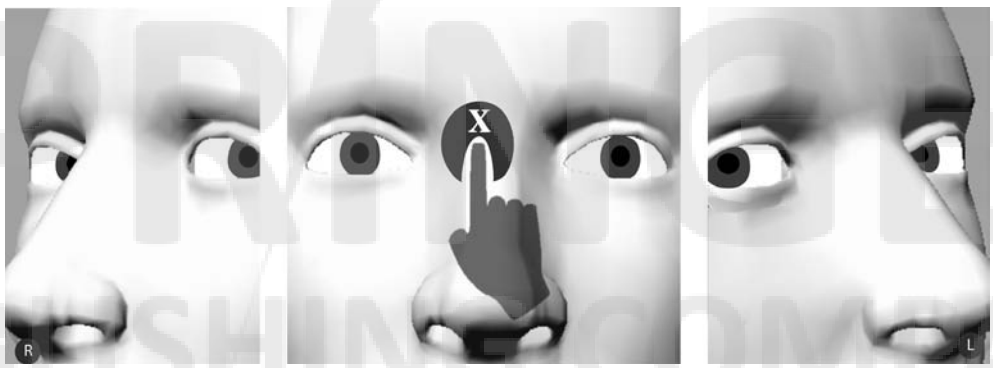

FIGURE 18.9 VOR adaptation exercises in the yaw plane. The patient moves the head to the right and left while fixating the eyes on the target.

Source: Adapted from aVOR, a free vestibular education app.

alternative strategies for gaze and posture control. Similar to adaptation exercises, substitution exercises can be modified as the patient improves. Many patients with central deficits will show impaired timing and uncoordinated strategies for postural control. In general, three main postural strategies are used to improve balance while standing: ankle, hip, and step strategies. The ankle strategy involves standing with a wide stance and performing sway maneuvers using ankle torques. This strategy is more dependent on somatosensory function. The hip strategy is more dependent on vestibular function and involves standing in a narrow stance, performing torques around the trunk. Patients with vestibular loss tend to use the ankle strategy for postural stability even when the hips strategy is required—for example while standing in tandem (195). The step strategy involves stepping movements under an altered center of body mass and is usually used after improvement in balance with other postural strategies.

Patients with vestibular dysfunction caused by stroke benefit significantly from a customized treatment program including balance and gait training, general strengthening and flexibility exercises, as well as adaptation and substitution exercises (119,195,196). Although the signs and symptoms of static vestibular imbalance (e.g., spontaneous nystagmus) resolve independently without intervention, the dynamic instability and head movement-provoked symptoms often require specific treatment (166). The objective measures of static and dynamic postural stability or gait pattern can be used to track improvement in these patients (175,195,197). In particular, it is shown that scores on the dynamic gait index may improve by an average of 4.7 points, with a 4.0 point or more change considered clinically significant. Patients with hemispheric stroke and chronic hemiparesis exhibit excessive sway when visual and somatosensory information are unavailable (i.e., when tested with eyes closed on a support surface that swayed with the subject) or inaccurate (i.e., when tested both visual surrounding and support surface swayed with the subject) (198). Overreliance on visual input in hemiplegic patients has been demonstrated in a task that involved aligning a rod to the vertical when a frame is tilted to the right or left. These patients were twice as likely to be biased by the orientation of the frame when compared to controls (199). There was a significant improvement in postural control after these patients underwent a rehabilitation program, regardless of whether they performed their exercises with or without visual input. The vision-deprived group, however, achieved greater improvement, suggesting the possibility that traditional treatment may have reinforced visual overreliance and limited potential benefit from treatment (200). As to the effect of visual correction, there are many anecdotal reports that bifocal glasses or progressive lenses increase the risk of falls in conditions that affect gait and balance (201).

In general, once the patient has enrolled in the rehabilitation program, progress should be assessed periodically to make appropriate adjustments. In this process, exercises that no longer produce symptoms are eliminated and replaced by those that trigger symptoms. The procedure continues until the improvements begin to plateau. At this point, maintenance exercises are important to ensure stability of the initial improvements. The efficacy of vestibular rehabilitation in patients with abnormal sensory organization was demonstrated in a prospective study in which over half of the patients showed objective improvement in balance function (202). Significant improvements are also reported in daily functions, emotional aspects of the symptoms, and overall quality of life (175,194,203,204). In a single-blind, randomized, controlled trial of primary care-delivered treatment, 170 patients with chronic dizziness were randomized to vestibular rehabilitation; the other received usual medical care. The treatment group received just one 30- to 40-minute appointment with a nurse, who instructed the patient in a home exercise program that was reinforced with a treatment booklet and log (available online as an appendix to the article). At 3 months, there were significantly fewer spontaneous and provoked symptoms of dizziness as well as improved dizziness-related quality of life. Postural stability with eyes open and eyes closed was objectively improved as well. Clinically significant improvement occurred in 67% of treated patients and benefits were maintained at 6 months, whereas only 38% of the control patients improved (205). For such a program to succeed, patients need to be motivated to carry out the exercises despite the fact that they may exacerbate the very symptoms targeted by the treatment. Patients must be reassured that they are not causing additional damage. Too often, patients abandon their exercises because, after several weeks of performing them, they still have the same symptoms of dizziness. What they often fail to realize is that they are doing much more activity before experiencing these same symptoms and are thus actually progressing in the therapy.

Safety is an important consideration with respect to the risk of falling during the rehabilitation period. Patients should be educated about common fall hazards in the indoor and outdoor environments and strategies that can be used for falls prevention (e.g., proper shoes/socks, assistive devices, etc.). Patients with vestibular loss often have falls because of larger than normal postural responses to perturbations, rather than failing to trigger a larger enough postural response. Light touch that provides somatosensory cues but not mechanical support can especially help these patients by providing a contact reference to earth vertical (206).

Patients with vestibular deficits also benefit from natural exercises or activities that involve coordinated eye, head, and body movements such as Tai chi, table tennis, and Tango dancing (207,208). In recent years, new technologies have also emerged for vestibular rehabilitation. One of these promising interventions is virtual reality, which can create the illusion of immersion in a real environment using computer-generated graphics. This technology specifically allows better control of the rehabilitation environment. For example, the patients who rely on vision to maintain balance can be immersed in a virtual environment enriched with challenging proprioceptive stimuli to train the use of proprioception for postural control (209–211).

The Nintendo Wii Balance Board is an alternative, user-friendly technology to rehabilitate patients with vestibular symptoms (212). Vibrotactile feedback devices, which fit around the waist and provide augmented feedback on body tilt position, can also reduce postural imbalance and trunk sway (213,214). Another useful intervention is based on the stimulation of mechanoreceptors in the sole of the foot with a balance-enhancing insole (215). The footwear insoles have a built-in wedge under the lateral aspect of the foot and can improve the ability to walk in a straight path (216).

BENIGN PAROXYSMAL POSITIONAL VERTIGO

Although cerebral ischemia can predispose patients to the development of BPPV, the occurrence of this common condition in the subacute or chronic stroke patient is probably more likely caused by the age of the population and their prolonged immobility. Acute management of stroke often includes maintenance of the head-down position, which could also promote the development of BPPV. It is important to recognize this condition so it is not confused with a recurrence of the patient's cerebrovascular disease. Often, BPPV symptoms are initially attributed to vertebral basilar insufficiency, although a careful history and brief examination is sufficient to distinguish these conditions, sparing the patient further evaluation or transfer from a rehabilitation facility back to an acute care setting. Imbalance and vertigo from BPPV may also interfere with the progress of rehabilitation in the poststroke population.

Symptoms of BPPV are always brought about by changes in head position with respect to gravity (217). Rotation of the head, as if the patient is saying "no," when upright is generally the only head movement that does not provoke symptoms. Rolling over, getting in or out of bed, and reaching to a high shelf when standing are other provocative maneuvers. The diagnosis and localization can readily be made using the Dix–Hallpike maneuver, particularly for the most common posterior canal variant (Figure 18.10). This begins with the patient seated in the bed with the legs extended. The head is turned 45 degrees to one side and then the patient is brought into the supine position. The examiner should observe the eye movements and query the patient about their typical symptoms of vertigo. Maintaining the head turn, the patient is then brought back into the sitting position. The head is turned 45 degrees to the other side, and the procedure is repeated. Generally, symptoms will only develop in the right- or left ear-down position, although bilateral cases do occur. Nystagmus that accompanies the symptoms of vertigo is mixed upbeating and torsional (beating toward the lower eye). The direction of nystagmus is determined by stimulation of the posterior canal. For instance, right posterior canal BPPV is diagnosed in right Dix–Hallpike when upbeat-torsional (toward the right ear) nystagmus is seen. Stimulation of the right posterior canal during this maneuver causes both eyes to conjugately move down and rotate toward the left ear (pathologic slow phase). Then, there is a position reset mechanism (fast, or named phase of nystagmus) to get the eyes back to midline, which is upbeat-torsional (toward right ear). This can be best observed if the effect of visual fixation on nystagmus is eliminated by using Frenzel goggles during the exam (Figure 18.10). The nystagmus develops seconds after the head is moved (latency) and usually lasts less than 30 seconds (duration). Although the vertical component may be suppressed by visual fixation, the torsional nystagmus can be visualized without the use of any specialized equipment because of a poor torsional fixation mechanism.

FIGURE 18.10 Dix–Hallpike maneuver for diagnosis of right posterior semicircular canal BPPV by using Frenzel goggles. The test is performed with the patient sitting upright with legs extended (A). The head is then rotated by approximately 45 degrees to the right (B). The examiner helps the patient to lie down backwards quickly, maintaining the head turn in approximately 30 degrees of extension (right ear is below the right shoulder) (C). The examiner would then observe for the typical BPPV nystagmus (torsional upbeating toward the ground).

The diagnosis of BPPV is certain if four criteria are met:

- There is a latency before the onset of the nystagmus.
- The duration of the nystagmus is less than one minute.
- The nystagmus is elicited only in the appropriate head orientation.
- The direction of nystagmus matches the head position (218).

If these four criteria are not met, alternative diagnoses should be considered, mainly including horizontal canal BPPV (pure horizontal nystagmus that changes direction when the supine head is turned from one side to the other) or central positional nystagmus. Treatment is extremely effective and can be performed readily at the bedside using the canalith repositioning procedure (CRP, or Epley maneuver) (219,220). Unlike Dix–Hallpike testing, during which the patient would be brought back into a seated position, the CRP proceeds with the patient supine: (a) Keeping the neck extended, rotate the head 90 degrees so that the unaffected (e.g., left) ear is now pointed 45 degrees downward, (b) Rotate the patient's head another 90 degree so the nose is now pointed 45 degrees toward the ground. The patient rolls themself into the left lateral decubitus position. Again observe for nystagmus, which should still be upbeat, with the torsional component (upper poles of the eyes) beating toward the affected (left) ear. The presence of nystagmus with a downbeat component indicates an ineffective procedure, (c) Instruct the patient to bring the knees up toward the chest and drop the legs over the edge of the table while the head is kept in the nose-down position, (d) Bring the patient up into the sitting position, keeping the head rotated 45 degrees on the body to the right with the chin down. In the upright position, keeping the chin tucked down, the head is rotated straight ahead, and then the patient may assume a normal head position. Hold on to the patient when he or she is brought upright, as vertigo and imbalance may occur. The entire procedure may be repeated as often as necessary until no further nystagmus or symptoms are present. Instruct the patient to keep the head upright (no more than 45 degrees from the vertical) for the remainder of the day to inadvertently avoid reintroducing the debris into the semicircular canal. It is not necessary to have the patient sleep sitting up after the procedure.

CONCLUSION

Because of the limited objective evidence of strategic and effective approaches, the decision to treat and type of treatment for patients with visual, ocular motor, and vestibular impairments secondary to stroke needs to be individualized. The associated deficits, level of functional impairment, as well as desired tasks and goals identified by the patient and family must enter into the tailored rehabilitative plan. Recovery of dynamic control of balance and gait after vestibular damage requires exercises that often provoke symptoms of dizziness and should be performed as soon as possible after the stroke. Encouraging normal head movement (like the forced use of the paretic limb) decreases symptoms (habituation) and improves function (adaptation). Visual, vestibular, and somatosensory information can substitute for one another in a variety of tasks, but overreliance on one modality can be maladaptive and should be addressed explicitly in a customized rehabilitation program.

SENSORIMOTOR IMPAIRMENTS AND THEIR TREATMENT

19

Patterns of Locomotor Recovery After Stroke

Carol L. Richards, Francine Malouin, and Francine Dumas

The main objective of this chapter is to describe patterns of locomotor recovery in persons who have sustained a cerebral stroke. A second objective is to examine the effects of stroke severity on locomotor recovery. This chapter:

1. Reviews recovery trajectories after stroke obtained from longitudinal studies using clinical measures and underlying mechanisms associated with the recovery of strokes of different severities.
2. Argues for the use of walking speed as a marker of recovery.
3. Presents data describing the recovery, from stroke onset to two years after stroke, of walking speed and its relation to movements and muscle activations of the lower extremity in a cohort of subjects with a middle cerebral artery ischemic stroke who participated in a clinical trial (1).
4. Uses data from a second clinical trial (2) to examine the magnitude of change in gait speed after two months of task-oriented physical therapy and the relationship between selected clinical measures and gait speed; also briefly reviews the kinetic patterns related to propulsion and generation of walking speed in healthy subjects.
5. Describes compensatory kinetic strategies during gait of persons with different stroke severities.
6. Summarizes the concepts introduced and their clinical implications.

RECOVERY AFTER STROKE AS MEASURED BY LONGITUDINAL STUDIES USING CLINICAL MEASURES

Traditionally, studies have described patterns of recovery on the basis of repeated assessments of recovery by means of clinical measures that rate change with recovery on the basis of observations made by trained evaluators or clinical benchmarks. Thus, it is generally accepted that the recovery curve after stroke rises rapidly in the first six weeks after stroke, when rehabilitation interventions supplement natural recovery, and that it reaches a plateau at about three months after stroke, with little further recovery after six months (3,4) although there are reports of recovery much later (5). Duncan et al. (4), on the basis of serial Fugl-Meyer (6) assessments over time in 95 patients with anterior circulation ischemic stroke, reported that, although in some patients the pattern of recovery (degree and time course) differed in the upper and lower extremities, for most the recovery patterns were similar and the most rapid recovery occurred within 30 days after stroke. Patients with initially severe motor deficits, however, had heterogeneous outcomes, with some recovering dramatically and others showing little change in the Fugl-Meyer motor score 180 days after stroke.

These results were confirmed and extended by the results of the Copenhagen Stroke Study (7–9), conducted in a cohort of 1,197 persons treated in the stroke unit of a hospital in Denmark. The capacity to return home after rehabilitation is often taken as a measure of recovery: 64% were discharged to their own homes, whereas 15% were discharged to a nursing home, and 21% died during the hospital stay (8). Stroke severity, as determined by the Scandinavian Stroke Scale, was initially very severe in 19%, severe in 14%, moderate in 26%, and mild in 41% of the patients. After rehabilitation, 11% of survivors still had severe or very severe neurologic deficits, 11% had moderate deficits, and 78% had no or only mild deficits.

One might ask how stroke severity relates to return of function. In the Copenhagen Stroke Study, the timecourse of functional recovery (8) was described by weekly assessments with the Barthel index (BI) (10). As expected, the timecourse of recovery was strongly related to stroke severity. Nevertheless, functional recovery was completed within 12.5 weeks from stroke onset in 95% of the patients, with best recovery attained by 8.5 weeks in those with initially mild stroke and within 20 weeks in those with very severe stroke. Furthermore, best functional recovery was reached by 80% of the patients with initial mild strokes within 3 weeks and by those with initial moderate strokes within 7 weeks.

In a more recent study, Verheyden et al (11) confirmed in 32 patients with ischemic stroke that the most striking improvement, as measured by a series of clinical measures (Trunk Impairment Scale [TIS], Fugl-Meyer arm [FMA] and leg [FML] subscores and the BI), occurred between 1 week and 1 month after stroke onset. Further significant improvements, though much smaller, occurred between one month and three months but not between three and six months after stroke. Like Duncan et al. (4), they described similar patterns

of recovery for the FMA and FML. They also found the TIS and BI to have a recovery pattern similar to the FMA and FML. Between 1 week and 1 month after stroke, the median improvement was 16% for the FMA and FML, 22% for the TIS, and 30% for the BI (a measure of functional independence); between 1 month and 3 months the median improvement in the TIS score was 2%, whereas all other measures had a median change of 0%, thus indicating that 50% of the patients showed no further improvement or deterioration.

The specific timecourse of recovery of walking function and lower extremity paresis was also assessed by the BI and the Scandinavian Stroke Scale at weekly intervals in a subgroup of 804 patients in the Copenhagen Stroke Study (9). Initially, 51% had no walking function, 12% could walk with assistance, and 37% could walk independently. At the end of rehabilitation, 21% had died, 18% had no walking function, 11% could walk with assistance, and 50% were independent walkers. A plateau in the BI score was attained in 95% of the patients within the first 11 weeks after stroke and, as expected, the rate and magnitude of recovery were related to both the level of initial impairment of walking function and severity of lower extremity paresis. Thus, when using the BI as a measure of walking function, Jorgensen et al. (9) state that a valid prognosis of walking function in patients with mild or moderate leg paresis can be made in three weeks and that further recovery should not be expected after nine weeks.

The longitudinal studies mentioned earlier indicate that after stroke, patients can be expected to have at least some predictable degree of functional recovery in the first three months and that the largest gains occur in the first month after stroke, with little change thereafter, as measured with clinical outcome measures that have a ceiling effect and are less sensitive to change in the later stages of recovery (7–9,11). This nonlinear pattern of recovery as a function of time is, however, not well understood. Several mechanisms have been invoked in an attempt to explain the "natural" recovery that occurs in the first weeks, including the restitution of penumbral tissue surrounding the lesion, resolution of the diaschisis, and recovery of neurotransmission in spared tissue near and remote from the infarct (12). This recovery process, which is presumed to underlie the recovery pattern early after stroke, has been referred to as "spontaneous neurologic recovery," and its contribution to the patterns of stroke recovery has been largely overlooked (13,14). Kwakkel et al. (14) have proposed the use of progress of time as a surrogate, independent covariate to reflect spontaneous recovery and have shown by means of a regression model that it explains 16% to 42% of the observed improvements in body functions and activities in the first 6 to 10 weeks after stroke onset.

In addition to so-called natural recovery, one must consider the effects of rehabilitation interventions that were not considered in the earlier studies. We do not know the exact parameters of the rehabilitation interventions (precocity after stroke, intensity, duration, and content). Also, after their poststroke rehabilitation phase, many patients may require further therapy in the three- to six-months poststroke phase to maintain their gains (11). It is not possible to tease out the effects of rehabilitation as opposed to spontaneous recovery in the first three months after stroke without a control group that does not receive rehabilitation. For obvious ethical reasons, rehabilitation cannot be withheld.

Another question that begs to be addressed after reviewing the studies on poststroke recovery profiles is whether there is a "window of opportunity" for optimal gains with rehabilitation. Studies in rats (15) have shown that the upregulation of growth-promoting factors that mediate recovery predominates over the upregulation of inhibitory factors in what is known as a critical period for rehabilitation in the first 15 days after stroke. We do not know specifically how this early "window of opportunity" relates to human recovery, but early intervention in the first days after stroke is recommended best practice (16). But how early is early? Recent work (17) shows that mobilizing medically stable persons in the first 24 hours after stroke is both safe and beneficial.

The main question appears to relate to intensity rather than to precocity. The current best practices recommendation is that intensity should be provided according to the patient's tolerance. For the upper extremity, the lesser gains obtained by high-intensity constraint-induced movement therapy (CIMT), in comparison to CIMT at an intensity similar to usual practice, provided to patients in the first month after stroke (18) have been interpreted to suggest that such a high-intensity approach should be avoided in the first month after stroke. For the lower extremity and mobility training, we know, from RCTs carried out in patients after stroke caused by a middle cerebral artery infarct, that patients tolerate very well the initiation of task-oriented therapy (including treadmill training) 1 week (1,19) or within 14 days (20) after stroke.

Unfortunately, studies have not compared the effects of initiating locomotor therapy early, defined as in the two weeks after stroke, to that of later initiation after the "window of opportunity." If we accept the existence of a "window of opportunity" for optimal results early after stroke, then it is important to understand the impact of recovery in this time period on long-term recovery potential as well as on how stroke severity affects its duration. The LEAPS study (21), which showed no difference in locomotor outcome at 12 months when the intervention was initiated 2 or 6 months after stroke, provides a partial answer to this question.

NEURAL PLASTICITY AND BEHAVIORAL COMPENSATIONS

Rehabilitation is believed to modulate recovery by interacting in some way with natural recovery processes. But, as mentioned, it is very difficult to tease out therapy effects when a control group receiving no therapy and relegated to recovering only by natural recovery is not possible. Prediction models that are adjusted for the effects of time after stroke suggest that outcome is largely defined within the first weeks after stroke, although functional improvement has been found to extend beyond six months after stroke (14,22,23).

The ground-breaking work of Nudo and colleagues (24,25), who examined neural plasticity in an animal model of stroke using cortical lesions in primates, demonstrated the potential of task-specific training to modulate brain plasticity and heralded a new era in the field of poststroke neurorehabilitation that is still evolving. In the past 15 years, there has been a dramatic change in the type and intensity of therapy provided to persons recovering from a stroke, as new information has emerged from animal and human studies of brain plasticity. Various types of noninvasive brain stimulation as an adjunct to task-specific training have generated much interest for the optimization of upper-extremity recovery (26,27), and promising studies point to its potential to promote the recovery of locomotion (28,29). These advances, spawned by the interest generated by brain plasticity mechanisms and technological advances in brain imaging that are able to document changes in the brain related to recovery over time or induced by specific therapies, give promise for further therapeutic developments and bode well for the field of neurorehabilitation. It is likely that these new, more effective approaches to enhancing motor recovery will lead to improved patterns of locomotor recovery after stroke.

Neuroplasticity mechanisms of recovery of the upper extremity after stroke can be divided into (a) those associated with spontaneous recovery and (b) treatment-induced recovery (30). Several patterns of change arise spontaneously during the weeks after stroke onset. A reduction in hemispheric laterality occurs. Instead of activity mainly in the contralateral hemisphere associated with normal unilateral arm movement, after a stroke, activity is often seen in both hemispheres. Activity also increases in multiple brain areas throughout the motor network. Moreover, these patterns occur along a gradient, such that in general, the poorer the behavioral outcome, the more these two mechanisms are invoked (31–33). Another pattern of spontaneous poststroke plasticity is a shift in the location of primary sensorimotor cortex (SMC) activity to a more posterior or ventral representation (34).

Behavioral gains in the affected arm following specific therapies in patients with chronic, plateau-phase stroke have been associated with an increase in the extent of activity, increased excitability of the motor cortex (35), and an increase in laterality back toward normal (36), such that there is a greater predominance of activity in the stroke-affected motor cortex rather than bilateral activation. Little is known, however, about the combined effects of spontaneous recovery and therapy-induced recovery in the acute poststroke phase.

Recovery mechanisms underlying unilateral upper-extremity function cannot be assumed to be the same as those for bipedal gait, a complex sensorimotor function controlled by integrated cortical, subcortical, and spinal networks. Given the technical difficulties associated with recording from the brain while walking, few studies have described patterns of brain activation during gait, even in healthy persons, and the neural substrates associated with gait recovery are only beginning to be understood.

Using motor imagery as a surrogate for actual walking in healthy elderly adults, Malouin et al. (37) studied the involvement of supraspinal structures in locomotion. They compared patterns of brain activation when imagining standing, initiating gait, walking, and walking while avoiding obstacles by means of positron emission tomography (PET). Their study revealed that higher brain centers become progressively engaged when demands of locomotor tasks require increasing cognitive and sensory information processing.

Imaging studies have started to elucidate the contributions of cortical activations to recovery associated with rehabilitation interventions such as treadmill gait training. Miyai et al. (38), using a near-infrared spectroscopic (NIRS) topography technique, found that body weight-supported treadmill training (BWSTT) led to a lower activation in the SMC as assessed by task-related changes of oxygenated hemoglobin levels. Importantly, changes in the SMC activation correlated with changes in the cadence, and improvement in the asymmetry of SMC activation also correlated with improvement in gait asymmetry. In a second NIRS study, Miyai et al. (39) measured cortical activity in persons with subacute stroke before and after two months of inpatient rehabilitation. They concluded that locomotor recovery after stroke may be associated with improvement of asymmetry in SMC activation and enhanced premotor cortex activation in the affected hemisphere (39,40).

Yen et al. (41), using focal transcranial magnetic stimulation, documented the relationship between motor improvement and corticomotor excitability change after gait training in persons with chronic stroke. They compared the effects of 4 weeks of general physical therapy in a control group (n = 7) to general physical therapy with the addition of BWSTT in an experimental group (n = 7). They found that, after general therapy, the patients improved their walking speed and cadence but had no significant changes in corticomotor excitability. The addition of BWSTT, however, led to changes in corticomotor excitability. The motor threshold for tibialis anterior muscles (TA) in the unaffected hemisphere, map size for TA in both hemispheres, and map size for the abductor hallucis muscle in the affected hemisphere were significantly improved. These changes in corticomotor excitability with BWSTT were correlated with improvements in balance and gait performance.

To date, functional magnetic resonance imaging (fMRI) studies attempting to document the neural correlates of recovery in locomotor function after stroke have used ankle dorsiflexion (42–44), knee extension movements (45), or activation of the tibialis anterior muscle as a surrogate to assay locomotor control. Sullivan et al. (46) documented activity-dependent cortical reorganization using fMRI mapping of the brains of persons with stroke who practiced walking on a treadmill. The fMRI changes were correlated with faster overground walking speeds and more precise voluntary control of the TA. Luft et al. (45) compared brain activations by fMRI during knee extensions in persons with chronic stroke due to cortical, subcortical, and brainstem lesions.

They found differences in brain activations between healthy controls and subjects with brainstem and cortical strokes and between subcortical and cortical strokes. Importantly, better walking ability was associated with reduced contralateral SMC activation in the brainstem but greater recruitment of ipsilateral sensorimotor and bilateral somatosensory cortices in subjects with subcortical and cortical strokes. These data thus reveal adaptations in networks controlling unilateral paretic knee movements in persons with chronic stroke that are related to walking ability and that are dependent on lesion location.

Enzinger et al. (43), using an ankle dorsiflexion paradigm and fMRI imaging, also demonstrated in persons with a single subcortical ischemic stroke that the degree of impairment of the paretic lower limb affected cortical activation. They observed that the extent of cortical activation, particularly in the primary SMC and supplementary motor area of the unlesioned hemisphere, increased with disability as measured with the Motricity Index. They interpreted this finding as potentially adaptive recruitment of undamaged ipsilateral motor control pathways from the supplementary motor area and possibly maladaptive disinhibition of the ipsilateral SMC (43).

In a second study (44), they used the same ankle dorsiflexion paradigm to demonstrate training-induced recovery of the lower limb associated with 4 weeks of BWSTT in a group of 18 persons with mild to moderate chronic stroke. Improved walking endurance after training (distance walked in 2 minutes [103.6 ± 38.1 vs. 119.7 ± 39.0]) was correlated with increased brain activity in the bilateral primary sensorimotor cortices, the cingulate motor areas, and the caudate nuclei bilaterally, and in the thalamus of the affected hemisphere during active ankle dorsiflexions of the paretic foot. They concluded that rehabilitation-associated walking improvements were associated with cortical activation changes despite the strong subcortical contributions to gait control. As in upper-limb studies of the effects of rehabilitation, they found bihemispheric activation to increase with greater recovery both in cortical and subcortical regions with movements of the paretic foot. They did not, however, find evidence of the involvement of the dorsal premotor cortex, important in upper-limb recovery.

Using a knee movement paradigm and fMRI, Luft et al. (47) studied the changes in brain activation related to 6 months of treadmill exercise (T-EX) in persons with chronic stroke in a large randomized controlled trial (RCT) that compared the effects of T-EX (n = 37) with stretching exercises (control group, n = 34). As expected, T-EX led to a significant improvement of 51% in walking speed and 18% in cardiovascular fitness in comparison to 11% and 3%, respectively, in the control group. Only the T-EX group, however, had changes during paretic but not nonparetic knee movements, with an increase of 72% activation in the posterior cerebellar lobe and 18% in the midbrain as well as in frontal, temporal, and parietal cortical areas. Moreover, subcortical recruitment in the cerebellum and midbrain was associated with exercise-mediated improvements in walking speed. The authors conclude that the observed changes in regional brain activation suggest that they are putative neuroplastic mechanisms by which T-EX restores functional walking capacity after stroke.

Contrary to reports of fMRI correlates of upper-extremity recovery of function (30), they (47) did not observe reductions in cortical activation after six months of T-EX, potentially reflecting the fact that subcortical, instead of cortical, networks are involved in mediating T-EX effects. They suggest that the increased activation in subcortical regions with T-EX may point to enhanced signaling in two candidate neural circuits: one consisting of the red nucleus (RN), the cerebellum, and inferior olive. Via projections to the RN, this circuit receives input from the cortex. It may provide timing cues and corrective signals necessary for coordinated phasic movements and movement learning (48). The second candidate circuit involves the cerebellum and the midbrain locomotor region that is part of the reticular formation in the immediate vicinity of the RN. The midbrain region receives neural signals from basal ganglia and cortex.

Together with the cerebellum, the midbrain locomotor region activates spinal locomotor pattern generators via the pontomedullary reticular formation (49). The findings of Luft et al. (47) could thus be interpreted as an activation of this pathway by T-EX to promote locomotor relearning.

The earlier mentioned studies suggest that therapy-induced changes in cortical plasticity may be related to the stimulation provided by treadmill walking with its entrained repetitive stepping and speed control, and also that these changes were associated with weeks or months of training. You et al. (50), however, showed that four weeks of exercising to target mobility, balance, and locomotor skills in a virtual environment that did not use a treadmill induced cortical plasticity. More specifically, using a knee flexion–extension paradigm, they showed fMRI changes in the laterality index in the primary SMC, which suggested that virtual reality (VR) training could induce cortical reorganization from aberrant ipsilateral to contralateral SMC activation. Other studies, using transcranial magnetic stimulation (TMS) have shown that 30 minutes of walking with functional electrical stimulation (FES), but not when walking alone, increases the corticospinal excitability of the tibialis anterior muscle and that this effect is related mainly to increased excitability of the cortex or its connections to the spinal cord more than that of spinal pathways (51). Liepert et al. (52) used TMS mapping to show that one hour after a single physiotherapy training session aimed at improving dexterity of the affected hand, the motor output map of the paretic abductor pollicis brevis was significantly enlarged and motor function was improved. One day later, these effects were partially reversed. Animal and motor learning studies (15,26) have shown that plastic changes begin almost immediately after a stroke. Studies, as yet, have not defined the timecourse of cortical plasticity related to locomotor therapy. The challenge is to better understand this process so that interventions are timely and appropriate to promote recovery.

We have limited knowledge of the recovery pattern after severe strokes because rehabilitation-related research studies focus on recovery after mild or moderate strokes.

Even the most widely used animal models fail to mimic the pathogenesis and clinical features of severe ischemic strokes (53). Clinically, we know that recovery from severe strokes takes more time (54), as expected from the patterns and timecourse of recovery (4,7–9,11), and that factors such as age and caregiver support affect not only recovery but also decisions made by rehabilitation personnel regarding recovery potential. Older patients do recover, but age alone is a weak predictor of functional recovery and its impact may be overestimated (55), predicting only 3% of the variance in the Functional Independent Measure score at discharge. Other factors such as the level of consciousness (sleepiness, attention problems) and possibly other comorbidities also affect recovery (56,57). Although persons with very severe stroke may rarely attain functional independence, they can benefit enormously from rehabilitation to reach their maximal functional level to facilitate transfers, to rise from a chair, and to walk with assistance, and may be able to return to their homes with the help of a caregiver (58).

There is little in the literature to guide the rehabilitation approach for persons with severe strokes. Will they benefit most from a regular intensive approach initiated as early as possible and as intense as tolerated, or should special parameters, such as a later and more gradual approach to intensity over time, apply? We also are only beginning to understand the effects of pain and fatigue (59), the depression that affects a very large proportion of stroke victims, apathy (60), psychological barriers, and perceptions that the "system" has given up on them (53) on the recovery potential. We also know little about the impact of cognitive impairments, such as of anticipatory processes and motor planning, on locomotor recovery (53,61).

After reviewing studies reporting neural correlates of recovery in persons with severe stroke, Sterr and Conforto (53) concluded that there was evidence that contralesional areas and augmented activity of networks not normally minimally or even active at all in healthy brains were related to recovery and limited behavioral gains. Severity of motor impairments thus influences patterns of rewiring after stroke, along with other factors such as age, brain status before stroke, and intensity and timing of rehabilitative interventions. To date, rehabilitation interventions have not taken into account the heterogeneity of mechanisms underlying the stroke and how these mechanisms may affect brain processes and behavioral and psychological factors that underlie recovery.

One can also question whether more effective, task-specific therapy, provided early and with sufficient intensity, could limit the development of disturbed motor control processes associated with spasticity, excessive coactivation, and paresis during walking (62). Furthermore, kinematic and kinetic studies have demonstrated that functional improvements in balance and gait or lower-extremity function can occur without the restoration of "normal" motor control, indicating that behavioral compensation strategies for impaired motor control are an important part of the "recovery" of function after stroke (62–75). One can ask whether these behavioral compensations, which reflect learned skills designed to overcome motor control impairments, are part of the recovery process that is triggered when restoration of "normal" function is not possible.

WALKING SPEED AS A MARKER OF RECOVERY AFTER STROKE

Walking speed has been shown to be a robust indicator of walking capacity (76). Supporting the validity of walking speed as a measure of locomotor recovery is its positive correlation with motor recovery (74,77,78), static muscle strength of the lower extremity (79,80), and the size of the "push-off" plantar flexor moment (70), with balance (80) and the use of walking aids (81) and its negative correlation to spasticity of the plantar flexors (68). Faster walking speeds are also indicative of the quality of the lower-extremity movements (73,82). Moreover, the reliability of the clinical measurement of walking speed has been established for test–retest and between-observer measurements (81–83), whereas repeated measurements of the simple, timed walking test over five and ten meters have been shown to be a responsive measure of walking performance in acute stroke (84). Gait speed, however, is not always the outcome of choice throughout the range of recovery. When subjects walk very slowly or need the support of a person, clinical outcomes such as the Barthel (10) ambulation subscale or the Fugl-Meyer (6) leg subscore may be more sensitive than walking speed (73). Nevertheless, chronicling the full extent of walking recovery may require measures more demanding than gait speed alone (85).

Importantly, Perry et al. (86) related the level of walking speed attained by persons after stroke to their capacity to participate in the community. Thus, to be able to be independent in the community, the stroke survivor must be able to walk at about 80 cm/s, but this speed is too slow to cross wide streets in large cities (87). At the end of their rehabilitation phase, relatively few persons with stroke walk at this speed (1,2,20,23,83). After stroke, persons lack what has become known as "walking competency" (23). Those reintegrating into the community after stroke walk at average speeds that are insufficient to cross the street safely, especially wide intersections, or have insufficient endurance and strength to walk distances necessary to accomplish basic and instrumental activities of daily living. They may be unable to negotiate curbs, to maintain balance and stability while turning the head or reacting to unexpected perturbations, and lack anticipatory strategies to avoid or accommodate obstacles (89). Moreover, they often are fearful and have cognitive impairments affecting decision making while walking (87,88). Desrosiers et al. (90) also found disability measures of the lower extremity, including gait speed, to be highly correlated to handicap situations as measured by the Life-H outcome measure in persons after stroke, thus emphasizing the importance of mobility to promote social participation.

Schmid et al. (91) stratified gait speed after stroke into the following clinically meaningful ambulation classes based on the Perry et al. (86) study: household ambulation (<40 cm/s),

limited community ambulation (40–80 cm/s), and full community ambulation (>80 cm/s). In subacute stroke survivors with mild or moderate deficits who participated in a randomized, clinical trial of stroke rehabilitation, they (91) found that a gait speed gain leading to a transition to a higher class of ambulation results in better function and quality of life, especially for household ambulators, thus suggesting that an outcome assessment based on transitions between gait speed classifications yields potentially meaningful indicators of clinical benefit. Such transitions in gait speed classification according to the Perry et al. (86) criteria were chosen as the primary outcome measure in the phase III Locomotor Experience Applied Post Stroke (LEAPS) trial (21).

As mentioned earlier, the patterns of recovery—and in particular, walking recovery—after stroke have essentially been defined by serial assessments made with clinical measures that detect little change beyond three months after stroke. When using walking speed as a marker of functional recovery, however, Richards et al. (74) found that walking speed continued to increase up to 12 to 18 months after stroke and that the increase in speed was related to increases in both cadence and stride length, thus redefining the timecourse of recovery. The recovery of gait speed, however, remained limited when compared to the gait speed of healthy, elderly persons asked to walk slowly, with the mean level of gait speed recovery attaining about 50% of the slow speed of the healthy subjects at 12 to 18 months after stroke (74). The latter study documented recovery in a cohort of patients with an ischemic stroke caused by a middle cerebral artery infarct who participated in a randomized, controlled trial comparing three physical therapy interventions (1,92).

Kollen et al. (83) documented the recovery of walking speed in a prospective cohort longitudinal study of 101 persons with acute stroke who participated in a clinical trial designed to study the effects of augmented therapy (20). None of the participants were able to walk unassisted in the first week after stroke. The mean interval between stroke onset and the first unassisted walk was 4.8 ± 2.9 weeks. They followed the subjects for 52 weeks, and not all of the subjects progressed to unassisted walking; however, comfortable walking speed was measured in 85 and fast walking speed in 81 participants. The mean comfortable walking speed progressively increased from 3.7 to 63.5 cm/s at 1 year after stroke, whereas the mean maximum speed increased from 7.1 to 85.1 cm/s, thus confirming the progressive increase in gait speed up to 1 year after stroke. Moreover, they found a systematic difference between comfortable and fast walking speeds. Regression analyses applied cross-sectionally and longitudinally demonstrated that the relation between comfortable and maximum walking speed does not change over time after stroke. Maximum speed was estimated to be 1.32 times that of comfortable walking speed (83). This is an important finding because it makes it possible to estimate the maximum speed a subject can attain, without actually measuring it, to predict, for instance, the capacity to cross a wide street.

The works of Richards et al. (73) and Kollen et al. (83) have clearly shown that gait speed continues to increase beyond six months after stroke when clinical measures may fail to show further functional recovery. The following section reports the extension of the Richards et al. (74) study of recovery in gait movements and muscle activations accompanying changes in gait speed in the 11 subjects that remained in the study 2 years after stroke (93).

RECOVERY, FROM STROKE ONSET TO TWO YEARS AFTER STROKE, OF WALKING SPEED AND ITS RELATION TO MOVEMENTS AND MUSCLE ACTIVATIONS OF THE LOWER EXTREMITY

Table 19.1 gives selected subject characteristics for 11 patients with complete data followed from baseline to 2 years after stroke. At 6 weeks after stroke, 23 of the 27 patients recruited into the study remained, and of these, 18 were able to walk, 15 with one-arm support for balance or independently, whereas 3 required maximal bilateral arm support to walk 4 m (73). Of the five patients who did not walk at six weeks after stroke, one refused to be evaluated and four others were unable to walk, even with maximal bilateral support. Two years after stroke, all of the patients remaining in the study could walk independently.

Figure 19.1 illustrates the recovery of gait speed over time in comparison to values obtained in healthy subjects walking slowly. At 6 weeks after stroke, the gait speed of two patients (cases 113 and 211) fell within the confidence limits of the healthy controls, and a third (case 206) was close. The mean gait speed was 31.8 ± 19.9 cm/s (mean, ± 1 SD, n = 11). Two years after stroke, all the patients walked faster and six attained normal confidence limits. The mean speed almost doubled, rising to 62.8 ± 19.1 cm/s (n = 11), a speed that is still much below the 104.3 ± 19.3 cm/s free speed of healthy subjects walking under similar laboratory conditions.

Recovery, as defined by comparison to healthy values, in the ankle movements and muscle activations that accompanied these changes in gait speed are shown in Figure 19.2. In most cases, the movement and activation profiles differ markedly from normal values at six weeks after stroke and are closer to normal two years after stroke. Interestingly, the movement profiles (top row) appear to show better recovery than the muscle activation profiles, particularly the TS (middle row). As previously mentioned, the mean speed approximately doubles during this time frame, and this increase in speed is related to both an increase in stride length (59–88 cm) and faster cadence (61–85 steps/min).

To examine more closely the relationship between gait speed and the patterns of movements and muscle activations with recovery, the 11 patients 2 years after stroke were divided into 2 groups: a slow-walking group (n = 5) and a fast-walking group (n = 6). The walking speed of patients in the fast group attained or surpassed the confidence limits of the healthy controls walking slowly (Figure 19.1).

TABLE 19.1 Selected Characteristics of the Subjects Evaluated at Baseline One Week After Stroke and Two Years After Stroke. These Subjects Participated in a Randomized Controlled Trial That Evaluated the Effects of an Intensive Task-Oriented Gait Training Program

			FUGL-MEYER LEG MOTOR SUBSCORE (MAXIMUM SCORE = 34)			BALANCE SCALE (MAXIMUM SCORE = 56)

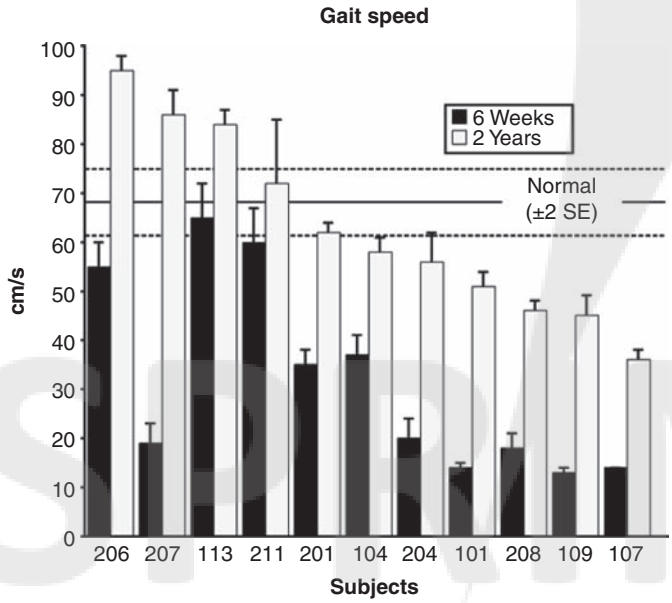

FIGURE 19.1 Bar graph representing changes in gait speed between 6 weeks and 2 years after stroke for 11 subjects with hemiparesis (case numbers given on x-axis). Horizontal lines indicate mean and confidence limits of gait speed obtained in a group (n = 10) of healthy subjects (aged 58 ± 5.6 yrs.) walking at 75% of their usual cadence (mean speed 68.3 ± 6.7 cm/s; ±2 SE, n = 8).

As shown in Figure 19.3, the movement and muscle activation profiles during gait of the fast group (H-N) tend to be more similar (except for the HAMST activations, which remain abnormal) to the profiles derived from the healthy subjects. Given the role of the TS in the generation of power to generate walking speed (71,72,94), one would expect more marked changes in the profiles (shape and amplitude) of the TS "push-off" activation bursts of the patients in the fast group.

To further examine the recovery (*recovery* is used in the general sense and refers to return in the capacity to activate the muscle) in the muscle activation profiles over time, the areas under functionally important activation bursts were compared (Figure 19.4). As expected from the profiles shown in Figures 19.2 and 19.3, the "push-off" activation burst in the TS does not change over time in this group of patients. In contrast, the TA activation burst that is related to foot lift at swing phase initiation (60%–80% of the gait cycle) shows recovery up to 2 years after stroke. The recovery in this burst is representative of recovery in the two other TA activation bursts (0%–16% and 84%–100% of the gait cycle) that were correlated with the 60% to 80% gait cycle activation burst ($r = 0.89$ and 0.86, respectively, $P < .01$). The QUAD also improves over time, but later than the TA, with the largest change occurring between 6 months and 1 year after stroke in the late swing activation burst (84%–100% of the gait cycle)

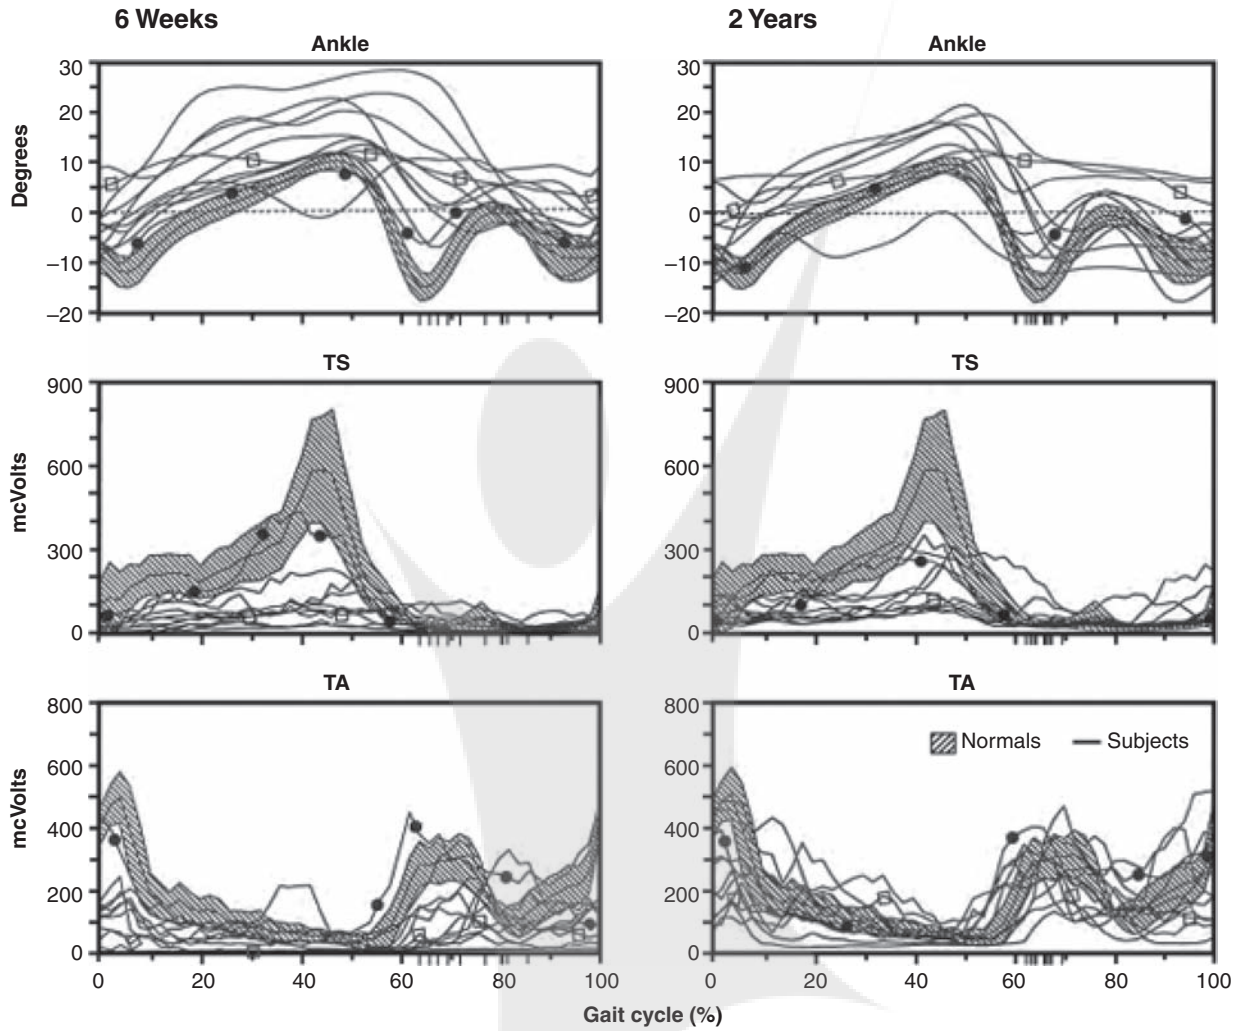

FIGURE 19.2 Profiles of ankle movements (obtained with a TRIAX electrogoniometer) and activations (surface EMG; rectified and time averaged; time constant 20 ms) of the triceps surae (TS) and tibialis anterior (TA) muscles during gait of 11 subjects at 6 weeks and 2 years after stroke in comparison with normal values (mean ±2 SE, n = 8). The patients who walked slowest (case 109: open squares) and fastest (case 113: filled circles) at 6 weeks are indicated.

that corresponds to knee extension preparatory to weight acceptance. Comparison of the magnitude of the activation bursts (TA, TS, and QUAD) in the patients with healthy values (Figure 19.4D) emphasizes the poor recovery of the TS two years after stroke.

Pearson correlation coefficients (Table 19.2) were calculated to further probe the interaction among the muscle activation bursts and gait speed during recovery, defined as the magnitude of change from baseline to two years after stroke. Recovery in the TA bursts (0%–16% and 84%–100%) was significantly associated (r = 0.74 and 0.64, respectively) with change in the TS (20%–50%). Recovery in the QUAD, mainly a knee extensor, was most highly correlated (r = 0.77, $P < .01$) with recovery in the ankle extensors (TS). Recovery of gait speed, in contrast, had a closer association with recovery in the TA (60%–80%: r = 0.60, $P < .01$) than with the two extensor muscle groups.

In summary, these data describe the longitudinal recovery of gait in a cohort of patients with a middle cerebral artery ischemic stroke (1). One week after stroke, their Fugl-Meyer leg subscores (6) varied from 4 to 30, indicating a wide range of impairment, and this was later reflected by the variable gait recovery. Although the mean gait speed at 6 weeks after stroke of about 30 cm/s doubled to a near-normal slow gait speed 2 years after stroke, some patients attained a relatively good walking pattern, whereas others were left with a very abnormal pattern. These results also show a clear relationship between gait speed and the quality of gait movements and muscle activations two years after stroke, confirming the findings of our earlier study (73) and in agreement with Wade et al. (82).

Recovery of activation profiles was not uniform among the muscles. The TA recovers consistently over time, whereas the QUAD recovers little until about one year after

stroke, and the TS was particularly resistant to change. The apparent resistance of the TS to recovery is a surprising and important result because of the importance of this muscle as a generator of propulsive force for walking and the emphasis put on the re-learning of "push-off" in gait rehabilitation approaches (71,95,96). One can ask whether the TS is more resistant to change for physiological reasons or, alternatively, if rehabilitation strategies are inadequate to provide the appropriate input to evoke recovery in this muscle. In this context, Colborne et al. (97) demonstrated that computer-assisted biofeedback (ankle position or EMG biofeedback) was more effective than conventional therapy in inducing improved force impulses of the plantar flexors at "push-off." Furthermore, in a subgroup of 25 subjects after stroke, participating in an RCT, who received task-oriented gait training, Richards et al. (2) found that an improved "pushoff" plantar flexor A2 power burst (see Figures 19.3 and 19.7 for illustrations of the muscle activations and power bursts) in late stance explained about 25% of the variance in the change in gait speed posttherapy.

Nevertheless, the close association between gait speed and recovery in the TA two years after stroke confirms and

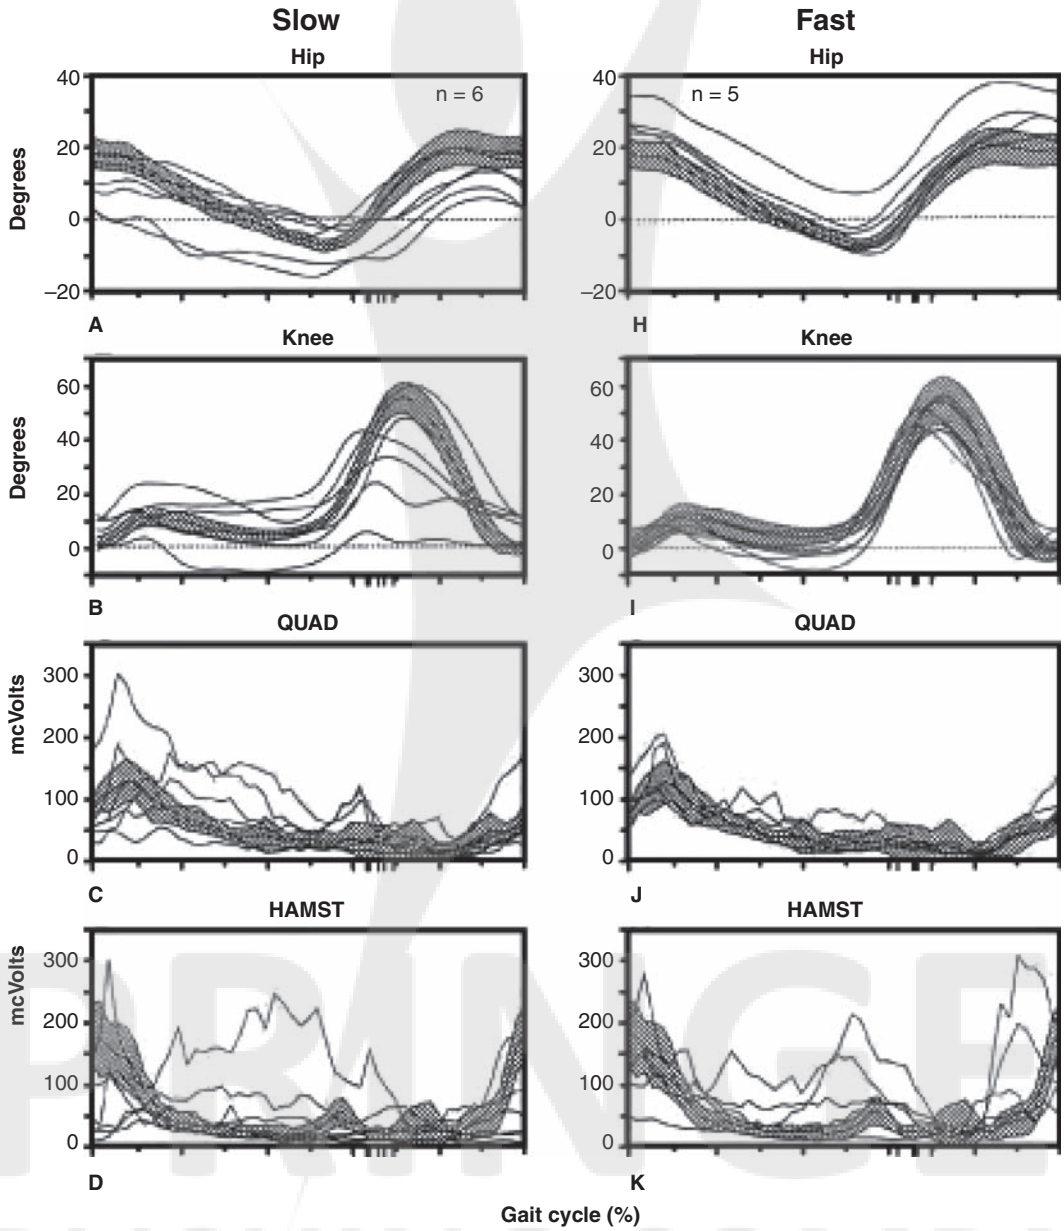

FIGURE 19.3 Comparison of the profiles of hip, knee, and ankle movements and activations (see Figure 19.2 text) of the quadriceps (QUAD), hamstrings (HAMST), triceps surae (TS), and tibialis anterior (TA) muscles during the gait cycle of a group of slow-walking (A–G) and a group of faster-walking (H–N) subjects at two years after stroke with normal values. Thin lines represent the profiles of individual subjects. Shaded area gives mean and confidence limits for healthy controls (n = 8). Additional vertical lines on x-axis indicate end-of-stance phase, which ranged from 62% to 69% and from 60% to 67% of the gait cycle for the slow and fast groups, respectively. (*Continued*)

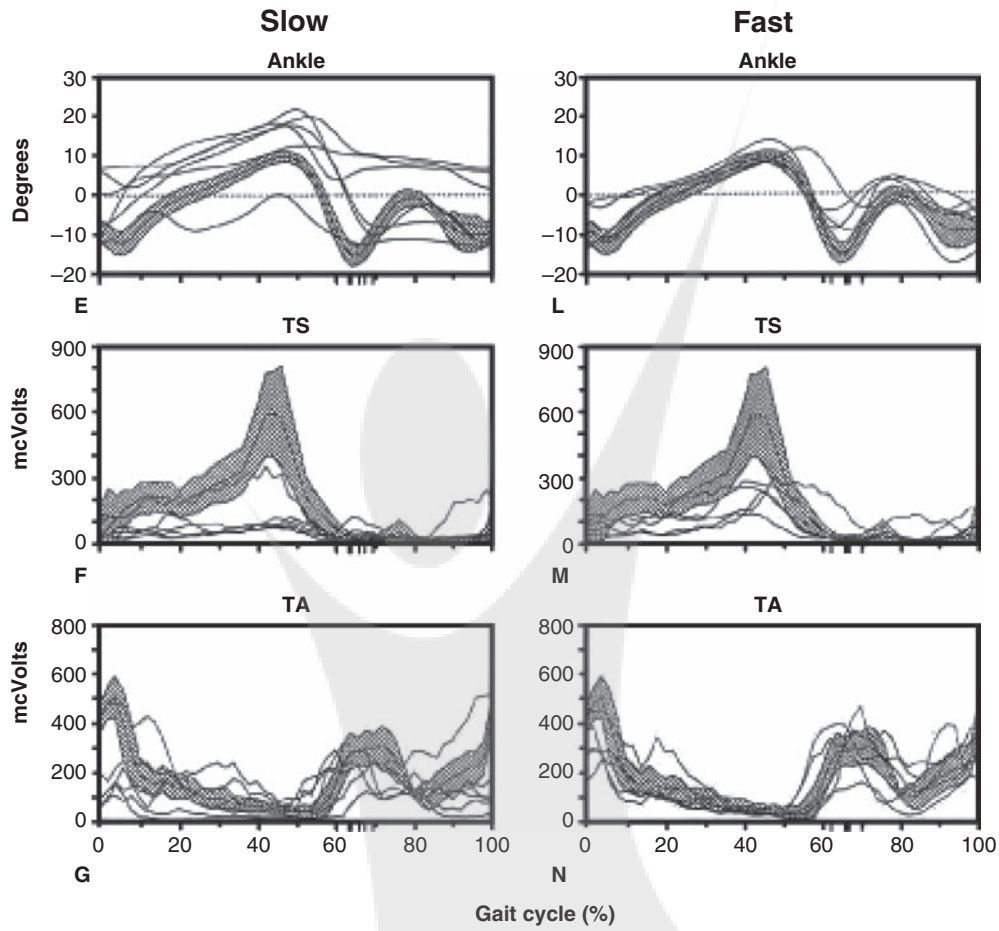

FIGURE 19.3 (*Continued*)

extends earlier findings (74) and suggests that the TA may be an important muscle to target in therapy given its recovery potential and association with gait speed recovery. Could it be that the TA is more easily controlled by voluntary drive (98) after stroke, whereas the TS is under control of the subcortical postural system and less accessible to voluntary drive after a lesion of the corticospinal tract? Clearly, these questions provide ample motivation for continued research in this area.

These changes in muscle activations during gait associated with recovery over time in persons after stroke may appear to be in opposition to previous reports (99–101) to the effect that recovery of gait is not associated with changes in the temporal patterning of muscle activations obtained with surface electrodes. These studies, however, only considered the timing of the muscle activations by defining "on" or "off" bursts during the gait cycle and did not take into consideration the amplitude of the muscle activations. Moreover, they did not imply that the timing of the muscle activations during gait was not perturbed after stroke, but rather that the pattern did not change over time or after therapy (100,101). Den Otter et al. (102) attributed the apparent robustness of neuromuscular timing characteristics in the context of varying task demands to differences in the control of the timing and amplitude of EMG bursts during locomotion. In particular, timing is understood to be determined mainly by central pattern generators, whereas amplitude is understood to be largely dependent on reflex loops (103,104).

Because paresis is a primary contributor to poststroke gait impairment (62), different methods have been devised to quantify the muscle activations during gait so that both the timing and the amplitude of the activation (EMG) bursts, which reflect the intensity of the contraction, are taken into account (62,105,106). The EMG analysis method depicted in Figure 19.4 allows the comparison of the muscle activations of the subjects after stroke with normal data in key functional activation bursts during the gait cycle. The area under these bursts represents both the timing and the amplitude of the activation bursts and assumes that the variability in EMG records as a result of factors such as electrode position, skin contact, and subcutaneous tissue are similar in the subjects after stroke and the healthy controls walking at slow speed to minimize differences in amplitude related to faster walking speeds (94). Den Otter et al. (102) argued that recovery-related changes in lower-extremity muscle activity during gait after stroke were primarily related to

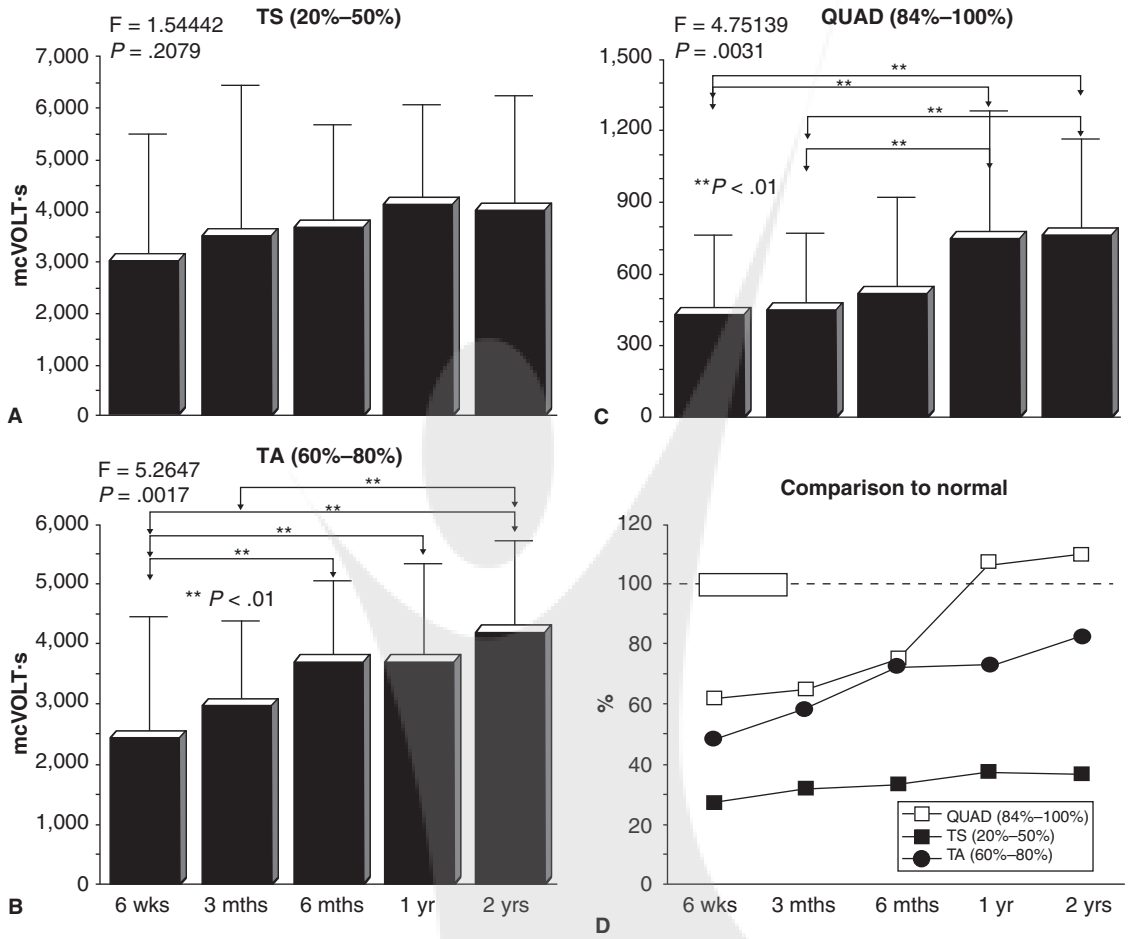

FIGURE 19.4 Bar graphs A–C, depicting recovery over time of selected muscle activation bursts of the triceps surae (TS), tibialis anterior (TA), and quadriceps (QUAD) muscles of 11 patients whose muscle activation profiles were depicted in Figure 19.3. Values in A–C give mean 1 SD. The area under specific activation bursts was used in comparisons. Three activation bursts were defined for the TA (0%–16%, 60%–80%, and 84%–100%). These bursts are related to footfall control after foot contact, toe lift at swing phase initiation, and foot lift preparatory to foot contact at the end of the cycle. Activation bursts related to functional events in the gait cycle were also defined for the other muscles: TS (20%–50%) and QUAD (84%–100%). An analysis of variance for repeated measures and the Scheffe post hoc test were used to compare changes over time (x-axis). Line graph in D compares recovery of the activation bursts (in % of values obtained in healthy subjects) in the three muscles. Statistical differences are indicated by asterisks (**$P < .01$) and horizontal lines above bars in A–C.

TABLE 19.2 Pearson Correlation Coefficients (r) Between Recovery (Change From Baseline to 2 Years After Stroke) in Gait Speed and Muscle Activation Burst That Are Functionally Important During the Gait Cycle in Persons With Chronic Stroke (n = 11)

	GAIT SPEED	TS (20%–50%)	TA (0%–16%)	TA (60%–80%)	TA (84%–100%)	QUAD (84%–100%)

the potential force output of muscles and, therefore, that increases in strength may be expressed as changes in the amplitude of muscle activity within relatively stable timing schemes.

MAGNITUDE OF REHABILITATION-RELATED CHANGES IN WALKING SPEED

To examine how changes in balance and motor function relate to changes in gait speed after rehabilitation, Berg balance scores (BBS), FML subscores, and gait speed at baseline, after rehabilitation, and at follow-up, were reviewed for 62 persons with subacute stroke who participated in an RCT that compared the efficacy of 2 task-oriented physical therapy (PT) programs to promote gait recovery (2). Because the therapeutic effects of both approaches were found to be equivalent, the subjects were pooled for these secondary analyses. They received a total of about 38 hours of task-oriented physical therapy over 2 months that was provided in two in-patient rehabilitation settings. Of the 62 patients who entered the study, complete data were available for 50 patients at follow-up 3 months later.

Figure 19.5A illustrates the more than doubling of gait speed after therapy (27 ± 15 to 61 ± 38 cm/s) and the continued increase, by an additional 8 cm/s to 69 ± 38 cm/s, at follow-up 3 months later. The total change from baseline 50.4 ± 18.3 days after stroke onset to follow-up about 5 months later was 41.99 ± 31.54 cm/s. This is a large change in relation to other studies that will be discussed at the end of this section. It is evident from the standard deviations, however, that there is much variability in the magnitude of the change in gait speed among the subjects. From baseline to postrehabilitation (Figure 19.5B), only 30 subjects increased their gait speed to greater than or equal to 16 cm/s, recognized as the minimal clinically important difference (MCID) (107). At follow-up (Figure 19.5D), 13 subjects had further increases in gait speed greater than the MCID, but most had very small or no change.

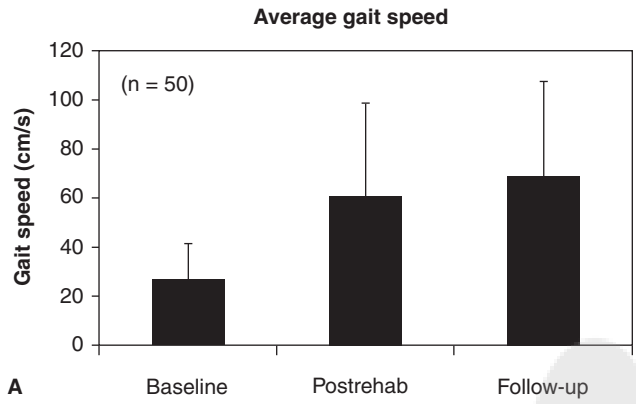
As expected, motor impairment (Figure 19.5E) of the lower extremity, as measured by the FML subscore, and balance, as measured by the BBS (Figure 19.5F), were significantly correlated ($P < .000$) with walking speed at baseline, and explained 36% and 30%, respectively, of the variance in gait speed. Importantly, the time after stroke when the inpatient rehabilitation program was initiated (subjects received undocumented rehabilitation services in the acute care setting before being admitted to the rehabilitation setting) was negatively correlated ($r = –0.39$, $P < .002$) with changes in gait speed from baseline to postrehabilitation (Figure 19.5G).

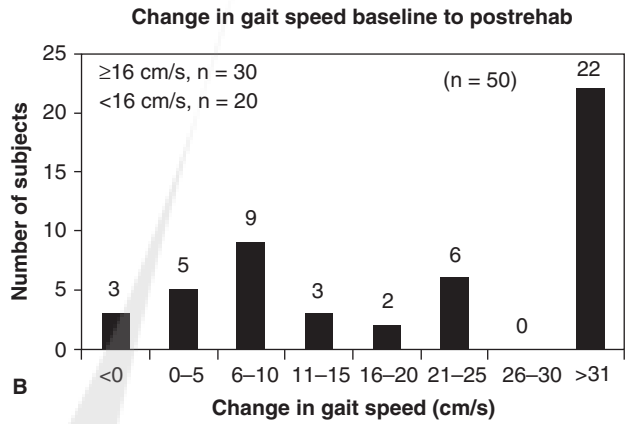
In this cohort of subjects, gait speed at baseline was significantly correlated with gait speed after rehabilitation ($r = 0.62$, $P < .0001$, $R^2 = 0.40$), indicating that about 40% of the change in gait speed from baseline can be explained by the initial gait speed. Also, the side of the hemiparesis had no significant effect on the change in gait speed with therapy ($P > .05$).

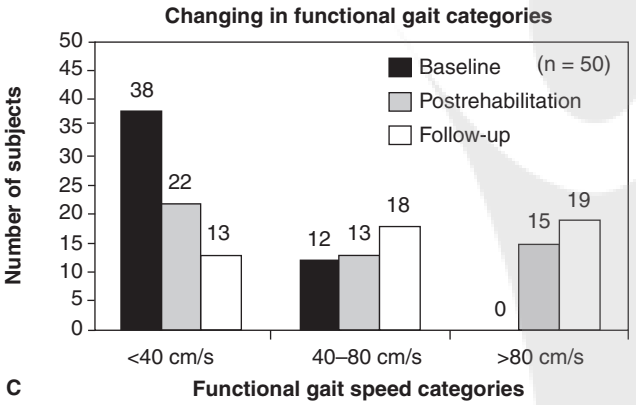
To further probe why some subjects improved more than others and why some continued to improve during the follow-up period, whereas others did not, further analyses focused on whether or not subjects changed functional gait speed category after two months of rehabilitation (21,91). Figure 19.5C shows the number of subjects in each functional gait speed category at the three time points. This analysis revealed that, at baseline among the 50 subjects, 38 had severe and 12 moderate gait impairment (21). After rehabilitation, 22 of the subjects in the severe category had "leaped" into another category, whereas 16 remained in the severe category. To better understand what characterized those who "leaped" as opposed to those who did not, gait speed, FML subscores, and BBS were compared as a group (Figure 19.6) and individually (Table 19.3).

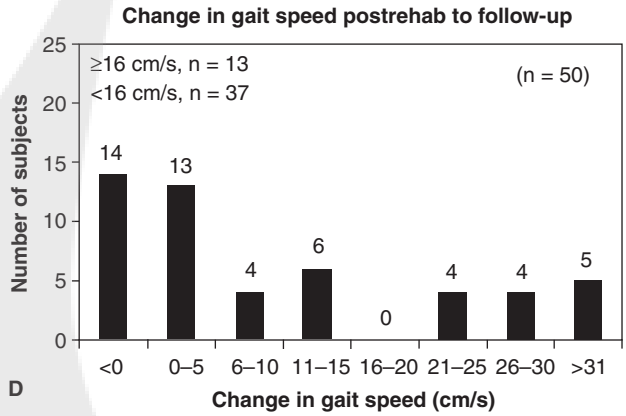
For the subjects with severe gait impairment (left column, Figure 19.6), the much faster gait speed ($P < .001$) in the subjects *that changed* category was associated with a higher BBS ($P < .05$) and FML ($P < .01$) at baseline and also after rehabilitation. At follow-up, the faster gait speed ($P < .001$) was associated with a higher FML ($P < .001$) but a similar BBS. The subjects in the group with a moderate gait speed impairment at baseline (right column, Figure 19.6) *that changed* category had a similar gait speed and BBS to those who did not, but a higher FML ($P < .001$). After rehabilitation, those *that changed* category had a much faster gait speed ($P < .001$) that was associated with higher FML ($P < .001$) and a trend in BBS ($P = .06$). At follow-up, the faster gait speed ($P < .001$) in the group *that changed* category was associated with a higher FML ($P = .05$) but a similar BBS, likely as a result of the ceiling effect with this measure. These results suggest that motor control is more discriminant than balance between the groups, but the ceiling effect of the BBS may be a confounding factor.

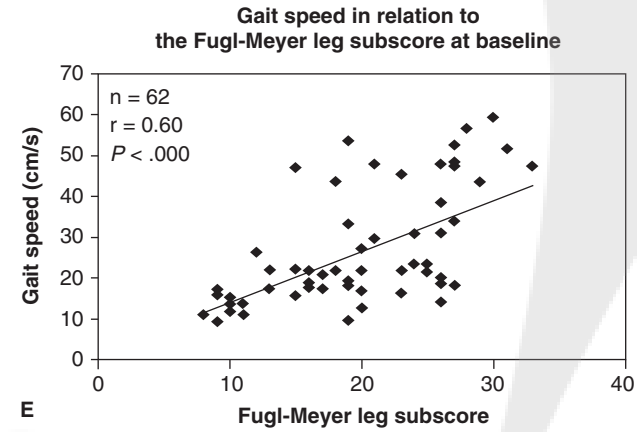
To further examine the association of BBS and FML scores with improvements in gait speed that allowed some subjects to "leap" category, a further analysis was made of individual scores by establishing threshold scores for the BBS and FML to distinguish the subjects. For the BBS, a threshold of less than 45 was selected because in elderly persons, the relative risk of falling is 2.7 times more likely in those with a BBS score of less than 45 and is associated with the need for a cane (112). For the FML, a threshold of 25 was used based on our previous work on recovery of gait speed in the first month after stroke (1). This analysis (Table 19.3) revealed that after therapy in the group with a severe gait impairment *that did not change* category (n = 22), 12 and 20 subjects, respectively, had BBS or FML scores below threshold, and 10 had both scores below threshold. In contrast, among *those that changed* category (n = 16), only one had BBS, two FML, and none both scores below threshold. In the moderate gait speed impairment group, of the six subjects *that did not change* category, two had BBS, four FML, and two both scores below threshold. In contrast, none of the subjects had either score below threshold in the group *that changed*

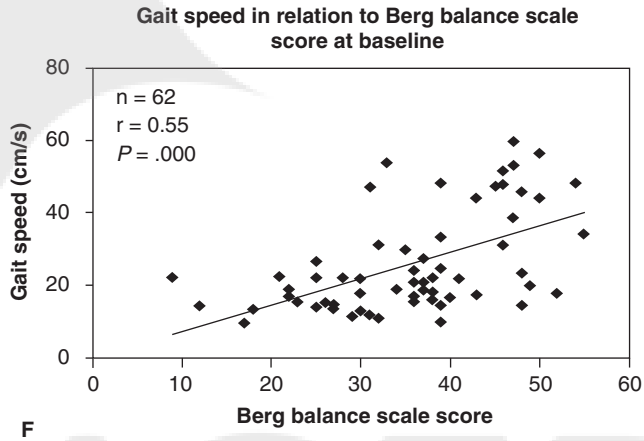












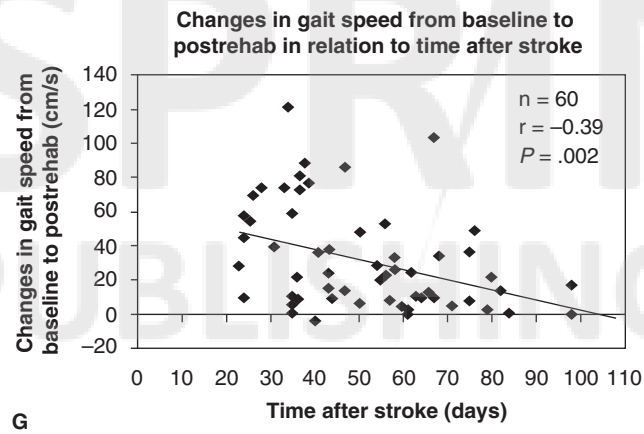


FIGURE 19.5 A series of graphs illustrating changes in gait speed in a cohort of subjects with subacute stroke who participated in an RCT. The size of the changes in gait speed are illustrated in A, B, and D, whereas C shows the number of subjects in gait categories at baseline, after therapy, and at follow-up. Selected correlations are illustrated in E–G.

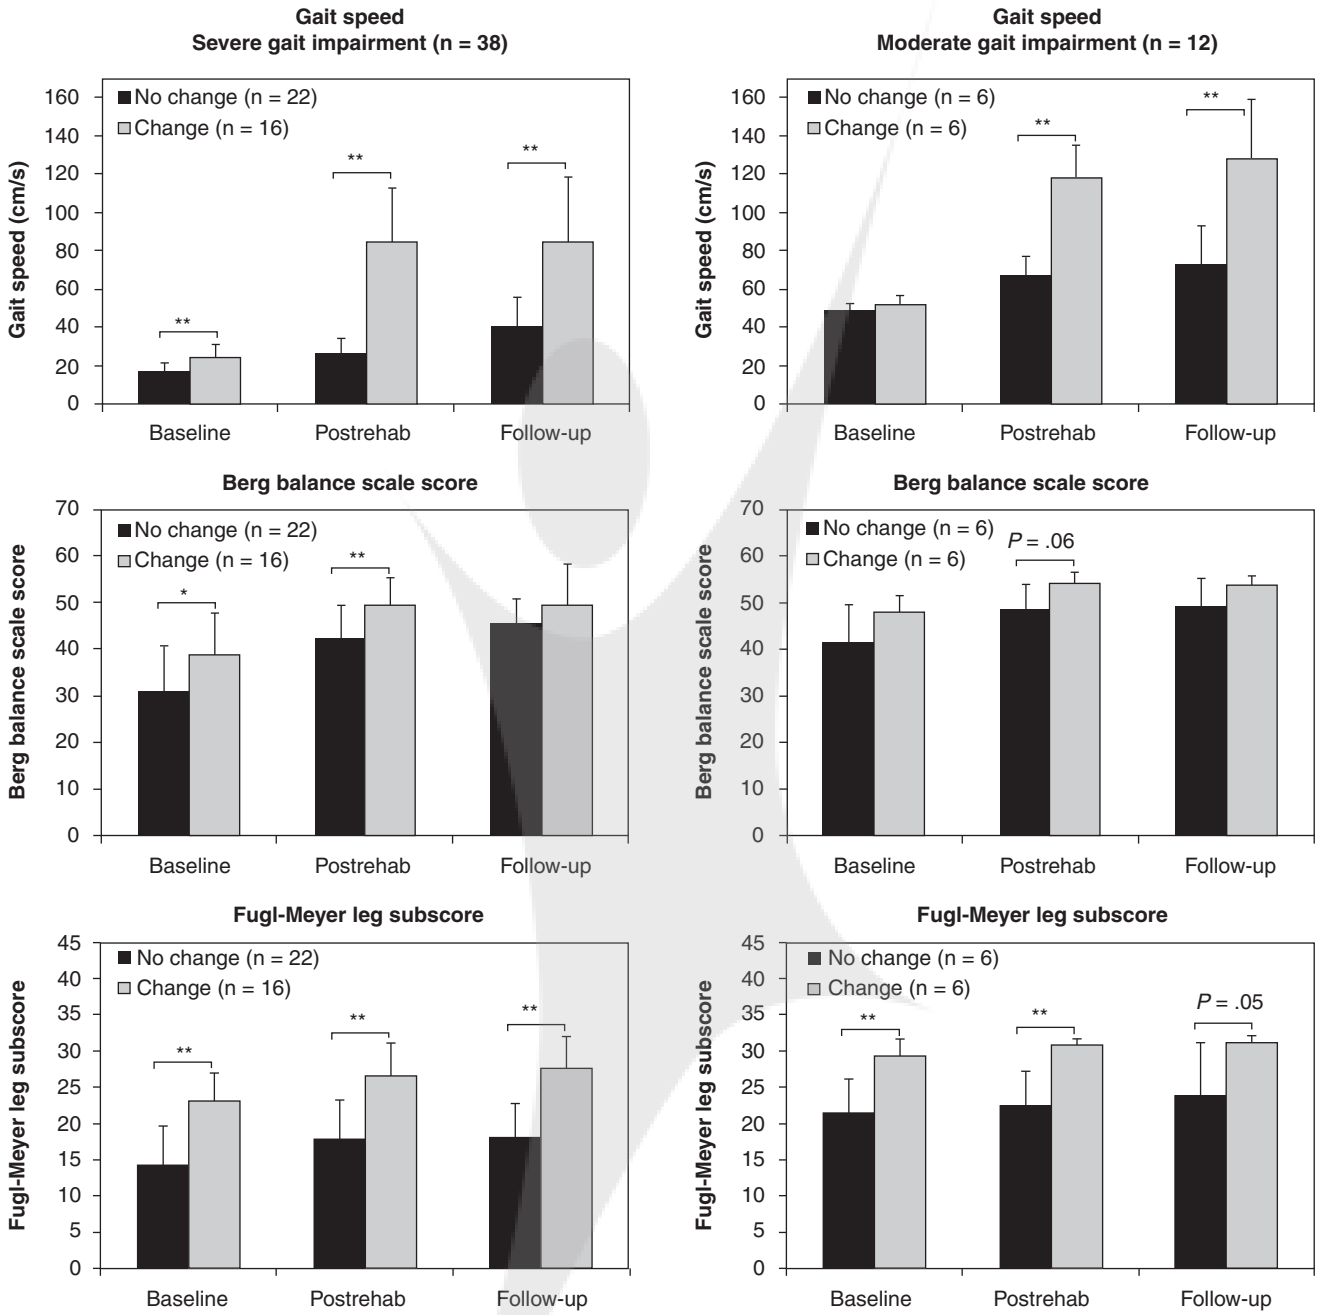

FIGURE 19.6 Bar graphs illustrating gait speed, the Berg Balance Score, and the Fugl-Meyer leg subscore in the subjects who changed or did not change functional gait category after therapy. Results for subjects in the severe gait speed impairment category (n = 38) are shown on the left, whereas those in the moderate gait impairment category (n = 12) are shown on the right of the figure. Statistical differences are indicated by asterisks (*$P < .05$, **$P < .01$) and horizontal lines above bars.

category. Thus, this analysis showed that, among subjects in the severe gait impairment category at baseline, those who attained the set thresholds for BBS and FML were likely to have improvements in gait speed allowing them to change functional category. In contrast, the fact that 20 of 22 subjects in the group who did not change category had FML scores less than 25, whereas 12 of 22 had BBS scores less than 45, suggests that the FML score may be more critical.

Despite the small number (n = 12) of subjects in the moderate gait impairment category at baseline, differences in the mean BBS and FML scores were found between those who changed category after rehabilitation and those who did not. In those who did not change category, two subjects did not attain both thresholds, and four did not attain only the FML threshold, possibly pointing to impairment as the limiting factor as with the subjects in the severe gait impairment

TABLE 19.3 Comparison of the Number of Subjects in the Severe and Moderate Gait Impairment Categories Who Attained the Berg Balance Scale (BBS) and the Fugl-Meyer Leg (FML) Subscore Threshold Among the Subjects Who Changed or Did Not Change Gait Category After Therapy

THRESHOLDS FOR BBS AND FML SUBSCORE AFTER THERAPY	SEVERE GAIT IMPAIRMENT (n = 38)		MODERATE GAIT IMPAIRMENT (n = 12)	
	NO CHANGE (n = 22)	CHANGE (n = 16)	NO CHANGE (n = 6)	CHANGE (n = 6)
BBS < 45	12	1	2	0
FML < 25	20	2/15	4	0
BBS < 45 and FML < 25	10	0	2	0

group. Such a finding is reasonable because it suggests that a certain level of motor recovery is necessary before independent gait that requires more balance control than walking with assistance or a cane can be attained (112). Nevertheless, these data clearly demonstrate the importance of recovering a threshold of motor and balance control before a change in functional gait speed can be reached. The high correlations between the BBS (r = 0.65, $P < .000$, n = 50) and FML (r = 0.71, $P < .000$, n = 50) after therapy and the change in gait speed from baseline to after therapy support this assertion. The suggested threshold values may be clinically important as predictors of gait outcome.

To complete this section, the magnitude of changes in gait speed in selected gait intervention studies are discussed in relation to the results of the Richards et al. (2) study. The subjects received 38 ± 12 (n = 60) hours of task-oriented physical therapy on the basis of 1 hour/day/5 days/week for 8 weeks, when possible. In a subset (see Figure 19.5) of subjects (n = 50), the baseline measures taken 59.1 ± 8.8 days after stroke were: (a) FML: 19.7 ± 7.0, (b) BBS: 36.6 ± 10.5, and (c) gait speed: 26.9 ± 14.6 cm/s. The change in gait speed from baseline to after intervention was 33.9 ± 31 cm/s and from baseline to follow-up 3 months later was 42.0 ± 31.5 cm/s, corresponding to about 5 months after stroke for these subjects. The magnitude of change is much larger than that reported in recent studies involving BWSTT (21,106,108,109), which report a change in gait speed varying from 13 to 27 cm/s (posttherapy-baseline) and 15 to 24 at follow-up (follow-up-baseline). Others report gains of 14 cm/s after task-oriented circuit training (23) or 25 cm/s at follow-up after a home program designed to improve strength, balance, and gait (21). Bowden et al. (108) divided 27 subjects with chronic stroke (22.9 ± 17 months after stroke) into responders (n = 18) and nonresponders (n = 9) after BWSTT. The responders, who had an intital FML of 24.7 ± 3.7 and a baseline gait speed of 52 ± 18 cm/s, gained 27 ± 12 cm/s after 12 weeks of an intervention consisting of BWSTT plus overground walking provided 3×/week for 12 weeks.

Although it is difficult to compare subjects included in different studies, the FML and gait speed at baseline provide an indication of stroke severity. In these studies, the FML baseline mean scores varied from 23.1 to 28.7 (21,106,108,109), whereas the BBS was 42 in the Salbach et al. (23) study that did not report the FML. Baseline gait speed varied from 37 to 50 cm/s, a strong indication that the majority of the subjects were less impaired at baseline than the subjects described in Figure 19.5. Moreover, the interventions were started later after stroke, suggesting that much of the early gait recovery (1,83) had already taken place, so that the gains in gait speed would be expected to be smaller. Thus, the earlier intitiation of the intervention (2) likely explains a large part of the relatively large change in gait speed after therapy. There is an urgent need to better understand the importance of specific motor control and balance threshold levels necessary to surpass before further recovery can proceed and also how to foster maintenance of gains once the intervention ends to ensure continued improvements at follow-up and the persistence of those improvements thereafter.

MUSCLE GROUPS CONTRIBUTING TO THE GENERATION OF ENERGY FOR FORWARD PROPULSION, THEIR RELATIVE CONTRIBUTIONS TO WALKING SPEED, AND STRATEGIES USED BY PERSONS WITH HEMIPARESIS

Kinetic analyses such as moment of force and power profiles over the gait cycle help to understand *why* a subject has a given movement pattern and gait speed. The reader is referred to Winter (94) and Olney et al. (70) for details of the equipment, data, and formulae required to calculate joint moments (a *moment* is defined as the turning effect of a force about any point) and power (the *power* generated by a moment is the product of the moment acting at an axis and the angular velocity of the rigid body about that axis). The method of calculating muscle power is such that power generation (above zero on the y-axis) indicates that the power burst is achieved by a concentric contraction (at least for muscles crossing a single joint), thus further helping understand the force deficit. Work is the integral of power, with concentric and eccentric contractions producing positive and negative work, respectively. Since the seminal work of Winter (94), the contributions of the major muscle groups of the lower extremity contributing to the work of walking have become well known. The three major bursts

of energy generation and the propulsive force for forward progression come from the hip extensors in early stance (H1 in Figure 19.7), the plantar flexors at "pushoff" (A2 in Figure 19.7), and the hip flexors at "pull-off" (H3 in Figure 19.7) in late stance and early swing. The knee extensors in early stance (K2) produce a small amount of positive work. Most of the absorption is provided by the ankle plantar flexors (A1), the hip flexors (H2), the knee extensors (K1 and K3), and the knee flexors (K4).

Winter (94) further showed in healthy subjects that faster walking speeds were related to larger power generation bursts, particularly of the ankle plantar flexors at push-off (A2) that contributed most (about 75%) of the propulsive force, with the H3 hip flexor burst and the H1 hip extensor burst contributing most of the remainder. The contribution of the knee to the propulsive force was considered to be minimal. Many studies have since confirmed the influence of speed on energy generation (110,111,113). A study (113)

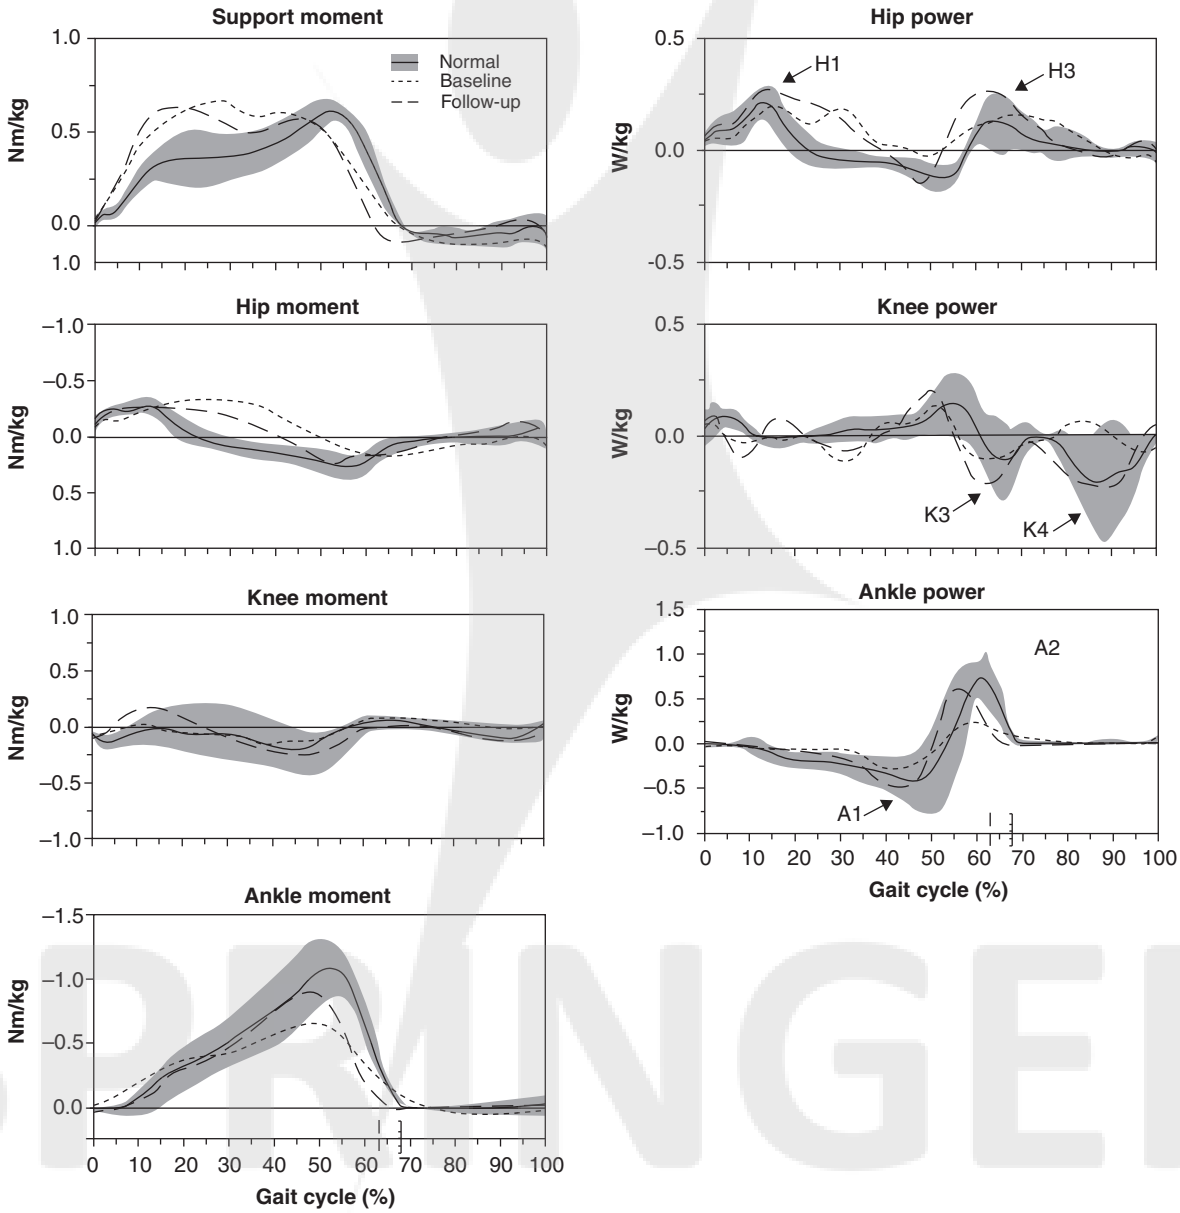

FIGURE 19.7 Comparison of the mean moment and power profiles for 19 subjects with subacute stroke who participated in the Richards et al. trial (2) before and after 2 months of task-oriented therapy with values obtained in healthy elderly controls walking slowly (59.7 cm/s, n = 5). Profile of moments and power (y-axis) are given in relation to the gait cycle in percent (x-axis). Mean baseline values for the subjects (dotted line) are compared to mean posttherapy values (interrupted line). Profiles in healthy controls represent mean 2 SD. The mean gait speed in the persons with stroke rose from 42 cm/s to 68 cm/s after therapy. Hip (H1 and H3) and ankle (A2) power generation and knee (K3 and K4) and ankle (A1) power absorption bursts are indicated.

that examined the effects of three metronome-induced cadences (60, 80, and 120 steps/min) on energy generation and absorption in healthy subjects found that the mean relative contribution of the ankle to mechanical energy generation was about 60% at the slowest cadence and fell to about 44% at the fastest cadence. In contrast, the 24% contribution of the hip at the slowest cadence rose to about 38% at the fastest cadence, whereas that of the knee increased from 16% to 19%. These findings indicate a large contribution from the hip muscles to the modulation of walking speed, whereas the ankle muscles are relatively insensitive to changes in speed—findings that are in agreement with previous studies (107,110,111,113). The variability, however, suggested that individual subjects likely used different strategies.

Do Persons With Stroke Employ the Same Kinetic Strategies to Produce Gait Speed as Healthy Subjects?

A stroke results in a walking disability because locomotor control is impaired. Although the impairment may be associated with different types of disturbed motor control (62,67–69,105), the net result is a diminished capacity of the lower-extremity muscles to act on the skeletal levers to produce rotational force at the hip, knee, and ankle. The impaired force output, in turn, results in altered power generation and absorption and can result in intralimb and interlimb compensatory gait patterns in which stronger muscle groups attempt to counter deficiencies by generating more than their normal work (70,71,96). In the first study examining the capacity for power generation in persons with chronic stroke, Olney et al. (70) divided a group of 30 subjects into slow (25 cm/s, SD = 5 cm/s, n = 10), intermediate (41 cm/s, SD = 8 cm/s, n = 10), and fast walkers (63 cm/s, SD = 8 cm/s, n = 10). Each subgroup comprised 10 subjects for a total of 30. They reported that in all three groups, the mean A2 power burst was smaller than that of healthy controls and, furthermore, that its magnitude was related to walking speed. The H3 power burst, in contrast, tended to be larger than in healthy controls, suggesting that persons with stroke compensate for a poor "push-off" burst by pulling off more at the hip. Not unexpectedly, given that walking is a bipedal task, they also reported that even if the power-generating capacity of the less-affected lower extremity differed from healthy values, the less-affected side performed a greater proportion of the positive work than the affected side at all speeds, approximately in a 60:40 ratio. From simulations, Higginson et al. (115) have shown that the contributions of individual muscles to the support moment in midstance of a person with stroke differ from those of neurologically healthy older subjects. The slower walking speed of persons with stroke, although no doubt a factor, cannot explain these differences in kinetic strategies, because persons with stroke walking at similar speeds may use quite different power combinations (65,114).

Data obtained from subgroups of the same cohort of patients that participated in the RCT (2) described in the previous section are used to illustrate the concepts relating to power generation and the production of gait speed. Figure 19.7 gives a comparison of the mean moment and power profiles produced by the affected side of 19 persons with stroke before (1.4 ± 0.5 months after stroke onset) and about 2 months after task-oriented gait training with values obtained in 5 healthy elderly persons walking at about 60% of their free gait speed (59 ± 7 cm/s). When comparisons are made with power profiles obtained from healthy subjects walking at free speed, the magnitude of the differences between the subjects with hemiparesis and the healthy subjects are much larger. As illustrated by the hip and ankle power profiles, the A2 ankle "push-off" power burst and the H1 hip extensor burst in early stance and the H3 hip "pull-off" burst in late stance and early swing phase increased after therapy. This increased power generation at the hip and ankle was associated with a mean increase in gait speed of 26 cm/s (42–68 cm/s). In this group of patients (n = 19), Richards et al. (72) found the peak of the A2 and H3 power bursts to be significantly correlated to gait speed ($r = 0.62$, $P < .01$, $r = 0.85$, $P < .01$, respectively) after stroke. At the end of the RCT, Richards et al. (2) reported a near-doubling of gait speed after therapy and reported that, in 25 of these subjects with prekinetic and postkinetic gait analyses, the increased gait speed was associated ($r = 0.52$, $P = .003$, $n = 25$) with an increase in the A2 ankle power generation burst of the affected leg.

The Relationship of Bilateral Ankle and Hip Power Bursts to Gait Speed

To further explore the choice of kinetic strategies used by persons with hemiparesis, bilateral kinetic analyses were made in a subgroup of 21 patients who participated in the RCT (Table 19.4) before and after task-oriented gait therapy for 2 months (2). Because we were particularly interested in the trade-off between a "push-off" (A2) or a "pull-off" (H3) strategy to create gait speed (dependent variable), the following variables (A2 peak power and H3 peak power on both the *affected* and *less affected* sides) were entered in the stepwise regression analyses, one on the baseline and the second on the posttherapy values (Table 19.5).

The regression analysis on the *baseline* values revealed that the peak A2 and H3 power bursts on the *affected* side explained as much as 84% (R^2) of the variance in gait speed in these subacute subjects who had an average gait speed of 40 cm/s. The results of the second stepwise regression analysis using the same bilateral kinetic variables *after therapy* (Table 19.5), however, show that the contribution of the *less-affected* side becomes important, with the H3 on the *less-affected* side replacing the *affected* H3 peak obtained in the baseline analysis. The A2 peak on the *affected* side and the H3 peak on the *less-affected* side thus explain about 82% of the variance in gait speed that had improved to an average of 58 cm/s after therapy. These results confirm the importance

TABLE 19.4 Selected Subject Characteristics of Slow and Fast Walkers. Subjects Walking ≥70 cm/s After Therapy Were Considered to Be Fast Walkers, Whereas Those Walking <70 cm/s Were Slow Walkers. These Subjects Participated in a Randomized Controlled Trial Evaluating the Effects of Task-Oriented Gait Training. Measures of Strength Were Obtained With a Hand-Held Dynamometer

	SLOW WALKERS (n = 13)	FAST WALKERS (n = 8)
Age (years)	67 ± 12	56 ± 11
Ashworth scale	2.4 ± 1.4	1.1 ± 1.1
Fugl-Meyer leg motor subscore	21.3 ± 6.1[a]	26.8 ± 3.5
Barthel ambulation subscore	20 ± 9.6	18 ± 8.5
Isometric hip flexor strength (Nm)	34 ± 23	48 ± 30
Isometric ankle plantar flexor strength (Nm)	16 ± 6	19 ± 6
Gait speed (cm/s)	28 ± 13[a]	52 ± 19
Change in gait speed with therapy (cm/s)	12 ± 12[a]	34 ± 20

[a]$P < .05$.

of the ankle A2 power burst both before and after therapy and demonstrate an interlimb strategy to gain speed after therapy.

Because the trade-off between hip and ankle power generators during walking is highly dependent on walking speed (94,107,110), comparisons of results in patients with different walking speeds are difficult. For example, in a group of subjects with chronic stroke who followed an 8- to 10-week training program, Parvataneni et al. (114) found that the mean gait speed increased from a mean of 69 ± 31 cm/s to 83 ± 33 cm/s (n = 28). When the change in gait speed was regressed on the chosen predictor variables of change in positive work, the first variable selected was the affected H1, which alone accounted for 66% of the variation in change of gait speed. A2 was the second variable selected, which, together with the affected H1, accounted for 75% of the variation in gait speed. A second model, which included only the affected and less-affected H1, accounted for 74.3% of the variation in gait speed. These models resulting from the regression analyses confirm that subjects with hemiparesis increase their gait speed with a combination of H1, H3, and A2 work on the affected side and H1 and H3 on the less-affected side (114). Clinically, this suggests that the gait speed of subjects with similar characteristics could be increased with appropriate changes in a combination of these positive work variables during gait.

Changes in Hip and Ankle Power With Recovery

To further examine the relationship of changes in the A2 and H3 peak power bursts bilaterally with gait speed, the 21 subjects were divided into fast (≥70 cm/s after therapy) and slow (≤69 cm/s after therapy) walkers (Table 19.4). Figure 19.8 illustrates the relationship between changes (posttherapy minus pretherapy values) in the H3 and A2 peak power bursts bilaterally in the two groups.

TABLE 19.5 Stepwise Regression Analyses of the Relationship Between Peak A2 and H3 Power Bursts on the Affected and Less-Affected Sides of 21 Persons With Stroke While Walking at Comfortable Speed, With Gait Speed Before Therapy (Baseline) in the First Model and With Gait Speed After Therapy in the Second Model

	R	R SQUARE	ADJ R SQUARE	STD ERROR
Model at baseline

H3, less-affected side				

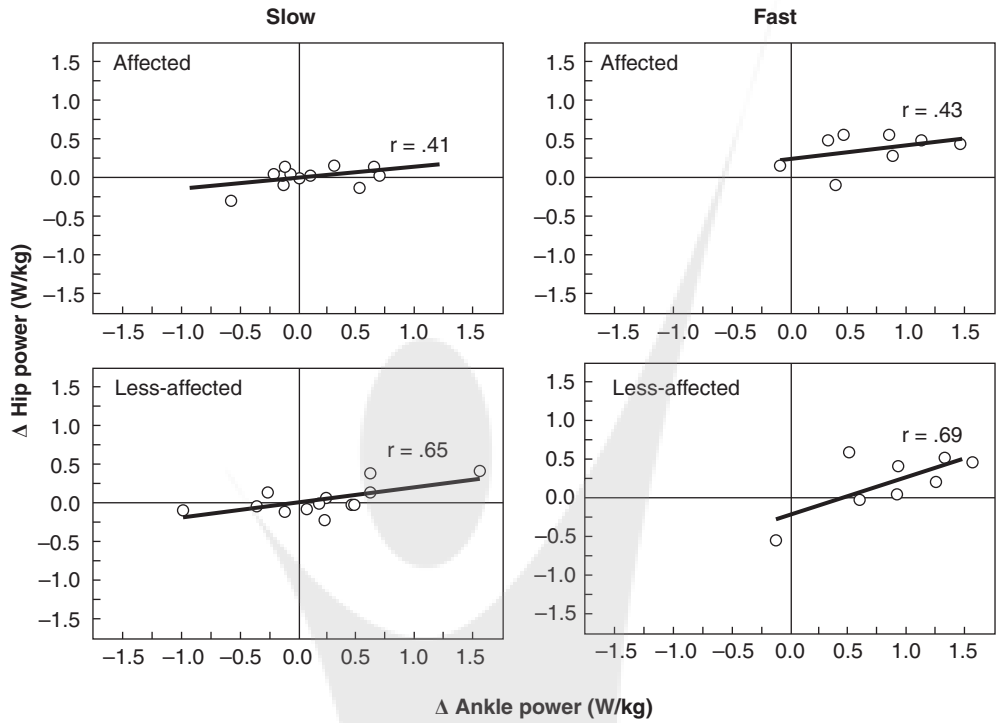

FIGURE 19.8 Concomitant change (after therapy minus baseline values), defined as recovery, in the A2 ankle power burst (x-axis) and the H3 hip power burst on the affected and less-affected sides of the group of slow (n = 13) and fast walkers (n = 8) described in Table 19.4. Correlations obtained with Pearson correlation coefficients.

In the group of fast walkers, the points cluster mainly in the upper right quadrants for both the affected and less-affected sides, indicating an increase in both the H3 and A2 power bursts. In one subject, the hip power decreased after therapy, whereas in another the ankle power decreased. Among the slow walkers, the points tend to cluster more near the intersection point of the quadrants, indicating that the changes are smaller. On the affected side, two subjects had concomitant decreases in the A2 and H3 bursts, whereas five had little change in the A2 burst. Only three had concomitant increases in both the hip and ankle powers. This graphical representation emphasizes the very small, lack of, or even negative changes in the power-producing capacity of the ankle plantar flexors and hip flexors on the affected side despite two months of task-oriented gait training. The magnitude of the correlations between change in the ankle plantar flexors and the hip flexors once again demonstrates the variability in kinetic strategies used to walk. The similar correlations for both the affected and less affected sides in the slow and fast walkers may be related to a matching of the sense of effort (116).

One can also question whether persons after stroke are capable of tapping into their full dynamic strength potential during walking. Milot et al. (116,117) have used a muscular utilization ratio (MUR) that relates the net moment produced during gait to the muscle's maximal capacity to quantify the level of effort in key muscle groups used by healthy persons and persons with chronic stroke during walking. When compared to a group of healthy individuals (117), they found the MUR values to be higher in the persons with hemiparesis, that the weakest paretic muscle groups had the highest level of effort during gait, and that persons with chronic stroke walking at self-selected and maximal speeds increase their MURs with gait speed. Thus, in a group of persons with stroke walking at a relatively fast mean self-selected speed (73 ± 27 cm/s, n = 17), the peak MURs on the affected side were 64%, 46%, and 33%, for the plantar flexors, hip flexors, and hip extensors, respectively. These values rose to 77%, 72%, and 58% at the maximal speed (126 ± 39 cm/s). Thus, the plantar flexors were the most used muscle group at self-selected speed, whereas at maximal speed, although the MUR value of all three muscle groups increased, that of the hip muscles increased more than the ankle. Thus, the analysis of the MURs concurs with that of the positive work generated at different speeds (113) during walking, with both showing the contribution of the plantar flexors to remain relatively constant at self-selected and maximal speeds, whereas the use of the hip muscles is increased at maximal speed.

In a subsequent study, Milot et al. (118) examined the effects of increased plantar flexor and hip flexor muscle strength following an isokinetic strengthening program on the levels of effort (MURs) during gait of a group of 24 persons with chronic stroke walking at both self-selected and maximal speeds. They observed a reduction in MUR ratios of 12% to 17% in the affected plantar flexors and

hip flexors and strength gains that were associated with a significant but small increase in gait speeds after training. Thus, as the subjects became stronger, they apparently favored a reduction in the levels of effort during walking instead of substantially increasing their gait speed. A logical extension of this work would be to test whether the decreased level of effort leads to better functional endurance during walking.

Interestingly, both healthy individuals and persons with stroke have similar MUR values for the muscle groups between sides at both self-selected and maximal speeds (117). This observation of similar levels of effort on the affected and less-affected sides, despite a more pronounced weakness of the affected distal muscles, led to the interpretation that the asymmetrical gait pattern of persons with hemiparesis could represent a means of preserving a similar, perceived sense of effort between the affected and less-affected sides. Simon and Ferris (119), building on work suggesting that healthy individuals use a sense of effort more than proprioceptive feedback to gauge force production in the upper limbs, recently demonstrated a similar mechanism in the control of asymmetrical force in the lower limbs in healthy subjects, providing evidence that the limb force asymmetry was related to neural factors rather than differences in mechanical capabilities between the limbs.

SUMMARY

This chapter has examined patterns of locomotor recovery after stroke as determined by different methods of evaluation. The use of clinical measures or the attainment of benchmarks, such as discharge from rehabilitation or the ability to walk with help or unassisted, provides an assessment of recovery of function that can be used to evaluate change related to therapy and in the planning of care programs. Such measures do not, however, assess change in biomechanical or neural variables related to locomotor control in relation to normal values. When an increase in gait speed is used as a surrogate for recovery, the poor recovery of the majority of stroke survivors, even after two months of therapy, becomes very obvious. Only the minority attain gait speeds that allow them to ambulate freely in the community (86,91), and it is those who walk at speeds less than 40 cm/s who benefit most, as reflected by a change in category (91). Nevertheless, few are able to cross busy streets in large cities (23,87). It is also important to realize that gait speed can continue to increase up to two years after stroke without formal therapy after discharge from rehabilitation, and that persons with chronic stroke can increase their gait speed with task-oriented circuit training (22,23).

These results also showed that gait speed at therapy initiation—at least in the subacute state when therapy in the rehabilitation center was started—predicts about 40% of the variance in gait speed after 2 months of task-oriented therapy. As expected, the change in the slowest walkers, who were likely the most severely affected, was small. The time of therapy initiation was also related to the recovery of gait speed, even though therapy was delayed because of constraints related to transfer from an acute hospital. Although the axiom "the earlier, the better" is used to describe the optimal time of therapy initiation, little is known about the optimal time, and further studies are indicated to guide therapy. In this group of stroke survivors, the recovery in gait speed was similar in persons with right and left hemiparesis. Again, these findings have to be confirmed in groups of persons with different severities, times of therapy initiation, and types of therapy.

As suggested in this chapter, it would also be beneficial if clinicians had access to full biomechanical gait evaluations (kinematics and kinetics) to guide their therapy selection in individual cases. Knowledge of the kinetics (muscle activations, muscle moments, and powers) helps understand "why" a subject walks with a given movement pattern and walking speed and provides clues for the choice of therapy. For example, the salient aspect of the disturbed motor control in an individual may be paresis, excessive muscle coactivation, spasticity, or hypoextensibility of the muscles because of nonneural factors (62,67–69); each of these requires different therapeutic approaches. Understanding the moments and powers acting at the joints to produce propulsive force mediating walking speed helps pinpoint not only the individual power-producing strategies but also the therapeutic targets for improvement (65,70,78,95).

Although the movement profiles of hip, knee, and ankle during the gait cycle tend to improve with increasing gait speed, they will only rarely return to "normal." Moreover, these abnormal gait movements are associated with patterns of muscle activations that differ in both timing and amplitude from normal values. Comparison of functionally important activation bursts in the TS, TA, and QUAD muscles over time with normal values revealed that the TA showed the most recovery and the TS the least. The late change in the QUAD also suggested that muscles may have different temporal patterns of recovery. Although these findings were obtained in a small number of subjects and must be confirmed in other longitudinal studies of recovery, they are intriguing and worthy of further study. The lack of recovery in the TS is particularly worrisome because of the role of that muscle in propulsion and the emphasis placed on it in locomotor therapy. In contrast, these findings suggest that the TA has an untapped and poorly understood potential in locomotor recovery.

Comparisons of the power and work profiles during gait in persons after stroke with normal values have revealed that persons after stroke tend to compensate for a poor power generation at the ankle by increasing the generation of power at the hip and that, with therapy, they may choose to produce gait speed by adopting a strategy that depends on the hip of the less-affected leg. Although variable, these compensatory power-generating strategies again point to poor recovery in the ankle "push-off" power-generating burst and the use of compensatory strategies involving the hip power generators to increase walking speed.

RESEARCH FRONTIERS

Sense of Effort and Force-Scaling

As persons with chronic stroke became stronger, they apparently favor a reduction in the levels of effort during walking instead of substantially increasing their gait speed (116). This finding opens a new area of inquiry into the mechanisms controlling the symmetry of effort at self-selected walking speeds. These investigators (117) have also shown that normalizing joint moments during gait to the maximum joint moment capabilities led to similar effort levels in the affected and less-affected limbs of persons with chronic stroke during walking. Thus, it seems that sense of effort is an important factor in determining lower-limb muscle activations in persons with hemiparesis. Force-matching studies (119,120) thus suggest that, in addition to strengthening the affected lower-extremity muscles, rehabilitation approaches should also address the impaired force-scaling ability. Simon et al. (121) advocate that symmetry-based resistance has the potential to improve both force-scaling ability and limb strength because subjects can learn to scale muscle activations more appropriately to achieve a desired force outcome. This would enable persons with stroke to better match paretic limb forces to task requirements during activities of daily living.

Functional Cognition and Walking Competency

Even though up to 65% of stroke survivors have new onset or worsening of cognitive deficits after stroke (122–125) that interfere with functional recovery and the potential benefits of rehabilitation (123,125,126) and lead to falls (127), the rehabilitation of cognitive deficits and, in particular, the impact of cognitive deficits on walking competency have been largely ignored. Members of the rehabilitation theme of the Canadian Stroke Network have identified cognitive deficits as a priority area for research (128), and recognizing the need, the National Institute of Neurological Disorders and Stroke (NINDS) and the Canadian Stroke Network have joined together to establish criteria for systematic study of cognitive deficits associated with stroke (129). In a recent paper devoted to conceptualizing functional cognition in stroke, Donavan et al. (123) defined *functional cognition* "as the ability to accomplish everyday activities that rely heavily on cognitive abilities." Walking competency (23) implies that, in addition to the physical capacity to walk fast enough to cross streets and far enough to be able to walk about in the community, a person also has the planning abilities to navigate among others and to find his or her way, as well as to make locomotor adjustments to meet the demands of the changing environment.

There is a growing body of literature from both the aging and clinical populations that examines the role of cognition in locomotion. The main approach to study of the interaction between cognitive processing and motor behavior is the dual task paradigm. Thus, Plumer-D'Amato et al. (130) have shown that, in persons with stroke living in the community, speech produced more gait interference than memory and visuospatial tasks and that, even though the participants were mobility impaired, they prioritized the cognitive tasks. Future research is needed to determine if dual task training can help reduce gait decrements in dual task situations. In this regard, the use of virtual reality paradigms provides the opportunity to combine physical locomotor training on the treadmill with cognitive training that is goal directed and motivating for persons with chronic stroke (131).

Studies are also needed to better understand the importance of *self-efficacy*, defined as a judgment of one's ability to organize and execute given types of performances (132), in the success of locomotor training programs. For example, Salbach et al. (133,134) found that enhancing balance self-efficacy in addition to functional walking capacity, when compared to enhancing functional walking capacity alone, may lead to greater improvement, not only in perceived health status, but also in physical function. Much work is needed to better elucidate the interaction between cognitive function and walking competency, as well as the development of adequate rehabilitation programs to target impaired cognitive function in persons with stroke.

Mental Practice as an Adjunct to Physical Practice

Another alternative for locomotor retraining in patients with severe motor impairment is the use of mental practice through motor imagery (135). Using transcranial magnetic stimulation, Pascual-Leone and colleagues (136) reported that mental practice produced representational changes in the brain comparable to those yielded by physical practice. Moreover, they found that subjects who had mentally practiced a one-handed piano exercise for five sessions and then added only one physical session reached the same level of performance as those who practiced physically for five sessions. The latter findings suggest that part of the behavioral improvement seen in the mental practice group may be latent, waiting to be expressed after minimal physical practice. Mental practice in subjects who cannot walk or with limited walking capacity could thus have a preparatory effect on the task, hence increasing the efficiency of subsequent physical training (136). The priming effects of mental practice have been extended to movements of the lower limbs in a PET study (137). Indeed, after five days of intense mental practice of a foot movement sequence, subjects were able to complete the sequences of foot movements faster, both mentally and physically. In addition, similar dynamic changes during both modalities (imagination and execution) were observed, hence demonstrating that learning a sequential motor task through motor imagery practice produces cerebral changes similar to those observed after physical practice of the same task (137). Combining physical and mental practice has also been found to promote the learning of a foot movement sequence after stroke (138).

To date, positive effects of mental practice on gait speed and step length have been reported after stroke in a series of patients with chronic stroke (139–141). Two recent

well-controlled trials (142,143) compared physical practice (physical therapy or treadmill training) alone or combined with mental practice and reported larger gains in gait speed with the addition of mental practice.

To conclude, results to date suggest that mental practice has potential as an adjunct to physical practice to promote the recovery of mobility tasks and walking ability after chronic stroke. Future studies should try to better control the nature and the dose of concomitant physical practice in both experimental and control groups so as to tease out the effects directly related to motor imagery. It is also essential to monitor adherence of the patients to the intervention by means of training strategies that favor vivid images that can be verified. The temporal congruence of imagined and physically executed movements is another way to monitor motor imagery. Patients should be trained in motor imagery to ensure that they are able to engage in motor imagery. To be able to attribute therapeutic effects to motor imagery, it is also essential to evaluate the motor imagery capacity of the patient prior to and during the intervention.

For patients who have difficulty or are unable to engage in motor imagery, action observation remains an interesting alternative for developing their walking capacity (144,145). This suggestion is based on findings that, like the imagination, the execution and the observation of a movement are controlled by more or less the same brain areas (146–148). Indeed, mirror neurons in the premotor cortex and the inferior parietal cortex discharge not only during the performance of a goal-directed movement, but also while observing the movements performed by another person. Thus, when a person sees an action performed by someone else, neurons representing that action are activated in the observer's premotor cortex so that, automatically, motor representations involved in the execution of that action are activated. Hence, observing an action directly activates the motor commands needed for performing that action.

ACKNOWLEDGMENTS

This work has been supported over the years by grants from the National Health Research and Development Program of Canada, the Canadian Stroke Network, the Canadian Institutes of Health Research, the Canadian Foundation for Innovation, and the "Fonds de recherche du Québec-Santé" and the CIHR-Sensorimotor Rehabilitation Research Team. Task-Oriented Training to Promote Upper Extremity Recovery

Carolee J. Winstein, Steven L. Wolf, and Nicolas Schweighofer

Task-oriented training has emerged as the dominant approach to motor restoration for stroke-induced motor impairments. Results from recent phase III randomized clinical trials (RCT) provide evidence that more intensive therapy and practice of functional tasks are far superior to the current standard of care (1,2). This updated chapter provides the background for the emergence of a task-oriented/task-specific approach to promote functional recovery after stroke. The first section, "Emergence of Task-Oriented Training for Neurorehabilitation" includes recent views on the restitution–substitution continuum of recovery. To move beyond a simplistic interpretation of task-oriented training, the section, "Criterion-Based Task-Oriented Training: What Are the Active Ingredients?" highlights recent evidence concerning the "active ingredients" for effective therapy approaches to promote motor learning and functional recovery. The section "Constraint-Induced Movement Therapy: A Special Class of Task-Oriented Training?" presents the argument that constraint-induced movement therapy is a special class of task-oriented approaches. In the section "Motor Control and Learning Considerations," we draw from the extensive foundations in the behavioral sciences of motor control and learning to consider the "pharmacokinetics" of training, including practice schedules, practice time and intensity of training, the organization of training, and the contents of training. Importantly, we include consideration of motor severity, timing of training, and dosing. In the section "Considerations From the Neuroscience Perspective," we review the behavioral signals driving neural plasticity in the context of rehabilitation. In the section "Emerging Innovative Approaches to Upper Limb Rehabilitation" two examples are provided of emerging innovative approaches to upper limb rehabilitation. The first is a multimodal combination intervention using noninvasive brain stimulation combined with physical therapy. The second example is a fully defined evidence-based hybrid combination of skill-based/impairment-mitigating motor skill training with embedded motivational enhancements that we define as the Accelerated Skill Acquisition Program (ASAP). Finally, the section "Research Frontiers" provides a revised and expanded overview of four related research frontiers in neurorehabilitation including an expanded section on predictive models.

EMERGENCE OF TASK-ORIENTED TRAINING FOR NEUROREHABILITATION

The 2006 National Institutes of Health, National Institute for Neurological Disorders, and Stroke (NINDS) Stroke Progress Review Group summarized what it considered to be the most significant of scientific accomplishments since its last published guidelines in 2001. In particular, the workgroup concluded that *task-oriented training* had emerged as the dominant approach to motor restoration. Other highlighted findings, including the delivery schedule of training, motivation, and characteristics of treatment participants (e.g., severity of motor deficits and co-existing sensory or cognitive impairments), continue to be active areas of research. Further, the panel identified that clinical trials in this area proved more challenging than previously anticipated, with variables in dosing, timing, and duration adding to their inherent complexity and resolving the question of whether the training paradigm matters (3).

In 2012, NINDS released its report from the Stroke Research Priorities Meeting pertaining to the top scientific research opportunities from workgroups on stroke prevention, treatment, and recovery research (4). For recovery, the report defined two priorities: (a) translational research using neural interface devices for stroke and other neurologic disorders, and (b) translational research targeting early recovery after stroke in humans (4). In October 2013, NIH established StrokeNet, a network of 25 regional research centers working with nearby satellite facilities around the country, each with teams of researchers representing every medical specialty needed for stroke care, to address the three prongs of stroke research: prevention, treatment, and rehabilitation/recovery. The network concept evolved from an NINDS planning effort in which stroke experts were asked what is most needed to reduce death and disability caused by stroke in the United States. They called for a nationwide stroke network that would allow for a more seamless transition between early safety and efficacy trials and phase II and III clinical trials.

There continues to be a substantial number of small-scale, preclinical feasibility studies pertaining to task-oriented approaches for upper extremity recovery. These

kinds of studies, if well designed, are important, particularly if they have a strong scientific foundation (conceptual and theoretical) for the kinds of translational research that could leverage the opportunity enabled by StrokeNet. The translational work that will be hosted by StrokeNet in the next five years will likely infuse new energy into the clinical research enterprise by promoting more basic work as well as the clinical translation of task-oriented approaches across different care settings (5,6).

What Is Task-Oriented Training?

Task-oriented training is now prevalent within the field of neurorehabilitation but continues to lack clear criteria, that is, there is considerable variability in the literature as to what constitutes a task-oriented training approach. From a disablement/enablement perspective, such as the World Health Organization's International Classification of Disability and Functioning (7), task-oriented training is described best as a top–down approach to rehabilitation (see top–down model) (8). This approach is one that addresses activity limitations, rather than the specific and isolated remediation of impairments (9–12) or specific movement kinematics (i.e., body functions/structures). In the literature, this top–down approach has been referred to as a "motor learning" or "movement science" approach to rehabilitation (13), "task-specific training" (9), "task-related training" (14–17), "functional task practice" (18), or "goal-directed training" (19–21). Task-oriented training is based on integrated models of motor control, motor learning, and behavioral neuroscience, where active participation and skill acquisition are critical components of recovery. Consistent with a patient-centered perspective of motor control, the manner in which voluntary movement is elicited after a stroke represents the best efforts to achieve "functional task goals" given the constraints imposed by the stroke-induced impairments, the personal attributes, the environment, and the demands of the task (22–25). With these assumptions, and considering this conceptual framework, the patient is viewed as an ***active problem solver***, and ***rehabilitation is focused on the acquisition of skills*** for performance of meaningful and relevant tasks. Although task-oriented training approaches highlight the importance of repetition and task specificity, they sometimes downplay the achievement of skilled movement in the service of functional tasks. A subtle but important point is that *the pursuit of skilled movement*, rather than merely functional actions (i.e., activities of daily living [ADL]), is both relatively demanding and engaging and invokes natural goal-directed advantages—that of seeking skilled performance rather than simply task accomplishment. These activities therefore are distinct from rote or exercise-based movements that can be abstract and without a preconceived and task-based functional goal (10,26–28).

It should be obvious from this discussion that a precise and evidence-based definition of task-oriented training is essential to stimulate further advances in neurorehabilitation. There is, however, a clear distinction between task-oriented training approaches and the more traditional bottom–up neuromuscular reeducation approaches that dominated neurorehabilitation well into the 1980s.

How Is Task-Oriented Training Different From Neuromuscular Reeducation?

When one reviews a magnificent compendium of work that characterizes rehabilitative efforts to improve movement among patients with central nervous system deficits and that is housed within the landmark Northwestern University Special Therapeutic Exercise Project (NUSTEP) volume (29), one is struck by the outstanding efforts set forth among a dedicated group of clinicians, whose collective treatment formulations were derived from elements of fundamental neurophysiology. The emergence of such "approaches" as advocated, for example, by Brunnstrom, Bobath, Rood, Knott, and Doman-Delgado were sincere efforts to guide practice by encouraging clinicians to treat patient impairments using specific directives. These efforts at "neuromuscular reeducation" were appreciated by physical and occupational therapists because they provided some of the initial foundations and translation of the science for implementation of clinical practice. Many of these techniques are still in use. However, even with their births and subsequent evolution, their collective value has been hampered by a series of concerns, the significance of which becomes more meaningful with the development of more sophisticated assessment tools and with advances in scientific exploration. Among these concerns is the fact that the bases for most "neuromuscular reeducation techniques" never were externally validated. That is, the relevance and verification of observations extracted from animal preparations (often using anesthetized animal preparations) were not confirmed in a convincing fashion among human subjects before the formulations of specific techniques were disseminated. Second, very few outcome measures existed, and those that did lacked confirmatory validation until subjected to study and refinement that did not begin until the mid-1980s. Moreover, many procedures permitted the use of compensatory behaviors rather than optimizing function within the context of maximal utilization of the impaired neuromuscular substrate. Last, much of the emphasis of neuromuscular reeducation was focused on the impairment level of disablement (i.e., "body functions/structures" in the ICF framework) without considering adequately the implications or relevance to voluntary participatory behaviors (i.e., "activity" in the ICF framework) or the importance of changes in life roles or health-related quality of life (i.e., "participation" in the ICF framework).

One area of clinical activity that gained considerable popularity during the last three decades of the 20th century was biofeedback, especially electromyographic (EMG), position, and force feedback. These forms of biofeedback were particularly applicable to rehabilitation of patients with musculoskeletal or neuromuscular disorders. Force feedback continues to thrive in the form of posturography to improve balance, whereas an interface like virtual reality is listed as a contemporary form of feedback (30). EMG biofeedback to

restore limb movements following stroke was the subject of considerable research during that 30-year interval. A recent PubMed search (May 10, 2014) cross-referencing the terms stroke and biofeedback identified 376 articles of which only 88 were published prior to 2000. However, a consistent direction followed by these studies highlighted the importance of knowledge of results (usually postresponse information about performance relative to the goal) to improve movement. In addition, the working hypothesis for training was dependent upon the neuromuscular reeducation principles previously discussed. For example, feedback about muscle activity was provided to reduce hyperactivity in "spastic" muscles. This was thought to be necessary prior to recruitment of antagonist muscles and was to progress in a proximal to distal direction. These concepts had been extracted from studies using animal models but without comprehensive clinical validation prior to implementation. Moreover, efforts to delineate the most critical elements or procedures to succeed in rehabilitative biofeedback applications did not systematically explore optimal provision of this training or integrate feedback forms within task reacquisition. As a result, emphasis was placed on altering impairment status without substantial consideration of: (a) activity or participatory changes, (b) integration of training within tasks deemed important to the user, or (c) quantification of outcomes using kinematic and kinetic measures to determine the extent to which outcomes could be classified along the restitution–substitution continuum. Even more contemporary work that examines functional magnetic resonance imaging (fMRI) changes with biofeedback training for improved ambulation (31), video gaming (32), or neurofeedback in combination with EMG biofeedback, (33) has thus far focused on the relationship of changes in impairments to measures of cortical reorganization. These studies could be more substantive if they also included outcome measures pertaining to the activity or participatory domains of the ICF model.

From this contemporary biofeedback work and other examples such as rehabilitation robotics, it is evident that a more traditional focus on the impairment/body structure domain of the ICF is important for providing insight pertaining to the restitution–substitution continuum of motor control (34). On the other hand, it has been argued that a change in function (e.g., better hand use) measured at the activity level of the ICF (e.g., using Action Research Arm Test [ARAT] (35)) may reflect adaptation of the movement behavior through a substitution–compensation mechanism rather than a restitution/–recovery mechanism. However, Krakauer and colleagues argue that if we do not measure the kinematics of the movement (36), or use some valid measure at the impairment level (e.g., Fugl-Meyer Motor Assessment), we cannot ascertain the mechanism of change in the behavior. Without such measures, we will not be able to develop new assessments or interventions that target specific mechanisms for motor control and learning (37). Maladaptive or "bad use" can occur when less optimal, unskilled solutions—ones that rely on compensatory strategies—are used (36,38–43). This can contribute to incipient declines after therapy ends and gains are not generalized (44). The hypothesis as yet untested is that if we do not understand how the movement problem was solved (i.e., restitution vs. substitution), we cannot optimize recovery. We will say more about this in the last section, Research Frontiers.

CRITERION-BASED TASK-ORIENTED TRAINING: WHAT ARE THE ACTIVE INGREDIENTS?

It is now fairly well accepted that ***behavioral demands*** and ***motor skill acquisition*** are critical drivers to cortical reorganization associated with positive functional outcomes following a stroke or stroke-like lesion in animals (45–48). In nondisabled adults, the kinematics of arm and hand movements have been shown to be uniquely constrained by the behavioral goals of the movement and the characteristics of the to-be-grasped object, such as spatial location and object shape and size (49–51). After stroke, there is evidence to suggest that the emergent movement kinematics are organized differently for real objects compared with simulated or artificial objects. Upper limb movement kinematics were more efficient when the goal-directed activity included reaching for a ringing telephone, compared to simulated contexts such as reaching for a stick (52) or no object (51). Thus, the fidelity of the task in the natural context seems to be a critical ingredient of effective task-oriented training programs. In addition, greater transfer of training to life activities might be anticipated from such task-oriented training, particularly given the focus on familiar everyday tasks, and transfer to unpracticed tasks might be possible given the focus on the development of problem-solving strategies.

It is well known that training programs that are designed to enforce the ***practice of problem solving*** usually are more effective for learning than those that are drill-like and enforce mere repetition of the previous solution to the movement problem (53,54). Taken together, and compiled from perspectives including brain, cognitive, and the social sciences, we propose a minimum of three active ingredients thought to be critical for an effective task-oriented training program. The program must:

1. **Be challenging** enough to require new learning and engagement with attention to solve the motor problem (48).
2. **Be progressive and optimally adapted** such that over practice, the task-demand is optimally adapted to the patient's capability and the environmental context. It must not be too simple or repetitive to not challenge and not too difficult to cause a failure of skill acquisition or a low sense of competence (55,56). Extending the environmental context outside the laboratory or clinic is an important aspect of an optimally adapted patient-centered program. This reinforces the "real-life" benefits through a virtuous cycle that becomes self-sustaining.
3. **Solicit active participation** to engage a "particular type of repetition" that Bernstein referred to as "problem-solving" (57).

It should be noted that these three criteria (i.e., challenging, progressive and optimally adapted, and active participation) are likely not independent but rather overlap and are complimentary in nature. Equally relevant to these criteria is the growing awareness of protocols that directly address the three fundamental psychological needs—autonomy, competence, and social-relatedness. Of importance, there is mounting evidence that when these needs are considered in the context of instructions or expectations, they benefit the motor learning and the rehabilitation process (58).

CONSTRAINT-INDUCED MOVEMENT THERAPY: A SPECIAL CLASS OF TASK-ORIENTED TRAINING?

During the last decade and a half, a class of intervention studies that has addressed the suboptimal recovery of upper extremity function, and for which there is mounting evidence, is the family of forced-use and constraint-induced movement therapy protocols (59–66). Along with the publication of the EXCITE trial results (1,67,68), there have been numerous small (69,70) and larger-scale (65) studies showing efficacious results for constraint-induced movement therapy in restoring motor function in patients with upper extremity motor impairments. A modified protocol was shown to be effective in outpatient (60), clinic (62), and home settings (61), and even feasible in the acute in-patient setting (71).

Constraint-induced movement therapy protocols combine the use of a constraint (restraint mitt worn on the less-affected limb) and training of the affected arm and hand. The restraint device can be thought to exert an indirect effect on paretic limb use by preventing compensatory use of the less-affected limb for some tasks, whereas the task-specific training with the paretic limb can be thought to exert a direct effect on paretic limb use. Several studies of constraint-induced movement therapy used a training duration of 14 days (2 weeks), in which 10 of those days included six hours per day of supervised in-laboratory task practice training with the participant's less-affected upper extremity placed in a protective safety mitt for a goal of 90% of their waking hours (64,65,72,73). One study compared the effectiveness of a six-hour per day training protocol to one half as long (three hours per day) and found that though the shorter training period produced significant and functionally relevant treatment effects, the longer training protocol produced even greater efficacy in young adolescent participants (73). Because the two groups had equivalent restraint use times, Sterr and colleagues suggest that the major factor contributing to the gains in upper extremity function comes from the massed practice that occurs during training. In essence, task-oriented training may exert a greater influence on recovery than the restraint when overcoming the effects of learned-nonuse, but this hypothesis is controversial with other findings using a modified protocol showing that reduced levels of training relative to mitt use are also effective (60,74,75).

In addition to mitt use, two distinct training procedures were employed with these participants as they practiced functional task activities: shaping or adaptive task practice (ATP) and standard task practice (TP). The former is a training method based on the principles of behavioral training (76–78) that also can be described in terms of motor learning derived from adaptive or part-task practice (79–82). In this approach, a motor or behavioral objective (task goal) is approached in small steps, by successive approximation (i.e., parts of the task), by making the task more difficult in accordance with a participant's motor capabilities, or by progressively increasing the speed of performance. Each functional activity is practiced for a set of 10 trials, and explicit positive feedback is provided regarding the participant's performance with each trial. Standard task practice (TP) is less structured (e.g., the tasks are not set up to be carried out as individual trials of discrete movements); they involve functionally-based activities performed continuously for a period of 15 to 20 minutes (e.g., wrapping a present, writing a letter). In successive periods of TP, the spatial requirements of the activity or other parameters (such as duration) can be changed to require more demanding control of limb segments for task completion. Global feedback about overall performance is provided at the end of the 15- to 20-minute period. For the majority of signature protocol CIMT studies, the training tasks are selected for each participant using the following criteria: (a) specific joint movements that exhibit the most pronounced deficits, (b) joint movements that trainers believe have the greatest potential for improvement, and (c) participant preference among tasks that have similar potential for producing specific improvements.

For the EXCITE trial, a large bank of tasks was created for each type of training procedure. Additional tasks could be submitted and added to the bank of approved tasks only after receiving approval from the EXCITE Training Core. The task bank consisted of 71 adaptive task practice (ATP) activities (e.g., ring toss, nuts and bolts, pouring from mug) and 42 TP activities (e.g., setting table, dusting, eating with chopsticks). All practice items were considered "task oriented" and were items from a broad range of everyday activities including: food preparation, dining, cleaning, home maintenance, laundry, office, recreational, and instrumental activities of daily living.

Published CIMT protocol descriptions have included shaping procedures to progress task difficulty, the provision of optimal challenge, and multifaceted approaches to encourage active participation (e.g., behavioral contract, constraint mitt). Taub and colleagues suggested that a key to the optimal outcomes with CIMT resides in the use of a comprehensive transfer package—a set of techniques to facilitate transfer of therapeutic gains from the laboratory to the life situation (83). Earlier work investigated the long-term effects of the "transfer package" to facilitate actual use of the trained affected arm in activities of daily living (44). One group received 4.5 hours of intensive task training and 0.5 hours of transfer package whereas the control group received 5.0 hours of intensive task training per day during 10 consecutive workdays. As expected, both groups showed increase in arm function after intervention, but at

the six-month follow-up, only the transfer package group showed continued increase in arm function compared to the control group.

To date there are no systematic "head to head" comparisons of these models that could determine if any one of them is superior. Accordingly, we suggest that CIMT be considered a special class of task-oriented training. The most important difference is that forced-use/CIMT protocols tend to negate other approaches for training, such as bimanual task practice (84). Further, there is no formal attention to impairment mitigation (e.g., strengthening, range of motion), use is promoted to a greater degree than skill, and personal social–cognitive factors such as perceptions, expectations, and motivations are lacking. Although disentangling the individual contributions to arm and hand improvements of constraint (i.e., mitt use) and task practice embedded in CIMT protocols are not possible at this time, there is emerging support for the effectiveness of task-oriented upper limb training in the subacute phase following stroke, particularly in those individuals who suffered their first-ever stroke that resulted in mild to moderate unilateral upper limb paresis.

In a majority of clinical trials during the subacute phase, and one case study, participants who received task-oriented training, without using a constraint, demonstrated significant improvements in upper limb motor impairment and in activity limitations immediately after intervention (16,85–87). However, significant between-group differences in favor of task-oriented training were most apparent when long-term upper limb outcomes were evaluated many months following the intervention (85). One interpretation of these findings is that in the subacute phase, there has been less opportunity (less time) for robust learned-nonuse strategies to dominate, and patients in this phase are less likely to benefit from an approach that emphasizes the reversal of learned-nonuse compared to one that emphasizes motor relearning through skill acquisition, problem solving, and self management. On the other hand, data from the EXCITE Trial provide a unique opportunity to compare an identical intervention (constraint-induced movement therapy) delivered by the same clinicians to participants within three to twelve months after stroke or exactly one year later to their enrollment date. Whether or not the delayed CIMT participants received other interventions during the year in which they were awaiting the provision of CIMT did not seem to matter. All those individuals improved equally after they received the constraint training and actually reached the same point of recovery using the Wolf Motor Function Test (88,89) as an outcome measure, but the rate of improvement following the two-week CIMT intervention was significantly greater in the subacute participants (68). Whereas the findings are restricted to stroke survivors with mild to moderate upper extremity impairment, the results suggest at least two key observations: (a) recovery can occur more than one year following stroke; and (b) the rate of that recovery appears more substantial when CIMT was delivered in a subacute population. The latter finding may be because of less profound learned nonuse, a greater substrate for functional plasticity earlier following stroke, or a combination of these and other factors.

MOTOR CONTROL AND LEARNING CONSIDERATIONS

There is a significant body of work from movement and psychological science that deals with the behavioral aspects of motor control and learning in nondisabled populations. Such knowledge can provide important direction to the implementation of task-oriented training to promote upper extremity recovery (90,91).

Massed Versus Distributed Practice Schedules

In the motor learning literature, the term "massed" practice is defined as a set of practice trials in which the performance–rest ratio is high and the proportion of rest between practice attempts is relatively shorter than the amount of time spent practicing. In contrast, "distributed" practice refers to a set of practice trials in which the performance–rest ratio is low and the rest time between trials is longer than the amount of time spent practicing (81). Although there are no direct comparisons (massed vs. distributed) in the neurorehabilitation literature, there is a long history of this debate in the motor learning literature (92).

The effectiveness for motor learning of various task performance and rest schedules seems to depend on the nature of the tasks that are practiced. For discrete tasks, such as tossing a ball or fastening a button, reducing the rest time (i.e., massed practice) has little or no influence on learning, and in some cases less rest may even be beneficial. However, for continuous tasks, such as handwriting, fatigue-like states are more apt to build up within a performance bout, suggesting that massed practice would be undesirable. The majority of the laboratory findings in nondisabled populations would support this notion—less rest between performance epochs degrades performance and has a detrimental effect on earning.

In the clinical literature, especially that used to describe the signature CIMT protocol, the term "massed practice" has been used to mean high intensity training conducted, for example, daily using a schedule up to six hours per day in the laboratory one-on-one with a "trainer." Though there is no doubt that the saying, "practice makes perfect" bears some truth and there is ample evidence to support the notion that "practice" is the most important variable for motor learning, conventional wisdom suggests that the design of that practice (schedule, duration), and the contents of practice (task-specificity) are equally important factors to consider when attempting to optimize the effectiveness of task-oriented training.

A concentrated "massed practice" schedule may be impractical to implement in today's health care environment. On the other hand, a more distributed schedule, though a departure from the signature CIMT massed schedule, is

closer to that prescribed in more recent reports that have used a modified CIMT protocol (74,75,93). Finally, such a distributed schedule is attractive from a practical perspective, both to the patient and clinic. Clinics consider a therapy visit to be approximately 45 minutes to an hour, and customary out-patient therapy for stroke ranges from two to three times per week for up to 10 weeks. Together, there is considerable practical and empirical support for implementing a task-specific practice program using these more distributed training schedules for upper extremity neurorehabilitation. This idea is consistent with recent work on memory consolidation and memory modification (reconsolidation) in which the off-line learning between practice bouts across days may represent a bridge between early and late procedural learning that underlies efficient skill acquisition (94).

Practice Time or Intensity of Training

Practice time, or the amount of time engaged with specific tasks, appears to be a major factor contributing to the effectiveness of constraint-induced movement therapy. However, in general, in clinical practice and even for published protocols, a precise quantification of task-specific practice usually is no more explicit than the length of stay or the total minutes or hours of each particular therapy delivered (95,96). The considerable outcomes and effectiveness research surrounding constraint-induced movement therapy seldom have focused on an explicit characterization of the intervention itself, including the very nature of the repetitions inherent to task practice. The signature CIMT protocol calls for a minimum of six hours per day of supervised training; however, from a task-oriented training perspective, the metric that is of interest is the amount of actual time practicing and time on task with the more impaired limb. We undertook a secondary analysis of time on task for one of the seven sites from the EXCITE RCT (96).

This retrospective analysis of a 2-week (range 11 to 16 days) administration of the signature CIT protocol revealed that on average, participants tolerated approximately four hours of actual task-specific practice per day or 62% of in-laboratory time. Further, we showed that there was 100% compliance with the specified 6-hour minimum supervised in-laboratory time averaged across the 10 days. The significant correlation between Mean Daily Practice Time (time on task) and in-laboratory time in the context of the large between-subject ranges for practice time prompts the question concerning the impact of training time and outcomes. For example, do participants who have longer training times benefit more from constraint-induced movement therapy than those with shorter training times? Although outside the scope of our single-site "time-on-task" project, a subsequent analysis was performed on the entire EXCITE database to address this (97).

In fact, when all participants enrolled into the EXCITE Trial and those who underwent 10 days of CIMT (n = 169) were examined for change scores on a primary outcome measure, the Wolf Motor Function Test (98,99), there was no apparent relationship between the intensity of training and outcome until the nature of the training was included in the analysis (97). Apparently, spending an excessive amount of training time in ATP training, which, arguably implements a "problem-solving" approach, yielded greater improvements with less overall practice time among those participants classified in the higher functional level, compared to other EXCITE participants. The lack of an overall intensity-to-outcome relationship along with the more detailed subgroup analysis suggests that total time spent practicing is less important than the nature of how tasks are practiced. As such, task-specificity may be more important than intensity of training (99,100).

From our single-site analysis, there was considerable variability (2.83–5.04 hours per day) across participants in mean daily practice time and the proportion of TP and ATP that constituted practice time. However, this variability did not appear to depend on functional level. In fact, two of the three in the low functional group were among the lowest for the entire group in Practice Time (22% and 23% below the mean), whereas the other had the third highest overall practice time at 20% above the mean. Instead, independent of functional level, it appears that those who engaged in more total practice time also engaged in more time on ATP/Shaping. However, this was not the case between total practice time and TP time. Therefore, other factors besides motor capability were more important in determining the time on task practice and the relative proportion of ATP and TP engaged in by any given participant. Individual subject motor capability and motivational and behavioral factors likely influenced important training parameters, such as task progression, training intensity, and choice of ATP/TP components. An understanding of these factors that are beyond training intensity, but relevant to the implementation of individualized patient-centered therapy programs, will be important for future developments in clinical practice (100,101).

Both the full-study and single-site EXCITE (96,97) analyses were limited to the temporal components of task-specific training, and the two classifications of tasks, ATP and TP, that represent only one of the active ingredients for efficacy of CIMT. The motor learning literature would suggest that there may be other critical elements of task-specific training that are important for the design of effective programs. We describe a few of these macro-level elements in the next sections.

Practice Schedules and Organization of Tasks

Random Versus Blocked Task Order Practice

The motor learning literature describes the contextual interference (CI) effect as an important and compelling variable for consideration in motor learning. For nondisabled learners, a practice schedule that promotes *interference* has been shown to be beneficial for skill learning (102–104). One way to manipulate interference during practice of multiple tasks

is to change the order in which tasks are practiced. For example, a random practice order in which tasks are practiced in a quasi-random order (i.e., C-A-B, A-B-C, B-C-A, where each letter represents a different task) is thought to introduce more interference than a blocked practice order in which each task is practiced repeatedly prior to switching to the next task (i.e., A-A-A, B-B-B, C-C-C).

Results from studies investigating the effects of practice order on motor learning typically show that if the total number of trials is the same for each group, the random practice order group shows enhanced motor learning compared with a blocked practice order group. However, there are exceptions to this random practice order benefit (105). This phenomenon is known as the CI effect (106,107). The CI effect elicited under random practice (i.e., high-interference) conditions has been explained in part by the additional planning and parameter specification that is required when different tasks are being practiced within the same session. For random order practice, every trial necessitates parameter specification and action planning. Both processes now are thought to implement a stronger memory representation of the practiced tasks (108–112). This enhanced processing related to the CI effect may in part take the form of increased cortical motor activity.

Recently, explorations into the neural bases of motor learning employ an imaging technique called transcranial magnetic stimulation (TMS). TMS is a technique that can introduce a transient perturbation to modulate cortical motor activity by means of noninvasive stimulation of the human brain (113). Single-pulse TMS was used *during* practice in healthy nondisabled participants as an identical external perturbation during both blocked and random practice (114). The TMS perturbation centered over primary motor cortex during encoding selectively disrupted motor learning under random, but not blocked practice conditions. More recently, Kantak and colleagues used low-frequency repetitive TMS (rTMS) *after* practice, over dorsolateral–prefrontal (DLPFC) or primary motor cortex (MI), during offline consolidation of a visuospatial movement pattern. Nondisabled participants practiced under constant or variable order conditions and were tested one day later for retention performance. Interference to DLPFC, but not to MI, after *variable* practice attenuated motor learning, whereas interference to MI, but not to DLPFC, after *constant* practice attenuated motor learning (115). Kantak and Winstein (2012) suggested a model of the learning-performance distinction and memory processes that can be used to explain these two sets of findings and to suggest additional testable hypotheses concerning the neural bases for motor learning.

Functional magnetic resonance imaging (fMRI) studies (116), together with recent TMS studies (114,115) exploring the neural bases of the CI effect, provide compelling support for the hypothesis that active information processing is greater under variable or random order practice compared to that under blocked or constant order practice. This observation suggests that task practice conditions used to invoke preparatory processing, might offer an important "active" ingredient to the design of effective task-oriented training programs for stroke neurorehabilitation. Recently, Schweighofer and colleagues (117) used a computational model of motor memory that contains a common fast process and multiple slow processes to predict and explain a set of counterintuitive CI effect results in participants at least three months after stroke. Nondisabled participants exhibited the usual CI effect with no forgetting from immediate to delayed retention in the random condition, but forgetting in the blocked condition. In contrast, the participants with at least three months stroke duration exhibited no forgetting in the random practice condition, but only marginal forgetting in the blocked condition (i.e., less forgetting than the control group). However, in poststroke participants, the integrity of visuospatial working memory (associated with the fast process) modulated long-term retention after blocked schedule training—that is, participants with poor visuospatial working memory exhibited little forgetting at 24 hours. This suggests that greater understanding of the neural bases for encoding and consolidation processes in the stroke brain will be important for future advances in this area.

Task Specificity and the Contents of Training

There is no doubt that behavioral experience can enhance function after brain injury. Studies of the effects of enriched environments show that rats exposed to complex housing environments before and/or after injury typically have improved functional outcomes compared to animals in standard housing (118,119). Further, general exercise, such as wheel running, which influences neuronal circuitry of brain and spinal cord when initiated before and after injury, is associated with activity-dependent plasticity. A landmark study conducted more than a decade ago showed that physical exercise has a direct, positive impact on enriching the blood supply (i.e., angiogenesis) to a brain region that is engaged by the exercise (120), but physical exercise by itself generated no changes in the elaboration of brain connections. In models of injury, exercise is beneficial for restoring plasticity-related proteins after spinal cord injury (121,122), increasing axonal regeneration in sensory neurons (123) and protecting from damage caused by cerebral ischemia (124). However, there is no evidence that the running rat or hamster has better memories, faster or more competent thinking, or stronger, more refined, and more flexible control of its actions because it spent considerable time on the running wheel. It seems that for the latter benefits to occur, for fundamental processes including remembering, reasoning, and fine motor control, *new experiences and learning* are a necessary and critical driver.

In support of this idea, considerable work using animal models of stroke suggest that functional brain remodeling may be critically contingent upon the behavioral demands of the training and the acquisition of motor skills associated with learning a novel task (48,125). Animals trained in skilled upper limb tasks show differential changes in the functional reorganization of the motor cortex compared

either to animals that had the unaffected limb restrained but received no additional training (126) or to animals that received an identical intensity of training in unskilled upper limb movement tasks that demanded less movement precision (48,127). The adult animals that were exposed to motor skill training demonstrated enlargement of the motor cortex representation of the wrist and digits, whereas comparable changes in functional reorganization of the cortical maps were not found in the animals that undertook repetitive unskilled upper limb activities. Thus, although exercise can be beneficial in some ways, learning motor skills results in neuronal structural and functional plasticity in the motor cortex and cerebellum that is not found with simple exercise or repetition of previously learned skills (125,127–130).

Maldonado and colleagues used a unilateral ischemic lesion model and asked if exercise could be used as a positive modulator of motor skill "relearning" in young and older rats. Motor skill training consisted of daily practice of the impaired forelimb in a tray-reaching task (task-specific training). Exercised rats had free access to running wheels for six hours per day. In the young adult rats (task-specific training group), motor skill training significantly enhanced skilled reaching recovery compared to controls (no activity or exercise groups). However, exercise did not significantly enhance performance when administered alone or in combination with task-specific training. Further, there was no major benefit of exercise in older rats, and no effects of exercise in a measure of coordinated forelimb placement or in immunocytochemical measures of several plasticity-related proteins (BDNF, NMDAR-1, spinophilin, MAP-2) in the motor cortex. Thus, the Maldonado et al.'s results support the importance of task-specific training over general exercise, either alone or combined, for improving skilled reaching after unilateral ischemic lesions of the sensorimotor cortex in rats (125).

Recently, researchers in Denmark showed that a single bout of exercise improves motor memory for a visuomotor accuracy-tracking task. Using a clever design in which 48 young nondisabled participants were allocated randomly into 3 groups, Roig and colleagues (131) investigated whether a single bout of intense aerobic exercise could improve motor memory and motor skill learning. They also explored if the timing of the exercise bout in relation to the timing of the practice had any impact on the acquisition and retention of a motor skill. Participants practiced a visuomotor task either before or after a bout of intense cycling exercise or after rest. Visuomotor skill acquisition was assessed during practice and retention was measured at 1 hour, 24 hours, and 7 days after practice. There were no differences in the rate of motor skill acquisition between the groups. In contrast, both exercise groups showed significantly better retention at 24 hours and 7 days after practice compared to the rest-only control group. In addition, the positive effects of acute exercise on motor memory are maximized when exercise is performed immediately after practice, during the early stages of memory consolidation. These results highlight the benefits of one bout of intense exercise performed immediately before or after practicing a motor task and that the timing of exercise in relation to practice is possibly an important factor regulating the effects of acute exercise on long-term motor memory.

Pak and Patten (132) conducted a comprehensive review of the impact of strengthening exercises on function (not skill). Most relevant to task-oriented training is that power training when combined with functional training can improve upper extremity movement accuracy more so than functional training alone (41). A combination of the two also can lead to improvements irrespective of the order in which they are provided (133). When examining the respective roles of functional task practice and power training, the former was found to increase upper extremity compensatory patterns whereas the latter led to more normal movement patterns (41). However, power training led to more normal movement patterns. If provided first, power training may enhance the benefits of repetitive task practice.

In noninjured humans, learning-associated activation of the primary motor cortex was found to be greater than the activation associated with simple repetitive motor use (134,135). Investigations of CIMT showed both increased use of the affected upper limb and changes in cortical activation after training (136–140). However, the specific contribution of task-oriented training compared with the "forced-use" associated with the constraint of the nonparetic limb cannot be determined without a control group (141).

Nelles and colleagues conducted a small RCT and compared the effects of upper limb task-oriented training and a similar intensity of passive movements and muscle-stretching activities in 10 subacute stroke participants (47). The task-oriented training group showed a trend toward diminished motor impairments (UL Fugl-Meyer) and significantly increased activation in several sensori–motor regions of the brain (bilateral parietal, premotor, contralateral precentral, and postcentral areas). In contrast, the control participants did not exhibit comparable changes in the fMRI BOLD signal response. Similar results were obtained in a study that used computer-aided training of finger tracking in 10 chronic stroke participants. Here the researchers found a significant shift in activation from the unaffected to the affected hemisphere in the primary sensory and motor areas and premotor cortices after training, as well as associated improvements in manual dexterity compared to pretraining (142). This same group compared the effects of two weeks of computer-aided training of finger tracking to repetitive simple finger movements in 20 mildly impaired chronic stroke participants (143). Surprisingly, they found no differences between the two training groups in the performance of clinical tests, including the Box and Block and Jebsen–Taylor hand function test. However, both groups showed improvements on these tests compared with pretraining levels. Similar findings prevailed for the fMRI activation results, with no consistent patterns or trends.

Compared to the animal studies, those in humans are less conclusive about the relative effects of the contents of training on cortical plasticity and associated upper limb functional recovery after stroke. However, there are several additional variables that deserve consideration, especially the *severity* of motor deficits of participants.

Severity of Motor Deficits

Two studies in particular highlight the importance of matching the task-specific training program to the severity of motor deficits of participants. Salbach and colleagues reported on the efficacy of a task-oriented intervention in enhancing competence in walking in people after stroke (144). This was a two-center observer-blinded, stratified, block-randomized controlled trial with 91 patients (44 experimental, 47 control) who exhibited a residual walking deficit within one year of first or recurrent stroke. All participants could walk at baseline, though some much slower than others.

The experimental intervention consisted of a task-oriented training program administered during three 90-minute sessions per week for 6 weeks. The task-oriented training consisted of functional tasks designed to strengthen the lower extremities and enhance walking balance, speed, and distance. The control intervention consisted of task-oriented upper limb practice of functional, unilateral, and bilateral tasks chosen to improve gross and fine manual dexterity. A baseline six-minute walk test was not different between groups (experimental 209 m, control 204 m), but the change in the task-specific training group was significantly greater (40 ± 72 m) compared to the control (5 ± 66 m) group. More importantly, though participants with mild, moderate, or severe walking deficits at baseline improved on average (36 ± 96 m, 55 ± 56 m, and 18 ± 23 m, respectively), the best responders to the task-oriented training program for walking were those who presented with moderate walking deficits at baseline.

Two years later, this same group published the results of the task-oriented intervention on arm function in people with stroke using the control group (n = 47) data from the same RCT described above (145). They reported that the 27 hours of upper extremity task-oriented training distributed over 6 weeks did not improve voluntary movement or manual dexterity of the affected arm. However, a closer look at the baseline upper limb motor deficit of the "control" group provided a reasonable explanation for these negative findings. Indeed, these results were not surprising when considering the heterogeneous sample that was selected based on walking impairment, rather than arm impairment. Sixteen percent of the patients had no distal (wrist/fingers) movement capability. It is well known that if no hand dexterity is apparent by six weeks after stroke, the likelihood of achieving hand function at six months is poor (146).

An international panel supported with funding from the Canadian Stroke Network has been working for the past three years to develop an algorithm for progressing poststroke upper extremity rehabilitation along with best outcome measures at each decision point of the algorithm. The group concurs that if no hand function is achieved by 12 weeks after the stroke, the likelihood for such gains to be made subsequently is poor (146,147).

Timing of Task-Oriented Training

Evidence from animal studies suggests that timing of training may play a critical role in its effectiveness in restoring or improving performance, enhancing the survival and neural reorganization of the surviving perilesional tissue, and establishing effective neural reorganization of the contralesional hemisphere (148–150). Although postlesion intensive training that commenced too early has been shown to have deleterious effects in animals (151–153), a modified CIMT protocol commenced within the first two weeks following stroke in humans was shown to be safe (71). In animal models, a delay in training results in poorer behavioral recovery and poorer preservation of penumbral areas representing the distal forelimbs (149,154). In an oft cited review, Murphy and Corbett (155) point to evidence from animal models that suggest that a time-limited window of neuroplasticity opens following a stroke, during which the greatest gains in recovery are made. They suggest that understanding how to optimally engage and modify surviving neuronal networks could lead to new response strategies that compensate for tissue lost to injury. In humans, the optimal therapeutic window after stroke for rehabilitation of the upper limb remains to be established (156). Further, the recent NINDS priority program for translational research targeting early recovery after stroke in humans suggests that more work is needed (4).

Regardless of severity, there is preliminary evidence to suggest that earlier, more aggressive therapy results in better upper limb outcomes (157,158). It is likely that the therapeutic window for rehabilitation might depend upon the severity of the stroke, as well as the presence of other comorbidities (159). Imaging studies provide evidence of ongoing cortical reorganization of motor systems for several months after stroke (160). Improvements in function have been observed from clinical measures in the first three to six months after stroke, after which relatively less change may be seen if no further intervention is undertaken (161). As mentioned earlier, changes in cortical activation and improvements in affected upper limb function have been reported with training in chronic stroke participants (137–139); however, there are several compelling arguments for introducing a task-oriented approach earlier after a stroke, during the immediate outpatient interval, especially for those who exhibit a mild to moderate upper limb impairment (i.e., enough residual capacity to benefit from therapy).

Although the exact proportion of stroke survivors who are mildly to moderately impaired is not known, conservative estimates range between 5% and 30%. These are individuals who return to the community but with significant disablement (162). The paucity of dose-equivalent designs in the stroke upper extremity clinical trial literature, and

the recent EXCITE trial (1), highlight an important need in this area (163,164). Unlike the EXCITE trial design, a task-oriented intervention that targets the immediate postacute period provides several advantages for the patient with a mild to moderate motor deficit. This timing is considered optimal for several reasons:

1. It enables a supportive interaction between processes associated with experience-dependent and injury-induced cortical reorganization that are known to influence functional recovery (165,166)
2. It is possible that earlier intervention may allow for more optimal cortical reorganization and potentially less use of behavioral compensatory strategies (149,167)
3. It may attenuate the detrimental effects of maladaptive compensatory strategies (e.g., learned nonuse) currently promoted during inpatient rehabilitation (168) that may with time be reinforced and become more difficult for the patient and clinician to reverse (11)
4. It is not so early as to be overly aggressive during a more vulnerable period both physiologically and psychologically (165,169)
5. The outpatient environment is a more practical setting for a distributed, relatively high dose of upper extremity task-specific training, especially given the already dwindling acute inpatient length of stay (164). Indeed, recently, Lang and colleagues showed that affected upper extremity use is minimal during the inpatient rehabilitation stay in patients with mild to moderate acute hemiparesis (170)

Dosing of Task-Oriented Training

The 2005 AHA/ASA-endorsed Clinical Practice Guidelines (171) reviewed the evidence for therapy intensity and duration. Though the heterogeneity of the studies combined with borderline results in many trials limited the specificity and strength of any conclusions overall, the trials supported the general concept that rehabilitation can improve functional outcomes, particularly in patients with lesser degrees of impairment. There is weak evidence for a dose–response relationship between intensity of the rehabilitation intervention and functional outcomes. For example, Sterr and colleagues demonstrated that in a 2-group randomized trial of 15 adults with chronic hemiparesis, the group receiving 6 hours of CIMT daily over 2 weeks improved significantly at 1 month on the WMFT and MAL than the group receiving 3 hours delivered daily over the same period (70). Despite limitations of these individual studies, the conclusions among several systematic reviews are fairly consistent: greater intensity produces slightly better outcomes (172,173). Kwakkel (173) reported a small but statistically significant intensity effect relationship in the rehabilitation of stroke patients. The literature specific to upper extremity treatment is mixed. Other than EXCITE, there are no multicenter trials of dosing of task-oriented training in the literature.

The very early constraint-induced movement therapy (VECTORS) phase II single center, single-blind RCT (71) begins within 14 days of stroke onset during acute inpatient rehabilitation. VECTORS compared traditional upper extremity therapy with dose-matched and high-intensity CIMT protocols. The primary endpoint was the total ARAT score on the more affected side at 90 days after stroke onset. As expected, all groups improved with time on the total ARAT score. Of particular importance, the high-dose CIMT group had significantly worse scores at Day 90 compared to the other two groups. No significant differences were found between the dose-matched CIMT and control groups at Day 90. ADC maps revealed no evidence of new neuronal damage. A dose–response relationship was observed, where a *higher dose* of CIMT was associated with *less motor recovery*. Given the importance of longer-term outcomes for rehabilitation, the implications of these results should be taken cautiously until more distal time points at six months and one year are reported.

For our currently running phase III stroke rehabilitation trial, Interdisciplinary Comprehensive Arm Rehabilitation Evaluation (ICARE), we chose a distributed dose of 30 hours of training for scientific and pragmatic reasons (174). We included a comparison control group, an observation only, usual and customary (UCC) outpatient therapy. We expect considerable variation in the UCC dose both by site and across the five-year monitoring period. These observation data will be important in the end from a policy standpoint and should be useful to estimate the cost if more prescriptive practice guidelines were to be implemented, especially if a higher dose can be shown to produce better outcomes. Pilot data from a multisite outpatient survey suggests that 30 hours distributed over 10 weeks would be on the higher side of what is commonly prescribed, but still practical in that it would allow patients to participate in other concurrent therapy services (e.g., physical therapy and speech therapy). Thirty hours is 33% more than what we used in our single site phase II trial that commenced during inpatient rehabilitation and extending to outpatient (20 hours distributed over 4–6 weeks) (85). It is 50% of that used for EXCITE (60 hours over 2 weeks) during the 3- to-9-month postoutpatient period (1), twice that used by Page and colleagues (75) (15 hours over 10 weeks, 30-minute sessions, 3 times per week) in a phase I acute trial of mCIT, and 55% of that prescribed in the home-based RCT of a multifaceted therapeutic exercise program (54 hours over 12 weeks) in subacute stroke (175). Therefore, the 30-hour dose is well within the range of previous intervention trials shown to be effective and is practical for the outpatient environment. Yet, it is likely higher than the usual average dose that is prescribed for this patient group.

The only head-to-head comparison—a single center, single-blind phase I RCT, dose optimization for stroke evaluation (DOSE)—is currently enrolling participants (ClinicalTrials.gov Identifier: NCT01749358). This study will enroll and adaptively randomize 60 individuals who are no less than six months in stroke duration and who meet inclusion criteria into one of four dose groups (0-, 15-, 30-, and 60-hours) of a principle-based, theoretically defensible ASAP for upper extremity recovery. Frequency is four times

per week, one week per month for three months in a train–wait–train paradigm. Follow-up assessments will be performed monthly up to 10 months after randomization. At the time of this writing, DOSE has enrolled approximately 50% of its target.

CONSIDERATIONS FROM THE NEUROSCIENCE PERSPECTIVE

In 2008, Kleim and Jones (176) reviewed a growing body of neuroscience research that used a variety of models of learning, neurologic disease, and trauma from the perspective of basic neuroscientists but in a manner intended to be useful for the development of more effective clinical rehabilitation interventions. Because neural plasticity is believed to be the basis for both motor learning in the intact brain and relearning in the damaged brain that occurs through physical rehabilitation, the recent advances in understanding experience-dependent neural plasticity can inform the application of task-oriented training interventions. Kleim and Jones argue that the "qualities and constraints of experience dependent neural plasticity are likely to be of major relevance to rehabilitation efforts in humans with brain damage." Recently, an interactive e-book, *Neural Plasticity: Foundation for Neurorehabilitation* (177) provides an updated and more fully developed expose of neural plasticity (especially good for students interested in the translation of neural plasticity to effective therapy programs). This e-book goes beyond a simple literature review (there are many excellent review articles and book chapters on this topic) and begins to integrate and apply the important principles of neural plasticity so as to inform therapeutic paradigms. To be clear, the book is not a handbook on how to treat people with brain injury. For our purposes, we review the seven behavioral signals driving neural plasticity as outlined in this e-book. For each behavioral signal, we consider a literal translation as it pertains to the promotion of upper extremity recovery and, where appropriate, include current behavioral perspectives and translational studies in stroke rehabilitation.

Behavioral Signal 1: Use It or Lose It

Failure to drive specific brain functions can lead to functional degradation. Behavioral signal 1 suggests that any intervention that encourages or promotes "use" of the paretic limb would be appropriate. Task-oriented training, CIMT, bilateral arm training, and functional task practice are just a few programs from the clinical evidence-based literature that would qualify for application of Behavioral Signal 1 (see "What is Task-Oriented Training," above, and "Emerging Innovative Approaches," below, for details). Recently, to better understand the interaction between arm function and use in humans after stroke, Schweighofer and colleagues used a computational approach to develop a first-order dynamical model of stroke recovery with longitudinal data from participants receiving constraint-induced movement therapy in the EXCITE clinical trial (178). Of most import, by comparing the model parameters before and after CIMT intervention in participants receiving the intervention one year after randomization, they found that therapy increased the parameter that controls the effect of arm function on use. Increase in this parameter, which can be thought of as the confidence to use the arm for a given level of function, lead to an increase in spontaneous use after therapy compared to before therapy.

Behavioral Signal 2: Specificity

The nature of the training experience dictates the nature of the plasticity. Behavioral signal 2 implies that *specificity* of training is important. Indeed, *specificity* effects are one of the oldest and most common findings in learning and memory research (179). Later in the twentieth century, work in the transfer of skills again supported a specificity effect, with the general finding that transfer of training was small unless the skills were essentially identical to one another (180). Similarly, a specificity effect was found in experiments in which participants learned a task during practice and then performed it under similar or changed conditions in a transfer test (181). As predicted by the specificity effect, performance was usually most effective when the transfer conditions matched those conditions that were available during the practice session. Therefore, there is considerable evidence suggesting that motor skills are represented in memory in a highly specialized way (182). Although the memory representation might be specific, recent behavioral findings from an examination of individuals with chronic hemiparesis suggests otherwise. In a small-scale study (n = 11), Schaefer and colleagues (183) tested whether training on one motor task (i.e., feeding task) would transfer to untrained tasks that were either spatiotemporally similar (i.e., sorting) or different (i.e., dressing) in individuals with chronic hemiparesis after stroke. Interestingly, after five days of supervised massed practice of a feeding task, performance of all three tasks improved significantly after training. Further, the amount of improvement in the untrained tasks was comparable but not dependent on the degree of similarity to the trained task. Given the small sample, these results are clearly not definitive, but rather they are suggestive that the effects of upper extremity task-specific training can transfer to other untrained tasks in individuals with chronic mild-to-moderate hemiparesis. One possible mechanism for this transfer effect may be attributed to a more general phenomenon such as improved self-efficacy or confidence to use the limb that comes with task success during training. Understanding how these social–cognitive factors modulate motor learning and transfer will be important for future research (58).

Taken together, the literature regarding specificity of training (see also "Task-Specificity and Contents of Training" section) shows that although general exercise and strengthening programs are thought to be effective when combined with task-oriented or task-specific training programs, the direct benefits are usually expressed at the system level (i.e., physiology, musculoskeletal) and not at the level of the specific task or skill that is being trained. Recent work has begun

to examine the degree to which practice on one task actually transfers in meaningful ways to another task.

Behavioral Signal 3: Intensity Matters

Induction of plasticity requires sufficient training intensity. Behavioral signal 3 implies that the dose, frequency, and duration of training are important parameters in the design of any effective task-oriented training program. Intensity is usually defined as an exceptionally great concentration, power, or force. In the field of physics, it is the amount or degree of strength of electricity, light, heat, or sound per unit area or volume. In earlier sections (see "Practice Time or Intensity of Training," and "Practice Schedules and Organization of Tasks"), we reviewed the studies that have manipulated the "intensity" of training by varying parameters of dose, frequency, and duration. There is considerable evidence to support this idea, but explicit guidelines for what constitutes a "sufficient" level of intensity is sorely lacking. The so-called "pharmacokinetics" includes "dosing of training" and has been identified as both a challenge and an important unmet need in the design of clinical trials in rehabilitation (see "Research Frontiers," below, for more discussion). The importance of "therapy dose" in neurorehabilitation is reflected in a recent trend for clinical trials of complex interventions to include at least one dose-equivalent control group in the design (184,185). In translating from animal models (155,186) to human clinical practice, Krakauer and colleagues suggest that there will need to be a substantial increase in the intensity and dosage of treatments offered in the first month after stroke with an emphasis on impairment (187).

Behavioral Signal 4: Repetition Matters

Induction of plasticity requires sufficient repetition. Behavioral signal 4 suggests that repeated attempts to solve the motor problem benefits plasticity and learning. There is considerable evidence for this idea that comes from the motor learning literature and is reviewed earlier (see "Motor Control and Learning Considerations," above). What is less understood is how the organization of those repetitions (e.g., massed vs. distributed) should be structured for the best outcomes. What is clear from the evidence to date is that mere repetition of simple tasks that are well within the capability of the performer will most certainly not induce neural plasticity or learning (48). It is likely that Bernstein's observation that "practice is repetition without repetition" is profound and fundamental to advancing understanding in this area of study (57).

Behavioral Signal 5: Time Matters

Different forms of plasticity occur at different times during training. Behavioral Signal 5 implies that timing of an intense, task-oriented training program is an important factor. Most of the clinical research up until recently has been conducted in the chronic phase of stroke recovery. The reason for this choice is complicated and multifaceted (e.g., confounded by spontaneous recovery and safety concerns related to glutamatergic toxicity from animal studies) but also an unfortunate one, especially in the light of more recent studies in both human and animal models suggesting that an earlier time frame would likely have a greater impact on important outcomes (148,149,154,155). In a provocative Point of View: Directions for Research piece, "Getting Neurorehabilitation Right: What can be learned from Animal Models?" (187) there is an impassioned plea for focused high-intensity interventions offered in the first month after stroke. This proposal is reflected in the recent NINDS priority program for translational research targeting early recovery after stroke in humans (4).

Behavioral Signal 6: Difficulty Matters

There is substantial evidence from the behavioral, computational, neuroscience, and social psychological literatures for the beneficial effects on motor skill learning of practice conditions in which the difficulty of the task matters (54,116,117,188–192). The level of task difficulty can be manipulated through practice schedules, contextual factors, dual tasking, and the actual task requirements (e.g., precision, magnitude, degrees of freedom). Perceived task difficulty can be manipulated through simple statements before practice that have been shown to increase confidence and impact motor learning (58). Various mechanisms have been suggested as the basis for this beneficial effect on learning including that which requires deeper information processing, working memory load, problem solving, and reward-induced consolidation.

Behavioral Signal 7: Salience Matters

The training experience must be sufficiently salient to induce plasticity. Behavioral signal 7 implies that the training must have the quality or state of being "salient." It must be prominent or stand out conspicuously or be noticeable. There has been considerable discussion about the nature of the recovery process from the patient's perspective (193–195). Barker and colleagues (194) reported that the single most important factor that contributed to upper limb recovery, from the perspective of the stroke survivor and through self-report, was "use of the arm in everyday tasks." From this observation, we suggest that a task-oriented training program which includes participant-selected meaningful tasks will likely be viewed as most salient in the context of the recovery process. In support of this notion, a recent qualitative study to identify themes and possible mechanisms of recovery of the hand suggested a therapeutic framework for continued rehabilitation and research that includes the patient's perspective (195). Finally, there is considerable evidence that self-controlled conditions of practice (e.g., self-controlled feedback) are better for learning than externally controlled conditions (192,196). Together, the behavioral evidence suggests that understanding salience

as defined by the patient or learner may be a fruitful direction for future work that seeks to drive positive plasticity and optimize recovery processes.

EMERGING INNOVATIVE APPROACHES TO UPPER LIMB REHABILITATION

In the Clinical Trials section of the 2006 Stroke Progress Review Group report, "multimodality combination interventions" were identified as an emergent research area. The most recent NINDS stroke priorities (4) specifically targeted "Translational research using neural interface devices for stroke and other neurologic disorders." The failure of the industry-sponsored multisite pivotal trial (phase III) of targeted subthreshold epidural cortical stimulation delivered concurrently with intensive rehabilitation therapy (197–200) warranted a critical appraisal. Plow and colleagues (201) summarized their concerns regarding cortical stimulation with the following comments: "it is important to determine the (a) location of peri-infarct representations by integrating multiple neuroanatomical and physiological techniques; (b) role of other mechanisms of stroke recovery; (c) viability of peri-infarct tissue and descending pathways; (d) lesion geometry to ensure no alteration/displacement of current density; and (e) applicability of lessons generated from noninvasive brain stimulation studies in humans. In terms of combining stimulation with rehabilitation, we should understand (a) the principle of homeostatic plasticity; (b) the effect of ongoing cortical activity and phases of learning; and (c) that subject-specific intervention may be necessary."

In the next section, we focus on the applicability of lessons generated from noninvasive brain stimulation studies in humans. Specifically, we describe research combining noninvasive stimulation with rehabilitation, which provides Class I evidence that time-locked rTMS before or after physical therapy improves measures of dexterity and force in the affected limb in patients with chronic deficits more than six months after stroke.

Multimodal Combination Intervention: Low-Frequency rTMS and Physical Therapy

Avenanti and colleagues demonstrated that low-frequency rTMS promotes use-dependent motor plasticity in chronic stroke using a cleverly designed randomized trial (202). Their aim was to investigate the long-term behavioral and neurophysiologic effects of combined time-locked rTMS and physical therapy intervention in chronic stroke patients with mild motor disabilities. Thirty patients were enrolled in a double-blind, randomized, single-center clinical trial. Participants received 10 daily sessions of 1 Hz rTMS over the intact motor cortex. In different groups, rTMS stimulation was either real or sham and was administered either immediately before or after physical therapy. Outcome measures included: dexterity, force, interhemispheric inhibition, and corticospinal excitability and were assessed for three months after the end of treatment to determine persistence of any effects. With regard to mechanism, they reported a treatment-induced cumulative rebalanced excitability in the two hemispheres and a reduction of inter-hemispheric inhibition in the groups that received real rTMS. Use-dependent improvements were detected in all groups. Improvements in trained abilities were small and transitory in the sham rTMS group (therapy only effect). They reported greater behavioral and neurophysiologic outcomes after real rTMS with the group receiving stimulation *before* physical therapy showing robust and stable improvements and the other group (i.e., rTMS *after* physical therapy) showing less persistence of the training effect over time. Their results suggest that priming motor networks with rTMS can promote effective use-dependent plasticity. These findings suggest that hypothesis-driven multimodal combination therapies using noninvasive brain stimulation that implement known mechanisms of neuroplasticity can be developed for future clinical use. Future work will need to determine if the present findings can be extended to stroke patients with moderate to severe motor impairments.

An Integrated Model: Accelerated Skill Acquisition Program

In this section, we introduce an integrated model of task-oriented training that proposes the infusion of contemporary motor learning research into neurorehabilitation practice (203). Neuroscientific evidence revealing the inherent plasticity of the brain (i.e., neuroplasticity) that allows new learning, adaptation, and compensation at multiple levels of the system, from early development well into old age, profoundly impacted conceptions of rehabilitation and recovery after stroke. In fact, this insight has heightened the relevance of the science of motor learning to physical therapy practice. Prior to the revolution in neuroscience, researchers in the field of motor learning had established a number of behavioral variables important for skill acquisition, chief among them being practice. The science of motor learning itself continues to evolve, providing new insights into the optimization of skill learning and its application to the complex process of neurorehabilitation. Throughout this section, we use the terms skill acquisition and learning, synonymously. Furthermore, we distinguish performance from learning. The learning–performance distinction (81,204) has relevance to physical therapy in that the concern is with the achievement of a sustainable or relatively permanent change in the capability for responding in contrast to a short-lasting temporary change. We now understand that some practice-related techniques such as drills and frequent feedback can have a performance-enhancing effect that boosts performance while available. Similarly, some practice-related interventions may appear to retard or slow performance gains when present, seen, for example, when tasks are ordered randomly (205) (see Behavioral Signal 6: Task Difficulty Matters above for more discussion). An assessment of learning and the associated memory processes is not reliable unless it is conducted at some time or context

that is removed from the practice period—during retention or transfer tests (185,206–208).

Neuroplasticity Heightens the Importance of Motor Learning

It took until the turn of the 21st century before studies that examined motor learning in patient populations began to appear in the literature (209,210). At about the same time, Nudo and colleagues published in 1996 the now seminal paper in the journal *Science*. In that study, using a primate model of stroke, they demonstrated the capability of the motor cortex to reorganize the digit representation area in response to postinjury motor training—but not as a consequence of spontaneous recovery, without training (126) (see Chapter 7). More importantly, Nudo and colleagues showed that cortical reorganization of the digit area was the direct result of the food-retrieval practice paradigm used to train the primates after the stroke lesion. In later work, Plautz and colleagues identified further that cortical reorganization was dependent on goal-directed, task-specific practice, likely the result of acquisition of a motor skill (i.e., motor learning) and not mere repetition of grasping movements from the easiest and largest food wells (48).

With the advent of new brain imaging technology, it is now well accepted that the learning of motor skills results in adaptive changes in the functional organization of the motor system (211,212). Attempts at skilled movements together with injury-induced plasticity (e.g., stroke or head injury) can influence the use of injury-affected musculature and subsequent reorganization of spared neuronal networks (213). Research over the last decade has provided considerable evidence that has advanced knowledge about how to shape plasticity to enhance recovery after injury (214,215).

Perspectives on Skill Acquisition, Sustainability and Generalizability

There is now sufficient evidence that the acquisition of a new motor skill requires progressive challenge, intensity, problem solving, sufficient motivation, and focused attention, especially in the early stages of learning (58,81,177 (chapter 2),216). We also know that skill-based learning involves active participation and requires a certain degree of voluntary neuromotor capability. Most motor skills involve procedural (implicit) memory and knowledge and require little attention once they are learned (190,217,218).

Recently, motivational factors involved in long-term behavioral engagement, including self-efficacy and support for fundamental psychological needs (competence, autonomy support, social-relatedness) (219–222), have been examined with respect to their role in motor performance and learning, as reflected in acquisition and retention of novel motor skills in clinical and nonclinical populations (58,223–225). For example, relative to a control group, older women learning a novel balance task and who were provided a single statement prior to beginning the task that "active people like you, with your experience, usually do very well on this task," retained learning, balanced longer, and had higher self-efficacy on a delayed test of learning (223). Individuals in inpatient stroke rehabilitation given feedback and encouragement of daily timed gait trials walked significantly faster both at discharge and three months later than those not provided with their times and encouragement (225).

In a manner not unlike the effects of exercise that will not be retained unless the exercise is continued, the concept of task-specific practice implies that without ongoing and progressive practice, movement skills will not be advanced (226). Task-specific practice may occur by deliberate and systematic set-aside sessions. It also may be induced transparently by responding to the demands of everyday activities (227), provided that those activities call for use of the more affected extremity. Because development and retention of movement skills over time require ongoing behavior, psychological science pertaining to behavior change or support (219,228,229) becomes highly relevant to those seeking to produce lasting effects in their clients. As such, another aspect of skill that will be important for sustaining gains and generalizing movement skills into everyday contexts (230) is a set of skills related to self-management of those gains and continued use in the natural environment (see "Behavioral Signal 7: Salience Matters" above for more discussion).

Infusing Contemporary Motor Learning Into Neurorehabilitation Practice

In essence, learning significantly underlies the recovery of function and the development of new skills after catastrophic or profound neurologic and other disabling disorders. Creating the conditions that optimize the processes of motor learning and relearning may have been the implicit intent of some rehabilitation and research programs. However, many lack a strong conceptual framework, have been narrow in focus, and have not included critical features to direct, sustain, and generalize effects into life activities and community participation.

The past decade has witnessed an explosion of different therapeutic interventions for stroke rehabilitation emergent from new insight about the brain–behavior relationship. Despite the varied intervention options, a significant percentage of individuals are unable to maintain and generalize the gains achieved in therapy to the natural environment after therapy ends (44,178,231). Though task-oriented training approaches highlight the importance of repetition and task specificity, they sometimes downplay the achievement of skilled movement in the service of functional tasks. Maladaptive or "bad use" can occur when less optimal, unskilled, solutions—ones that rely on compensatory strategies—are used (36,38–43). This can contribute to incipient declines after therapy ends and gains are not generalized.

The opportunity, therefore, is to integrate the known benefits of intense, challenging, and progressive task practice programs with those that optimize skill, transfer, generalization, and persistence of gains made in therapy to the natural environment. Recently, we suggested an

evidence-based solution—one in which the benefits of progressive, task-oriented training could be integrated with patient-centered strategies to facilitate translation of the therapeutic gains into skilled use in the home and community and in which the patient is empowered to incorporate the paretic limb into valued activities (185,232).

The Accelerated Skill Acquisition Program

We developed an evidence-based intervention, the ASAP, which integrates contemporary principles of motor learning (40,185,233,234). ASAP is a hybrid combination of task-specific and skill-based/impairment-mitigating training with embedded patient-centered motivational enhancements. Targeted task-specific training (skill) emerges as the single most important approach to intervention for the disabling consequences of stroke in mildly to moderately impaired participants. The fundamental problems that ASAP addresses are conceived as the learning or relearning of motor skills to optimally affect neural plasticity (177), as well as skills to self-direct posttraining activities (195). Development of skill is facilitated by the amelioration of impairments (e.g., muscle weakness, low self-efficacy) to enhance capacity (17,41,235). Attention to motor learning, motor control (e.g., goal-directed whole tasks with natural synergies) (81 (p. 382), 236), and basic exercise physiology (e.g., overload in terms of training load/intensity, speed) principles are very relevant (237). Social–cognitive psychological theories of motivation are applied in this intervention for immediate and particularly longer-term participant motivation. These assume that intrinsic sources of motivation, including perceptions of self-determination (choice, control, collaboration) and self-efficacy (confidence in one's capabilities) are key contributors of continued choice, effort, and persistence to use paretic limbs, which in turn, leads to mitigation of disability and of self-imposed participation restrictions. A note of historical interest, the ASAP intervention draws upon research from motor learning and several overlapping fields of study, and in fact incorporates principles of even more subfields of movement science (e.g., exercise physiology). As such, we do not consider ASAP as a motor learning approach per se (238).

Conceptual Framework: Integration of Skill, Capacity, and Motivation

In this section, we outline the conceptual framework for ASAP. A pathway from impairment reduction to functional capability to more general use of restored limbs in natural contexts often is implicit but less frequently operationalized in therapeutic practice. This conceptual model derives from the infusion of motor learning, neuroscience, and behavioral science described earlier (81,212,214,220), with the developing evidence base of neurorehabilitation as outlined in this chapter. Figure 20.1 illustrates the conceptual framework that skill (motor learning and self-management), capacity (impairment mitigation), and motivation (intrinsic drive) together form the fundamental components for effective

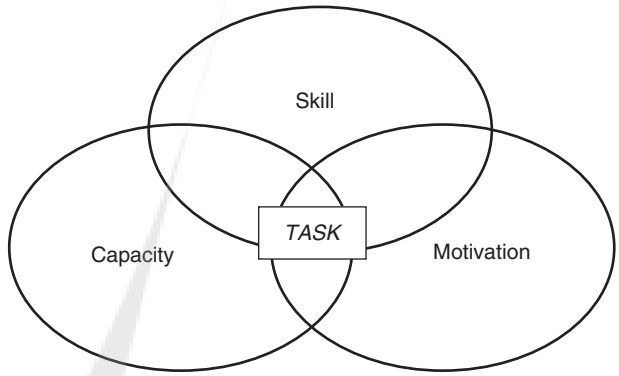

FIGURE 20.1 Conceptual framework for the Accelerated Skill Acquisition Program (ASAP). Activities to increase capacity, skill, and motivation were centered around meaningful tasks of the participant's choosing.

incorporation of impaired extremities into life activities. These three essential elements result in a set of eight nonexclusive principles that inform rehabilitation practice (Table 20.1). Activities to increase capacity, skills, and motivation are centered on specific tasks of the participant's choosing. Here the task is viewed as an important vehicle for the acquisition of skilled movements, a means to promote capacity building, and as a mechanism to foster the development of motivation for meaningful task engagement in the natural setting. Table 20.1 lists the principles of ASAP along with implementation examples.

As of this writing the ICARE phase III, randomized controlled trial (185) is currently underway. ICARE was developed to compare the effectiveness for paretic arm recovery of the investigational intervention, ASAP, with a dose-matched usual care group. It was designed with a relatively high dose of therapy in large part to ensure a reasonable test of the intervention that is dependent on sufficient practice for skill acquisition and generalizability beyond the clinic setting (i.e., 30 one-hour visits distributed over 10 weeks delivered in the outpatient setting). Primary outcomes from this trial are to be released during the first quarter of 2015. It is our expectation that the ASAP principles would apply across a diverse spectrum of disabling conditions to rehabilitation interventions for a number of different patient groups and are not unique to the case example of upper-extremity function in neurological conditions. Further refinement and testing of ASAP, and in varying populations and permutations, in well-conceived and sound clinical research is encouraged (5,239). The principle-based approach of ASAP relative to most protocol-driven approaches (e.g., CIMT) was undertaken to provide for a more flexible and customizable intervention, including innovative technologies for participants of varying clinical needs, severity levels, and personal preferences for therapeutic goals. The identification of multiple principles guiding dynamic clinical decisions means that in any given moment, some principles will be emphasized to the downplay of others. However, it is usually the case that therapeutic actions can satisfy one or more principles

TABLE 20.1 Principles of ASAP With Implementation Examples

ASAP PRINCIPLE	IMPLEMENTATION EXAMPLES
1. Ensure challenging and meaningful practice (48)	Demonstrate the challenge threshold (the performance threshold above which movement breaks down and is unsuccessful, and below which the task can be accomplished relatively successfully)
	Focus on skillful performance of important activity to participant
2. Address important (interfering) changeable impairments (235,278)	Focus on mitigating a particular area of weakness (e.g., wrist), pain, or interference with progress
3. Enhance motor capacity through overload and specificity (279)	Practice at a clearly intense level
	Provide task repetitions to physical limits
4. Preserve natural goal-directedness in movement organization (280)	Perform the natural task, practice with natural coordination demands
5. Avoid artificial task breakdowns when possible (281)	When feasible, practice the whole task in its functional entirety
	Break down the functional task when key to pinpointing or addressing the problem area
6. Assure active patient/participant involvement and opportunities for self-direction (228,229)	Encourage participant activity/response involving problem solving or task construction/determination
7. Balance immediate and future needs (55)	Participant problem solving (problem identification, solution generation, education, and action plan discussions focused on future, action plan extrapolations of session activities for home practice/recovery); focus is on knowledge and choices for the future
8. Drive task-specific self-confidence high through performance accomplishments (220)	Assess participant's task self-efficacy
	Demonstrate progress through clear measurement (timed performance, counts, repetitions, increased weight, etc.)
	Celebrate or attend to success

without contradicting others (203). It is expected that all of the principles will be supported over the course of a therapy session and especially over a multisession episode of care. The ability to take advantage of frequently occurring "teachable moments" is one strength of a principle-driven approach. Conversely, this abstraction and flexibility can be challenging for inexperienced clinicians but exciting to those seeking new challenges in their practice and high-quality interactions with their clients.

RESEARCH FRONTIERS

In this section, we briefly highlight four important research frontiers including: predictive models, mirror neuron system and the action observation network, quantification of the restitution–substitution continuum, and Attention and motor skill learning. Each topic is relevant to task-oriented approaches to promote recovery after stroke.

Predictive Models

This area is particularly challenging and identified by the NINDS Stroke Progress review group as one of the important unmet needs of the 2006 strategic planning process. Because poststroke recovery lasts several months, long-term outcomes must be considered to make informed decisions for individual patients. Two possible methods can be envisioned. First, the treatment modality and dose can be determined postdictively based on measured outcomes and iteratively. This method, however, is lengthy, costly, and may lead to sub-par outcomes because of the delays involved. Second, the treatment and dose can be determined predictively, based on a computational model of stroke recovery that predicts long-term outcomes. Predictive models, based on variants of the generalized linear model (GLM), are commonly used in clinical prediction rules. Several studies have employed such models with quantitative measures of anatomical and functional neural capacity (e.g., corticospinal tract) to determine functional potential in chronic stroke (240) or to determine the relationship between corticospinal tract injury and peduncular asymmetry (241). Recently, the predicting recovery potential (PREP) algorithm was developed for determining the recovery potential within the first 72 hours after stroke (147). Given that neural capacity largely determines potential for recovery and the choice of an appropriate rehabilitation strategy (242), patient specific models that include neural resources would be particularly appealing to optimize health care services.

However, because stroke recovery is a dynamic, time-varying, process, time should be included in predictive models. Although time can be added as a regressor in GLM models to predict recovery (243,244), GLMs are not well suited to model time-varying quantities. In addition,

because GLM models are nonmechanistic, parameters are empiric and generally have no true physical or physiological correspondence. In contrast, theory-driven and mechanistic dynamical, or state-space, models naturally encode time in differential equations that model "the change in states." Because of the multiplicity of plastic processes involved, upper extremity recovery is best modeled and predicted by dynamical state-space models that include both short and long time scales. On the one hand, change in performance during motor training occurs at a variety of time scales, some as short as 10s of seconds (245,246). We and others have shown that state-space models with short time scales can account for motor adaptation in stroke (247) and motor learning in poststroke individuals (117,148). On the other hand, recovery after stroke is characterized by a number of repair and plastic processes that happen at time scales of weeks to months. For instance, the initial performance changes after stroke are mostly because of "spontaneous recovery," which involves both reduction of the ischemic penumbra and brain reorganization (155), and are maximally expressed in the first four weeks after stroke, but continue until about six months (249). In addition, rehabilitation, consisting of thousands of practice movements over weeks, influences recovery (1,250–252). In previous work, we showed the existence of time-varying interactions between the amount of daily arm use and recovery of function via a dynamical model of stroke recovery in the two years following therapy (178,227,253). The model notably showed that learned nonuse, and its possible reversal, can be best framed in terms of interactions between motor learning and adaptive decision making (253,254). In addition, the model predicted that there is a threshold in function above which spontaneous use and function can spontaneously improve in a virtuous circle (253). We provided supporting data at the group-level for such a threshold (227). In these models of recovery, the main recovery time constant was several weeks. However, the time constant controlling the change in the decisions to learn one hand or the other was much smaller, and as a result, the model developed learned nonuse soon after stroke. Because it is unknown how fast learned nonuse actually develops after stroke, hand choice and kinematic data collected soon after stroke would lead to better parameter estimation, and hence, better predictions from these models.

Mirror Neuron System and Action Observation Network

A second exciting research frontier involves the *mirror neuron system* (255). Evidence for a human mirror neuron system and action observation network is mounting (256,257). However, there still is considerable controversy and confusion about the homologue to the primate mirror neuron system (258) as well as the purpose of the action observation network (259) in humans. Studies have been conducted to examine the sensitivity of the action observation network to physical and observational learning in humans (260). A provocative review suggested that the mirror neuron system might provide a useful circuitry to enhance recovery of the severely affected upper limb early after stroke (261). One of the first studies that provided empirical support for the use of action observation with intent to imitate in the context of stroke rehabilitation was published in 2007 (262). Recently, action observation was classified as one of several specific priming techniques to increase the excitability of the stroke-affected motor system and promote plastic reorganization in response to subsequent practice of physical activity (263). A small-scale study with eight chronic stroke patients provided evidence that a single session of action observation that was congruent with the practiced movement (i.e., voluntary thumb movement in a specific direction) enhanced motor memory more than practice alone or action observation of thumb movements that were incongruent to the practiced movement (264). However, a recent translational RCT found that observation-to-imitate plus practice for 15 days of treatment could add little to physical therapy benefits early after stroke (within 31 days) (265). Given the variable response to action observation in the stroke population, it will be important to understand how the stroke brain responds to action observation. Garrison and colleagues conducted the first fMRI investigation to determine if and how the motor system is modulated by action observation after stroke (266). Functional MRI was used to compare brain activity during right and left hand action observation in right-handed nondisabled matched participants (n = 12) and participants who were right-handed before left hemisphere stroke (n = 12). Action observation was found to activate specific motor plans in damaged motor circuits after stroke, and this activity was related to the motor capabilities to perform the same actions. Cortical motor activity during action observation may be relevant to motor learning and motor relearning in stroke rehabilitation. Harnessing the action observation network after stroke represents an exciting frontier for neurorehabilitation and a potentially important underutilized circuit for driving relevant recovery after stroke.

Quantification of the Restitution–Substitution Continuum

As discussed earlier in the first section, considerable attention has been directed toward defining the optimal outcome with reference to the rehabilitation process along the restitution–substitution continuum (36,37,187). Recently, a very reasonable argument has been put forward to the research community that to achieve restoration of upper extremity function in poststroke survivors requires intense therapy early after injury, but not too early (37,267). However, an unresolved but important issue that may impact the interpretation of outcomes following neurorehabilitation and, by extension, reimbursement decisions, is the need for a valid and unified distinction between compensation and restoration. A distinction between the two should be predicated upon objective data.

Recently, a collaborative group developed a quantification schema called the kinematic impairment measure (KIM).

KIM is a compellation of 43 kinematic measurements acquired simultaneously during reaching movements performed in the context of an adaptive mixed reality system for stroke survivors (268,269). KIM values are compiled for each variable and averaged across all of them to create a composite KIM score. The scoring system is based upon a binary where a "0" is an average value (and its variability) extracted from age-matched able-bodied participants and a "1" is the maximal deviation beyond the normal variance as measured from a patient with stroke. In this way, at least three objectives are achieved: (a) quantifying quality of movement; (b) assigning a specific metric that can serve as a model to distinguish compensatory/substitution from restorative behaviors; and (c) informing a clinician about which kinematic dimensions of movement need to be emphasized in the rehabilitation process, information specification that might not ordinarily be achieved through casual observation. This scheme, therefore, would define restoration as any value among the multiple kinematic measurements that falls within the variance derived from each kinematic measurement and compensation as any that does not. Hence, the collective components of the movement are reduced to a series of independent kinematic measurements, some of which may fall within the restorative range and some of which may not. Ultimately, the argument could be made that for a given functional task (e.g., goal-directed reaching movements), the average KIM score would be indicative of a compensatory behavior containing subcomponents that have both compensatory and restorative features. This KIM quantification scheme has shown promise as part of a mixed reality interactive neurorehabilitation system (270,271).

Attention and Motor Skill Learning

Finally, the area of *attention and motor skill learning* is an important one for motor retraining (272). There is considerable evidence that a simple manipulation of attentional focus can benefit motor learning (273–276). Instructional manipulations that focus attention on external cues are more effective for motor learning than those that direct attention on internal cues (i.e., the moving limb or pressure under the feet). Fasoli and colleagues tested this simple concept in an experiment dealing with functional reach actions in persons with and without cerebrovascular accident (277). One group was instructed to focus on the to-be-grasped object, and the other was instructed to focus on their arm movements. The results showed that both nondisabled and disabled groups performed the tasks more effectively (e.g., more effective movement kinematics) if given external rather than internal focus instructions. This finding suggests that participants with stroke and controls preplanned these functional actions to a greater extent and used more automatic control processes when they focused externally. The importance of this work for task-oriented training in rehabilitation is tremendous. It suggests that the nature of the instructions about attentional focus can impact the effectiveness of the training program and could be as important as the specific training paradigm for determining the most effective dose of training. For example, a task-oriented training program administered using instructions for an external focus of attention would be expected to achieve a clinically meaningful outcome with greater efficiency (e.g., shorter time, smaller dose) than one using instructions for an internal focus of attention. This area is clearly important for future developments and in conjunction with determining the pharmacokinetics of task-oriented training.

CONCLUSION

We find ourselves in a particularly exciting time for neurorehabilitation, repair, and recovery, with significant advances both in the basic and clinical sciences. In this chapter, we merely scratch the surface of the most relevant foundations including opportunities and limitations of the dominant approach to motor restoration, a task-oriented or task-specific approach. Contrary to current medical reimbursement models that support early acute and subacute stages of rehabilitation, substantial evidence supports the effectiveness of task-oriented training in the postsubacute and chronic stages of recovery. More work is needed to determine the best predictors of recovery and the nature of that recovery (restitution vs. substitution) so that therapies can be personalized for optimal recovery. Further, more work is needed in the area of clinical translation of task-oriented approaches across different care settings to maximize outreach and dissemination.

We are encouraged by how much is known, and at the same time, how little is known, for example, about the "pharmacokinetics" of training and how that training can be personalized to the individual's characteristics including social, cognitive, and neural factors. Building a strong theoretical foundation will be important for future advances in this exciting field of neurorehabilitation. We hope this updated chapter provides a beginning and impetus for these future advances in rehabilitation science.

Neuromuscular Electrical Stimulation for Motor Restoration in Hemiplegia

Lynne R. Sheffler, Jayme S. Knutson, and John Chae

This chapter provides a comprehensive review of upper- and lower-limb clinical applications of neuromuscular electrical stimulation (NMES) specifically for the hemiparetic stroke survivor. NMES is the application of a low-level electrical current for the purpose of eliciting a contraction of muscle fibers that have been paralyzed secondary to an upper motor neuron injury such as stroke. NMES is applied in hemiplegia as either a therapy or an assistive device. In therapeutic applications, a regimen of NMES may produce a lasting effect that reduces motor impairment level and/or improves functional performance. A therapeutic effect is both measurable and sustained after the NMES device is turned off. An example of a therapeutic effect of NMES in hemiparesis is motor relearning, which is defined as "the recovery of previously learned motor skills that have been lost following localized damage to the central nervous system" (1). Another therapeutic application of NMES, the management of poststroke shoulder pain, is addressed in Chapter 30 ("Musculoskeletal Complications After Stroke"). Applications in which NMES is used as an assistive device to perform an upper- or lower-limb task are called functional electrical stimulation (FES) applications (2). Specific movement tasks may include grasping an object or stepping over an obstacle. An FES device is called a *neuroprosthesis*, and the measurable improvement in functional performance that occurs when the neuroprosthesis is being used is called the *neuroprosthetic effect*. In clinical practice, a neuroprosthesis may produce a neuroprosthetic effect, a therapeutic effect, or both.

This chapter is organized to first provide an overview of the basic neurophysiologic principles that underlie all NMES applications. These include principles of electrical activation of muscle, modulation of muscle contraction, and safe delivery of electrical current. Second, we describe basic NMES system components, which include the electrodes, neurostimulator, and controller. Third, we present an overview of therapeutic applications of NMES, limited to upper- and lower-limb poststroke motor relearning. Fourth, clinical poststroke neuroprosthetic applications for upper-limb activities of daily living (ADLs) and lower-limb mobility are reviewed. Lastly, we present a critical review of the stroke NMES literature and our perspective on promising research initiatives for future clinical NMES systems.

NEUROPHYSIOLOGY OF NMES

Principles of Electrical Activation of Muscle

When applied to a healthy, intact nerve, an electrical current can cause the initiation and propagation of action potentials (AP) within motor neurons that ultimately result in the contraction of muscle fibers. An NMES system uses a pair of electrodes to deliver an electrical current and create a localized electric field that depolarizes the axonal membranes of the motor neurons in closest proximity to the electrodes. If the magnitude of the depolarization reaches a critical threshold for any given neuron, an influx of extracellular sodium ions into the intracellular space is triggered, and an AP is generated (3). The AP propagates the length of the axon to the axonal terminal and, in the case of a motor neuron, triggers the release of neurotransmitter from synaptic vesicles into the neuromuscular junction that results in muscle fiber contraction. The so-called "all or none" phenomenon of an AP that is produced by natural physiologic means is identical to an NMES-initiated AP.

The stimulus threshold necessary to generate an AP in neural tissue is much lower than the threshold for activating muscle fibers directly (3). Therefore, what is often termed "muscle stimulation" is in reality the activation of motor neurons that innervate target muscles. That is why denervated or partially denervated muscles do not respond well to NMES and why stroke survivors who have a concomitant peripheral nerve injury, severe peripheral motor neuropathy, disease of the neuromuscular junction, and/or a congenital or acquired myopathy, may not be good candidates for NMES. The most common targets for NMES are peripheral nerves and motor points of the target muscles. Nerves and motor points closest to the stimulating electrodes are more likely to be activated than those farther away because the transmembrane potentials generated by the electrical current are greatest in the axons closest to the stimulus source. Therefore,

selectivity of stimulation is increased, and less current is required by placing the electrodes in closest proximity to the target neural tissue.

Under normal physiologic mechanisms, as more muscle force is needed, neurons with smaller diameter axons are recruited prior to neurons with larger diameter axons. With NMES, however, larger diameter axons are recruited preferentially before small diameter axons because large diameter axons have lower stimulus thresholds. This phenomenon is referred to as "reverse recruitment order." Nerve fiber recruitment order is important clinically because of the relationship between nerve fiber recruitment and activation of motor units. A *motor unit* is defined as a single neuronal cell body located in the anterior horn of the spinal cord, its motor axon, and all of the muscle fibers innervated by that axon. All muscle fibers of a single motor unit are of the same type (Type I or Type II muscle fibers), and all associated muscle fibers contract when a motor unit is activated. Larger diameter axons innervate Type II muscle fibers and are associated with larger motor units, whereas smaller diameter axons innervate Type I muscle fibers and are associated with smaller motor units. Thus, clinical NMES systems preferentially activate large diameter motor neurons that innervate larger motor units comprised primarily of Type II muscle fibers.

In most clinical NMES applications, the primary recruitment of Type I muscle fibers (physiologic recruitment order) would be preferable to the recruitment of Type II muscle fibers ("reverse recruitment" order) because of the physiologic characteristics that differentiate the two fiber types. Skeletal muscle contains "fast" and "slow" muscle fibers that are distinguished on the basis of their contraction kinetics. Slow-twitch, oxidative Type I muscle fibers generate lower forces, but are fatigue resistant, whereas fast-twitch glycolytic Type II muscle fibers generate higher forces but fatigue more rapidly (4). The primary activation of muscle fibers that are fatigue resistant is highly desirable, particularly in neuroprosthetic (FES) applications where functional movement tasks require sustained, repetitive muscle contraction. Recent research has explored the viability of selectively activating smaller diameter fibers by reshaping the extracellular voltage profile along the nerve, effectively reversing the recruitment order elicited by NMES (5,6), although these methods remain experimental and are not available for clinical use.

Unfortunately, disuse muscle atrophy, which is a common sequela of an upper motor neuron injury, is characterized by the conversion of fatigue-resistant Type I muscle fibers to fast-fatiguing Type II muscle fibers (7). Chronic NMES applied at stimulus frequencies of 10 to 12 Hz has been demonstrated to effectively reverse this natural conversion of muscle fibers and convert fast-fatiguing fibers to fatigue-resistant fibers to some degree (8). The ability of NMES to "reverse" Type I to Type II fiber conversion is proposed to be related to NMES-induced changes in the motor neuron firing patterns that control expression of specific contractile proteins and metabolic enzymes in muscle fibers (9). Because of muscle fiber conversion, many clinical NMES applications include a conditioning component that is intended to both increase and optimize the functioning of fatigue-resistant muscle fibers.

Modulation of Muscle Contraction

In NMES, electrical current usually is delivered as a train of pulses. The strength of a NMES-elicited muscle contraction may be modulated by varying three stimulus parameters of the applied electrical current: the stimulus pulse frequency, pulse amplitude, and pulse duration. A minimum stimulus pulse frequency (i.e., fusion frequency) is necessary to produce a "fused" muscle contraction and not simply a series of individual muscle "twitches." In general, a higher pulse frequency produces a stronger muscle contraction; however, the clinical trade-off of a higher pulse frequency is more rapid fatigue of the muscle fibers. The optimal pulse frequency for a muscle contraction is thus the minimum pulse frequency that generates a fused muscle response without discomfort given the muscle fiber type, degree of muscle conditioning, and electrode type used to deliver the stimulation (surface or implanted). The pulse frequency is determined experimentally for any given application. The strength of a muscle contraction also may be modulated by changing the magnitude of the electric charge per pulse by adjusting either the stimulus pulse amplitude or the pulse duration (10). A greater electric charge creates a larger electrical field that allows activation of more neurons, including those at a greater distance from the electrode, and thus activation of a greater total number of motor units. In most NMES applications, the stimulus pulse frequency is kept constant. Either the stimulus pulse amplitude is kept constant and the pulse duration is manipulated to optimize the strength of the muscle contraction, or the pulse duration is kept constant and pulse amplitude modulates contraction strength.

Muscle fatigue is defined as a decrease in the force-generating ability of a muscle that results from recent muscle activation (11). Muscle fatigue may limit the ability of a stroke survivor to use a neuroprosthesis with consistent performance for an extended period of time. As a result, research has focused on the variable relationship between stimulus pulse frequency patterns and muscle force generation as one way to mitigate muscle fatigue. Usually, NMES applications stimulate skeletal muscle using a constant pulse frequency. Binder-Macleod et al. (12) experimented with specific stimulus waveforms characterized by doublets, pulses separated by short interpulse intervals (5 ms). In a study of repetitive isometric activation of the quadriceps muscles of subjects with paralysis, Scott et al. (13) found that a variable stimulus pattern that combined constant-frequency pulses and doublets resulted in achieving a targeted isometric force 14% more frequently than the constant-frequency pulses alone and 18% more frequently than the doublets alone. In fatigued muscle, multiple studies have demonstrated that isometric (12,14) and nonisometric (15) muscle force generation is optimized when stimulus waveforms are characterized by doublets combined with constant-frequency pulses. These studies and others

(14,16–21) suggest that manipulating stimulus waveform characteristics may be a method to minimize skeletal muscle fatigue while optimizing performance in FES applications.

Safe Delivery of Electrical Current

Clinical NMES stimulators may be either current-regulated or voltage-regulated. *Current*, which is defined as the charge delivered per unit of time, is directly controlled using a current-regulated stimulator. Thus, the quantity of charge per stimulus pulse is chosen and can be maintained within safe limits given the material composition of the electrode. Current density (charge per unit area) thresholds determine if electrode corrosion or tissue damage occurs. In general, current-regulated stimulators must be used with implanted NMES electrode applications and current- or voltage-regulated stimulators can be used with surface NMES electrode applications. With a voltage-regulated stimulator, the magnitude of the current (and therefore, charge density) delivered to the tissue may be variable because it is dependent on the impedance (resistance) at the electrode–tissue interface, which can change over time. Per Ohm's Law, as resistance (impedance) increases, current decreases for a fixed voltage [I (current) = V (voltage)/R (resistance)]. The impedance at a surface electrode–tissue interface is much greater and more variable than impedance at an implanted electrode–tissue interface. Because the risk of tissue injury in any given patient is directly related to the magnitude of the charge density, one advantage of voltage-regulated stimulation is the decreased likelihood for tissue injury. If a surface electrode pulls away from the skin, the current delivered by the electrode will decrease because impedance has increased. However, the disadvantage of voltage-regulated stimulation is that it can result in inconsistent muscle contractions. A current-regulated stimulator can be used to provide more consistent muscle contractions as long as the electrodes are charged frequently to keep the electrode–skin impedance consistent.

SYSTEM COMPONENTS

Electrodes, Neurostimulator, and Controller

NMES systems generally consist of at least three components: electrodes, a neurostimulator, and a controller. Surface, percutaneous, or implanted electrodes deliver electrical current pulses to the neural tissue. The neurostimulator generates the current waveforms from a power supply. The controller regulates the stimulation in response to an input signal, switch, or preset program. With surface NMES systems, the electrodes, neurostimulator, and controller all are external to the body. With percutaneous NMES systems, an electrode is implanted into the muscle or near a nerve and a lead attached to the electrode exits the skin and connects to the neurostimulator and controller, both of which are external. With implanted NMES systems, the electrode, connecting lead wire, and neurostimulator all are fully implanted. An implanted neurostimulator generally receives both power and command instructions through a radio-frequency telemetry link to an external control unit.

Each NMES system, classified by electrode type, has specific features that should be considered when used for clinical or research purposes. A surface-electrode NMES system, although generally well tolerated in most patients, may pose a risk of tissue injury in patients with concomitant sensory and/or cognitive deficits. Thus, careful patient selection is required. Activation of cutaneous pain receptors, electrode positioning, limited selectivity of nerve and/or muscle fibers, insecure fixation on moving limbs, skin irritation, and undesirable cosmesis are common limitations of surface electrodes. The advantages of using surface electrodes to deliver NMES include easy application in clinical settings, low cost, noninvasiveness, and the commercial availability of surface neurostimulator units for home use. Percutaneous NMES systems are particularly useful in activating small, deep muscles such as the intrinsic muscles of the hand. Percutaneous electrodes are inserted through the skin into the target muscle and thus carry the risks of displacement or breakage, infection, and granuloma formation secondary to retained electrode fragments when the electrode is removed (22). The advantages of a percutaneous electrode include elimination of skin resistance, bypassing of cutaneous pain receptors, and greater muscle selectivity. Lastly, implanted electrodes are designed for longer-term use and are attached directly to muscle or nerve tissue via a surgical procedure. Epimysial electrodes are sutured directly to the epimysium or fascia of the target muscle (23). Epineural electrodes are sutured to connective tissue directly surrounding the nerve (24). Intramuscular electrodes are inserted at the motor points of the target muscles. Direct nerve stimulation is most commonly achieved via a nerve cuff electrode that encompasses the nerve trunk and requires approximately one-tenth of the current necessary for intramuscular stimulation (25).

For any NMES system to be used as a neuroprosthesis, there is the additional requirement of volitional control to carry out a specific functional task. A key component to the design of FES control systems, thus, is the correlation of user intent or the movement task desired to actual functional performance. Many clinical FES systems utilize an open loop control system in which the user regulates the stimulation based on feedback for necessary system modifications; this is limited to visual and/or proprioceptive input. Though closed loop control systems are not clinically available, such a system would allow continuous automatic real-time modification of the stimulation via feedback input. The optimal clinical FES system, given the nonlinearity and temporal variability of contractile muscle forces, would be a closed loop system modulated by sensor-derived feedback signals (26,27). An ideal FES control system would yield consistent and predictable response to internal time variations (e.g., fatigue, effort) as well as external perturbations to the system (e.g., changing muscle loads, resistance).

MOTOR RELEARNING

Basic Science and Theoretical Considerations

Goal-oriented active repetitive movement training of the paretic limb following injury to the brain has been demonstrated to enhance motor relearning in both research and clinical applications. Researchers have explored possible mechanisms for movement-associated motor relearning based on the known plasticity of the central nervous system. In an animal model, Asanuma and Keller showed that electrical stimulation of the somatosensory cortex alone or in conjunction with thalamic stimulation induced long-term potentiation (LTP) in the motor cortex (28). They hypothesized that proprioceptive and cutaneous afferent impulses associated with repetitive movement modify the excitability of specific motor neurons to facilitate motor relearning (29). Ke et al. (30) showed an association between exercise-induced upregulation of hippocampal brain neurotrophic factor (BDNF) and motor recovery following brain ischemia. Nonhuman primate research has demonstrated that after local damage to the motor cortex, goal-oriented, active repetitive movement training of the paretic limb shaped subsequent functional reorganization in the adjacent intact cortex, and the undamaged motor cortex played an important role in motor relearning. Specific types of behavioral experiences that induce long-term plasticity in motor maps were repetitive movements that entail the development of motor skills (31). That is, the motor tasks were new and therefore, "required" significant cognitive effort to learn and complete. Training to acquire new skills such as retrieving food pellets from a small well or a rotating well were associated with task-specific cortical reorganization. However, this was not the case with repetitive movement tasks that did not require new skill acquisition (i.e., motor tasks are already mastered and, therefore, are easy to carry out and require minimal to no cognitive effort) (32).

Because goal-oriented repetitive movement therapy facilitates motor relearning, electrical stimulation-mediated goal-oriented repetitive movement therapy also may facilitate motor relearning. There is evidence that electrical stimulation of the peripheral nerve is associated with concomitant physiologic changes in the brain. Electrical stimulation to a peripheral nerve has been associated with activation of both sensory and motor structures in the brain (33) and reduction of intracortical inhibition (34). Han et al. (35) demonstrated that NMES-mediated wrist extension elicited activation of the contralateral somatosensory cortex and bilateral supplementary motor areas using functional magnetic resonance imaging (fMRI). Smith et al. (36) used fMRI to demonstrate a dose–response relationship between selected NMES stimulation parameters and the hemodynamic responses in sensorimotor regions. Research supports that repetitive movement therapy mediated by NMES has the potential to facilitate motor relearning via cortical mechanisms (37). NMES can be used by stroke survivors with hemiparesis who do not have sufficient residual movement to take part in volitional, active repetitive movement therapy. Regardless of mechanism, the experimental and theoretical considerations suggest that the necessary prerequisites for NMES mediated motor relearning include repetition, novelty of activity, concurrent volitional effort, and high functional content.

Several forms of NMES systems are available clinically for poststroke motor relearning applications: cyclic NMES, electromyography (EMG)-triggered NMES, and neuroprostheses. Cyclic NMES systems contract paretic muscles at a set duty cycle for a preset time period without any input from the patient beyond turning the device on and off. The patient is a passive participant and is not required to invest cognitive effort in the form of either initiation of muscle contraction, interpretation of afferent signals, or functionality of motor task. EMG-triggered stimulation requires that the subject generate a detectable EMG signal by attempting volitional muscle contraction. The EMG signal is recorded by a surface electrode and that signal is used to turn on NMES for a preset duration. Thus, EMG-triggered NMES systems have the ability to couple motor intent to motor response. This technique may be applied to patients who can partially activate a paretic muscle but are unable to generate sufficient muscle contraction for adequate exercise or functional purposes. Alternative patient-initiated volitional triggers are being evaluated for clinical use. Mann et al. recently described an accelerometer-triggered NMES system, which also requires volitional muscle contraction but triggers in response to change in joint position (38). Whereas the patients who use cyclic NMES are passive participants, EMG-triggered NMES requires greater cognitive investment, which may theoretically result in greater therapeutic benefit (39). The third type of NMES system is a neuroprosthetic application that provides FES for completion of ADL and mobility tasks. Because repetitive movement training is performed in the context of meaningful, functional behavioral tasks, neuroprostheses have a theoretical advantage over both cyclic and EMG-triggered NMES systems for motor relearning. Neuroprosthetic applications are discussed in greater detail in a later section.

Contralaterally controlled functional electrical stimulation (CCFES) is an innovative research application of NMES (40,41). Upper-limb CCFES uses surface NMES to open the paretic hand in direct proportion to the degree of volitional movement of the unimpaired contralateral hand, which wears an instrumented glove (Figure 21.1). The rationale for using CCFES for poststroke motor relearning is that, as compared to cyclic NMES or EMG-triggered NMES, CCFES maximizes the degree of coupling between motor intention (central or presynaptic activity) and stimulated motor response (peripheral, or postsynaptic activity). The subject not only controls the onset and duration of the stimulation but also controls the intensity of stimulation and resultant degree of hand opening, potentially creating a stronger perception of restored motor control. In addition to enabling active repetitive goal-oriented movement and coupling motor intention to motor output and afferent feedback, the CCFES paradigm incorporates both bilateral symmetric

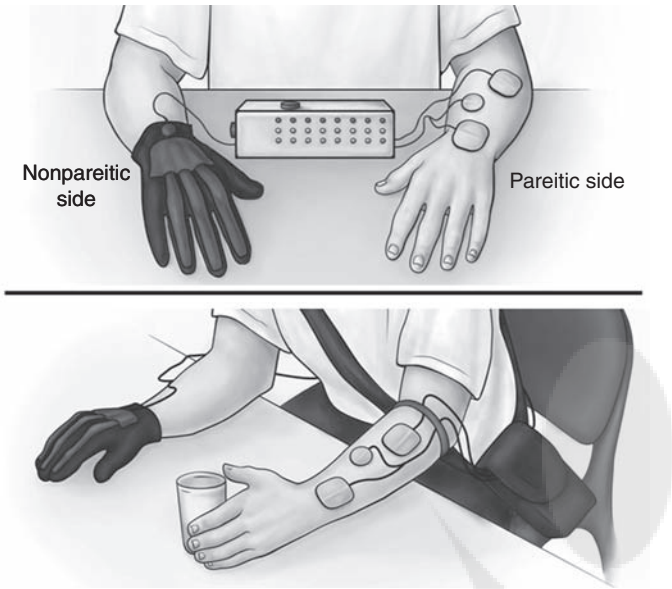

FIGURE 21.1 Contralaterally controlled FES system for repetitive intention-driven hand opening exercise and functional task-practice therapy after stroke.

Used with permission, Cleveland Functional Electrical Stimulation Center, Cleveland, Ohio.

movement and motor imagery, rehabilitation techniques that have been associated with improved motor recovery. CCFES also enables stroke survivors to practice functional tasks, similar to a neuroprosthesis.

Upper-Limb Applications

Multiple randomized clinical trials have evaluated the efficacy of cyclic NMES in enhancing upper-limb motor relearning (42–50) and demonstrated improvement in motor impairment. Rosewilliam et al. (47), recently found that acute stroke survivors (<6 weeks after stroke) with severe upper-extremity disability who received 6 weeks of surface NMES demonstrated significant improvement in wrist extensor and grip strength at end of treatment as compared to a control group, though arm function as measured by the action research arm test (ARAT) scores did not differ between groups. In a study by Lin et al. (48), stroke survivors who received 3 weeks of NMES and a control group both demonstrated gains in Fugl-Meyer (FMA) and Modified Ashworth scores (but not modified Barthel index) at end of treatment, though the gains in the NMES group were significantly better than the control group at 3 and 6 months after treatment. Improvement in activity limitations has been demonstrated as a secondary outcome in a subset of those studies that demonstrated an improvement in motor impairment (45,46,49,50). In various studies, NMES treatment groups have demonstrated significantly greater functional performance, as compared to a control group, on end-of-treatment ARAT score (45,50), object manipulation (49), Barthel index (49), and the functional independence measure (FIM) (37).

Several clinical trials have evaluated EMG-triggered NMES for upper-limb motor relearning (51–56). In general, these studies demonstrated improvement in motor impairment at end of treatment. In the few studies that evaluated activity limitations, improved outcomes were also noted (52,55,56). Kimberley et al. compared 3 weeks of EMG-triggered NMES to the extensor muscles of the forearm to sham NMES treatment in chronic stroke survivors (55). The EMG-triggered NMES group demonstrated significant improvements in measures of isometric finger extension strength, grasp, and release of objects (Box and Block Test and Jebsen Taylor Hand Function), and self-rated activity limitation (motor activity log). In addition, fMRI and a finger-tracking task demonstrated significantly increased cortical intensity in the contralesional somatosensory cortex from pretest to posttest following treatment. The participants receiving sham treatments failed to improve on any of the outcome measures except isometric finger extension strength. EMG-triggered NMES research also suggests that central mechanisms, evidenced by changes in assays such as reaction time (54), fMRI cortical activation patterns (55–57), and positron emission tomography (PET) scanning (58), may be associated with improved outcomes.

These studies suggest that EMG-triggered NMES reduces upper-limb motor impairment, possibly through central mechanisms, and that these changes may translate into improvements in activity limitations. However, a paradigm shift in the clinical application of NMES in stroke would require that one application (in this case, EMG-triggered) be clearly superior to standard of care treatment (cyclic and/or sensory stimulation). Two recent randomized controlled trials suggest that EMG-triggered NMES does not have a greater therapeutic effect on motor recovery than either cyclic NMES and/or sensory stimulation. DeKroon et al. (59) compared the efficacy of a six-week trial of upper-extremity surface EMG-triggered NMES versus cyclic NMES in chronic stroke and did not detect a significant difference with respect to improvement in motor function at end of treatment. Similarly, Chae et al. (60) compared the effect of surface EMG-triggered, cyclic NMES and sensory stimulation (placebo) on motor recovery in a randomized clinical trial (RCT) that enrolled 122 subacute stroke survivors. Although all three groups experienced significant improvements in FMA and arm motor ability test (AMAT) scores following eight weeks of treatment, EMG-triggered NMES and cyclic NMES were no more effective than sensory stimulation.

The therapeutic efficacy for NMES delivered via percutaneous electrodes has been evaluated specifically because pain tolerance and muscle specificity are limiting factors in some applications with surface electrodes (61). Chae et al. (62) randomized 26 chronic stroke survivors to either percutaneous NMES for hand opening or percutaneous sensory stimulation only. The percutaneous NMES group received six weeks of cyclic, EMG-triggered, or EMG-controlled

NMES depending on baseline motor status. There was no significant treatment or time × treatment effects for any of the outcomes (FMA, AMAT, delay, and termination of EMG activity) at end of treatment or at 1, 3, or 6 months follow-up. The authors concluded that percutaneous NMES (delivered as cyclic, EMG-triggered, or EMG-controlled) was no more effective than percutaneous sensory stimulation for the recovery of the hemiparetic upper limb among chronic stroke survivors.

Studies of the neuroprosthetic effect of a hand neuroprostheses for hemiplegic stroke survivors are reviewed later in this chapter. However, a motor relearning effect associated with the use of the upper-extremity neuroprosthesis, which is sustained and measurable after removal of the neuroprosthesis, has been evaluated (63–70). Two studies (63,64) parenthetically reported evidence of improved motor ability when the upper-extremity neuroprosthesis was turned off after a period of use. Alon et al. (65) evaluated the therapeutic effect of five weeks' use of a hybrid brace-NMES device that incorporated surface electrodes into a brace for hand grasp and release (Bioness H200) and found significant improvement in motor impairment and activity limitation. More recently, Page et al. (68) compared the effect of 30, 60, and 120 minutes of repetitive task-specific practice incorporating an upper-extremity neuroprosthesis in chronic stroke survivors over an 8-week treatment period and found significant increases in FMA, AMAT, and ARAT performance limited only to the 120-minute intervention group. A subsequent study (69) evaluated the retention of the upper-extremity gains in the treatment group and found no significant change in scores from end of treatment to 3 months after treatment. Improvement in motor impairment in eight chronic stroke survivors following eight weeks of upper-extremity neuroprosthesis use also was associated with an increase in cortical activation on fMRI (71). Lastly, the neuroprosthetic effect of an FES grasp-assist glove for use with task-oriented robotic stroke therapy for hand opening (72), a hybrid wrist splint with volitional electrical stimulation (73), and a fully implantable upper-extremity neuroprosthesis (74) have been described, though none has been studied in a controlled trial nor evaluated for a motor relearning effect.

Finally, a recent RCT (40) of subacute stroke survivors demonstrated that six weeks of CCFES produced greater improvement in voluntary finger extension angle, finger movement tracking error, FMA score, Box and Blocks test, and AMAT scores as compared to cyclic NMES. Maximum voluntary finger extension showed the largest treatment effect, with a mean group difference across the posttreatment time points of 28 degrees more finger extension for CCFES. Additional studies are planned to further evaluate the therapeutic effect of CCFES as a poststroke rehabilitation intervention.

In summary, although the strength of many of these NMES studies rests on a randomized study design, methodological limitations render results difficult to interpret, including inadequate blinding, unequal treatment intensity, inconsistent follow-up beyond end of treatment, inadequate accounting of dropouts, and failure to use intent-to-treat analysis. Nevertheless, the literature suggests that upper-extremity NMES is effective in enhancing poststroke motor impairment, although interval after stroke (44,45,49), baseline level of motor impairment, and NMES dose (50) may affect the potential for motor relearning. The effect of upper-extremity NMES on activity limitations is suggested by many studies, though not conclusive. In terms of motor relearning theory, EMG-triggered NMES would be expected to have a greater therapeutic effect than either cyclic or sensory stimulation. However, recent RCTs (59,60) did not demonstrate superiority of upper-extremity EMG-triggered NMES. Whereas sensory stimulation, cyclic NMES, and EMG-triggered NMES using surface electrodes remain therapeutic tools in the armamentarium of rehabilitation clinicians, these RCTs strongly challenge a prevailing clinical belief that EMG-triggered NMES provides greater therapeutic benefit in the stroke patient population. Clinical prescription of NMES for the upper extremity thus should be primarily driven by clinical considerations including residual motor function, ease of application and compliance, and patient preference without expectation that a specific mode of delivery will have greater benefit. Future NMES research for upper-extremity motor relearning should expand on exploratory studies that have combined various upper-extremity NMES therapies with other motor relearning strategies to enhance efficacy, including mental imagery (58), mirror therapy (75), robotics (76–78), botulinum toxin plus task practice (79), various forms of bilateral upper-extremity therapies (80,81), and noninvasive brain computer interfaces (82).

Lower-Limb Applications

Surface NMES lower-extremity applications have been shown to improve motor recovery in controlled clinical stroke trials. Surface NMES has been demonstrated to improve strength of paretic ankle dorsiflexors (83,84), ankle dorsiflexion moment (85,86), and EMG agonist activity (86) and decrease plantar flexion spasticity (83,84,87) and antagonist co-contraction (83,86). In a recent randomized trial, Sabut et al. (88) found that a hemiparetic treatment group that received 12 weeks of NMES to the dorsiflexors applied during a daily therapy session demonstrated greater improvements in plantar flexor spasticity, dorsiflexion strength, active and passive ankle range of motion, and lower-extremity FMA motor impairment score as compared to a control group. EMG-triggered NMES to enhance ankle strength, range of motion, and balance has been evaluated for stroke survivors with residual dorsiflexion movement (89–91).

In a case series, Knutson et al. (92) recently evaluated the application of CCFES to the lower extremity as a therapy intended to improve poststroke motor recovery. CCNMES dorsiflexes the paretic ankle by stimulating the peroneal nerve in direct proportion to the degree of voluntary dorsiflexion of the (nonparetic) contralateral ankle. In two of the three subjects evaluated, improvements were noted in maximum voluntary ankle dorsiflexion, ankle tracking error,

and lower-limb FMA score at end of treatment and were sustained at three months posttreatment.

Lieberson et al. (93) described the first single-channel surface peroneal nerve stimulator (PNS) to provide ankle dorsiflexion during the swing phase of gait for stroke survivors. He commented, "On several occasions we observed, after training with the electrophysiologic brace [PNS] . . . patients acquire the ability of dorsiflexing the foot by themselves." A PNS device stimulates the common peroneal nerve near the head of the femur to activate both the tibialis anterior and the peroneus longus and brevis muscles. Multiple subsequent case series evaluating PNS neuroprosthetic systems described similar observations of improved ambulation function, more normal EMG muscle activation patterns, emergence of EMG signals in previously silent muscles, increased strength of EMG activity, and/or decreased co-contraction of antagonist muscles (94–103). Studies that have demonstrated a therapeutic effect of PNS have hypothesized that central mechanisms may be responsible (104–106). Everaert et al. (105) studied the effect of long-term use of a PNS device on residual corticospinal connections in people with central nervous system disorders. Following 3 to 12 months of use of the PNS device, both motor-evoked potentials (MEP) elicited by transcranial magnetic stimulation applied over the motor cortex and maximum voluntary contraction (MVC) of the anterior tibialis muscle were significantly improved in the subgroup of their subjects with stroke. The authors hypothesized that the increases in MEP and MVC were evidence that regular use of a PNS device strengthened activation of motor cortical areas and their residual descending connections, which may explain any therapeutic effect.

Presently, the standard of care intervention for moderate to severe poststroke dorsiflexion weakness associated with gait dysfunction is an ankle–foot orthosis (AFO). To challenge standard of care practice, definitive evidence would be necessary to show that an alternative intervention (PNS device) provided either an equivalent orthotic (neuroprosthetic) effect on walking or a superior effect on motor relearning in stroke. Importantly, two recent RCTs (107,108) did not demonstrate a motor relearning (therapeutic) effect associated with the use of a lower-extremity PNS device in chronic stroke survivors. In a single-blinded RCT, Sheffler et al. (107) compared the effect of 12 weeks of ambulation training with a surface PNS device to ambulation training with usual care treatment (*ankle–foot orthosis* or no device). One hundred and five stroke participants were evaluated at baseline, end of treatment, and 3 months and 6 months posttreatment. Primary outcome measures were the lower-extremity FMA (motor impairment), modified Emory Functional Ambulation Profile (activity limitation), and the Stroke Specific Quality of Life score (quality of life). At end of treatment, there was no evidence of a motor relearning effect on motor impairment (FMA score) in either group. However, both the PNS and usual care groups demonstrated improvements in functional ambulation and quality of life outcome measures that were sustained at 6 months after treatment. Similarly, a randomized trial by Kottink et al. (108) found no therapeutic effect of an implantable two-channel PNS system on walking speed in chronic stroke participants followed over a 26-week period of intervention. However, the authors did note a significant increase in voluntary muscle output of the tibialis anterior and gastrocsoleus muscles after the use of FES, which they hypothesized was indicative of some degree of neuroplasticity in the study participants. The implantable PNS device has not yet received FDA approval for clinical use in the United States, although the device is available for clinical use in Europe. The neuroprosthetic efficacy of both a surface and implantable PNS device is described later in this chapter.

Multichannel surface stimulation systems have been evaluated as neuroprostheses for stroke survivors with functionally significant proximal as well as distal lower-extremity weakness. Two case series demonstrated improvements in qualitative and quantitative measures of gait after training with a six-channel surface neuroprosthesis system (109,110) that provided ankle dorsiflexion, knee flexion and extension, and hip extension. A follow-up controlled trial demonstrated significantly greater improvement in gait performance and motor function in the treatment group (111). In general, as the number of electrodes increases, surface systems become increasingly difficult to implement and maintain clinically. The practicality of multichannel surface lower-limb systems is limited further by reduced muscle selectivity, poor reliability of stimulation, and pain of sensory stimulation. Accordingly, Daly et al. developed a multichannel percutaneous system to facilitate lower-limb motor relearning and mobility (112). A single-blinded randomized clinical trial demonstrated that percutaneous NMES-mediated ambulation training improved gait components and knee flexion coordination relative to controls (113).

As with upper-limb applications, many of the controlled studies of NMES for lower-limb motor relearning exhibit methodological limitations, including inadequate blinding, small sample sizes, limited follow-up data, and outcomes limited only to motor impairment measures. Evidence suggests that NMES in the form of cyclic stimulation or in combination with biofeedback may be effective in facilitating lower-limb motor relearning. Studies with multichannel lower-extremity surface and percutaneous systems suggest therapeutic benefit. However, these devices have not translated into clinical practice. Two recent controlled clinical trials of surface (107) and implanted (108) PNS systems did not demonstrate a therapeutic motor relearning effect of a PNS neuroprosthesis using standard clinical outcome measures. The use of a surface PNS device as an alternative to an AFO in select stroke survivors is a reasonable clinical decision. However, clinical decision making for use of a surface PNS device should be based on neuroprosthetic efficacy, as clinically relevant therapeutic effect has not been established at this time. Future research should focus on NMES delivery systems, including lower-extremity CCFES applications, NMES dosage, and lower-extremity FES paradigms.

Summary, Clinical Considerations, and Future Directions

Despite the methodological limitations of some controlled trials to date, there is evidence to suggest that NMES-mediated repetitive movement therapy reduces motor impairment in upper- and lower-limb hemiparesis. However, it remains uncertain whether any measured effect can translate into clinically relevant improvement in ADLs and mobility. A number of surface NMES devices are presently commercially available for clinical implementation for upper- and lower-limb paralysis. Because risks associated with NMES are low, a select group of stroke survivors should be considered for and may benefit from NMES therapy.

In the upper extremity, sensory, cyclic, or EMG-triggered NMES systems may reasonably be offered, and mode of delivery should be primarily a clinical decision based on residual motor function, ease of application and patient compliance, and clinician preference. For the paretic lower extremity, stroke survivors may benefit from cyclic peroneal nerve stimulation (85,114) and EMG-triggered NMES may be applied to those with evidence of volitional activation (90). Despite the high functional content and active, repetitive nature of ambulation, a surface PNS device was not shown to facilitate motor relearning in the largest controlled trial of chronic stroke survivors to date (107). However, gait training with a neuroprosthesis may be considered as an alternative to usual care gait training (AFO or no device), as functional ambulation and quality of life improvements were equivalent at end of treatment. Presently, multichannel lower-limb surface systems remain under evaluation, and percutaneous upper- and lower-limb NMES systems remain limited to research applications and are not as clinically accessible. The CCFES system is limited presently to research applications, but may be commercially available as a therapeutic option for both the upper and lower extremity in the near future.

Optimal timing of NMES treatment has not been determined. Nevertheless, because therapeutic benefit may be related to acuity, onset of treatment in the acute rehabilitation service should be considered if possible. Patients and family may be trained by an experienced therapist, and treatment may be continued in the home environment following acute rehabilitation discharge. Optimal dosing and duration for most NMES applications have not been determined. However, the consensus of studies reporting positive results suggests that patients should be treated for at least one hour a day for a minimum of three weeks.

Care must be taken to implement NMES in the context of the stroke survivor's clinical status. Many stroke survivors have concomitant cardiac conditions, so monitoring of blood pressure, heart rate, and clinical signs of cardiac distress should be done during ambulation training with NMES. NMES should not be used with patients who have demand-type pacemakers. NMES should be used with caution in stroke survivors with poorly controlled seizures, though there is no definitive evidence that NMES causes seizures. In stroke survivors with sensory and/or cognitive impairments, vigilance should be used to protect from skin irritation associated with both the electrode and the electrical current. Limb edema is a general contraindication for NMES. Lastly, the application of NMES during pregnancy should be avoided, as the effects of NMES on fetal development and health are not well known.

Future investigations on NMES for motor relearning should address issues on two fronts. First, the effect of NMES on motor relearning and impact on clinical outcomes should be confirmed by addressing the methodological limitations of prior studies. Randomized clinical trials, which carefully define the subject populations, identify potential confounds, and evaluate long-term outcomes using valid and reliable measures of motor impairment, energy consumption, activity limitations, and quality of life, should be completed. These trials should compare the various types of NMES, stroke patient populations and intervals after stroke to identify the most effective paradigm and the subgroup of patients that most likely will benefit from each approach. Second, future investigations should refine the stimulation technique to maximize patient compliance and clinical outcomes, as well as determine optimal dose and prescriptive parameters. Systems that increase cognitive investment by requiring initiation, maintenance, and termination of NMES, should preferentially be considered. Future studies should also investigate more natural proxies such as cortical control for cognitive intent (115). Neuroprostheses, which provide clear functional benefit to a broad range of stroke survivors, should continue to be developed and refined to provide goal-oriented, repetitive movement therapy in the context of functional and meaningful tasks. Finally, basic studies should investigate mechanisms further to optimize the treatment paradigm.

NEUROPROSTHESES

Introduction

A neuroprosthesis utilizes NMES to contract specific muscles in a specific sequence to move the upper limb to perform ADL or the lower limb to carry out functional mobility tasks. The objective of a neuroprosthesis is the safe and efficient completion of functional tasks while using the device.

Upper-Limb Applications

Several studies have evaluated the upper-limb function of limited sample sizes of stroke survivors with and without a hand neuroprosthesis (63,64,116,117). In 1973, Rebersek et al. (64) published the first paper on the use of a hand neuroprosthesis in which surface NMES opened the hand, and closing was mediated by termination of the stimulation and the subject's own volitional ability. The intensity of stimulation was controlled proportionally with a position transducer mounted on the contralateral nonparalyzed shoulder. With training, subjects demonstrated progressive improvements in the number of hand positions they were able to maintain and the extent of hand opening using the device. A subset

of subjects demonstrated progressive improvements in their ability to use the device, although upper-extremity ADL performance was not assessed.

In 1975, Merletti et al. (63) evaluated a similar surface hand neuroprosthesis system. The device provided hand opening such that subjects were trained to pick up and move a small plastic basket or bottle from one defined area to another and back again using a shoulder-mounted position transducer controlled stimulation. All subjects were able to perform the tasks with triceps and hand stimulation, although with varying degrees of success. None of the subjects could perform the assigned tasks without stimulation or with hand stimulation only. The authors noted that the functional tasks required a considerable amount of mental concentration. In several cases, voluntary effort to control the paretic limb produced tremors, spasticity, and erratic shoulder movement that compromised functional performance.

Alon et al. (116) evaluated the previously described hybrid NMES-orthosis neuroprosthesis (Figure 21.2). The orthosis positions the wrist in a functional position and five surface electrodes built into the orthosis stimulate specific muscles to provide coordinated hand opening and closing. Twenty-nine chronic stroke survivors participated in a home-based, three-week case series. Three ADL tasks were evaluated with and without the neuroprosthesis at baseline and at three weeks: (a) lifting a two-handled pot, (b) holding a bag while standing with a cane, and (c) performing a subject-selected ADL task. The authors reported significant improvements in the percent of successful trials to complete the ADL tasks. Leeb et al. (118) recently described an adaptable passive hand orthosis that, when coupled with FES, is proposed to synchronize grasping movements to produce a more functional hand grasp.

FIGURE 21.2 A hybrid brace-transcutaneous neuroprosthesis system that is worn on the hand and forearm. The orthosis positions the wrist in a functional position and the five surface electrodes built into the orthosis stimulate specific muscles to provide coordinated hand opening and closing.

NESS H200, courtesy, Bioness, Inc., Valencia, CA.

Due to the limitations of surface NMES, Merletti et al. (63) originally suggested that an implanted system might best meet the clinical needs of persons with hemiplegia. Chae et al. (117) evaluated four chronic stroke survivors implanted with percutaneous intramuscular electrodes to demonstrate the adequacy of intramuscular NMES for hand opening and closing, identify control strategies that reliably open and close the hand under subject control, and demonstrate functional utility. The percutaneous hand neuroprosthesis was able to open a spastic hemiparetic hand as long as the limb was in a resting position, the wrist and proximal forearm were supported, subjects did not try to assist the stimulation, and an individual other than the participant modulated the NMES. However, when subjects attempted to assist the stimulation or complete a functional task, hand opening was significantly reduced as a result of increased finger flexor hypertonia, even with increased stimulation intensity. Similarly, electrically stimulated hand opening was significantly reduced following voluntary hand closure, which precluded formal testing of ADL function. Makowski et al. (119) have focused on identifying the clinical ramifications of variable upper-extremity co-contraction patterns (synergies) on upper-extremity neuroprosthesis use noted when combining voluntary effort and FES.

Recently, Knutson et al. (74) described their experience with the first stroke survivor to be implanted with an upper-extremity neuroprosthesis to assist arm and hand function. The neuroprosthesis consisted of an implantable stimulator-telemeter (IST), 12 intramuscular stimulating electrodes, two epimysial EMG-recording electrodes, and an external control unit (Figure 21.3). The IST produced 12 independent channels of electrical stimulation and recorded, processed, and transmitted 2 independent channels of EMG signal to the external control unit. The external

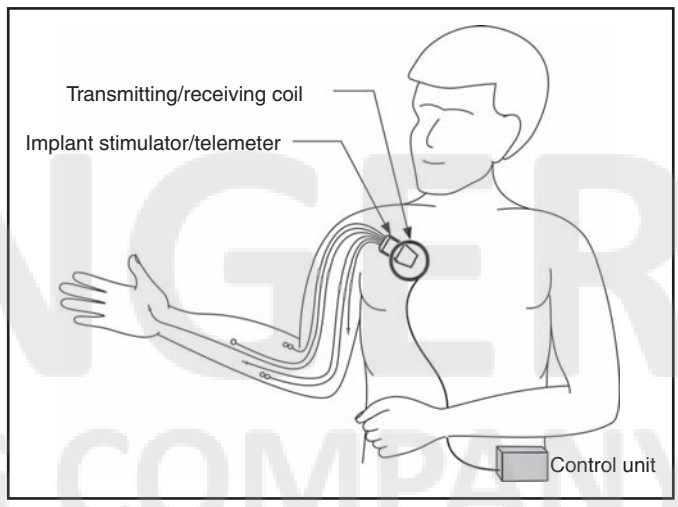

FIGURE 21.3 Implantable stimulator-telemeter (IST).

control unit transmitted power and stimulus commands for each electrode back to the IST. Following implantation and training, the subject was able to perform some bimanual tasks and use the neuroprosthesis for several ADLs and functional tasks, including meal preparation, eating, gardening, and exercising. The primary issues, which hindered consistent daily functional use of the neuroprosthesis, included inability to consistently achieve full extension of all digits, variable hand and wrist flexor tone associated with fatigue and/or extensor stimulation, inadequate EMG control signals necessitating an alternative push-button control system, and cumbersome size of the external control unit. Translation of an implantable neuroprosthesis into clinical care will require additional research focusing on mitigating hand and wrist flexor spasticity, optimizing EMG-recording electrode and EMG control strategies, adding implantable limb position sensors, increasing the number of stimulating channels to improve stimulation patterns and muscle recruitment, and miniaturizing the external control unit for ease of use.

Lower-Limb Applications

The initial application of a lower-extremity neuroprosthesis in hemiplegia focused on a surface PNS device that dorsiflexed the ankle during the swing phase of gait (93). In an early randomized study of surface peroneal stimulation, Burridge et al. demonstrated that stroke survivors treated with the device exhibited significantly greater increases in walking speed with the device relative to baseline performance without the device, whereas the control group did not (120). More recent studies have demonstrated the neuroprosthetic efficacy of these devices (102), including studies that suggest comparable orthotic effects of an ankle–foot orthosis and a PNS device in hemiparetic gait (121–124).

Presently, there are three FDA-approved surface PNS devices prescribed in the United States for dorsiflexion weakness in hemiplegia. These devices are the Ness L300® Footdrop System (Bioness, Inc., Valencia, CA; Figure 21.4), the WalkAide® System (Innovative Neurotronics, Austin, TX; Figure 21.5), and the Odstock Dropped Foot Stimulator® (ODFS) (Odstock Medical Limited, Salisbury, UK; Figure 21.6). These devices utilize either a heel switch or a tilt sensor as a control to time stimulation to the swing phase of gait. From a clinical standpoint, use of a lower-extremity neuroprosthesis may not obviate the need for a custom-molded ankle–foot orthosis. Muscle fatigue, specificity of electrode placement, discomfort and inconsistent reliability of stimulation, insufficient medial–lateral control during stance phase, and limited technical support may all interfere with consistent extended-day use of the device. Prescription guidelines include dorsiflexion weakness with gait instability with the absence of lower-extremity edema, significant sensory deficit, skin breakdown, intolerance to stimulation, significant loss of passive range of motion at the ankle, or genu recurvatum.

These criteria should be considered in the context of general medical contraindications to NMES described in the motor relearning section.

Lower-extremity neuroprosthetic systems using surface electrodes have clear inherent limitations that might be remedied by implantable systems. An early study by Waters et al. (99) reported a significant increase in walking speed, stride length, and cadence with a single-channel implantable device relative to preimplantation performance. However, technical limitations included difficulty in balancing inversion and eversion, lack of an in-line connector that necessitated the removal of the entire implant in the event of component failure, and poor reliability of the heel switch and foot–floor contact transmitter. Kljajic et al. (100) also reported significant neuroprosthetic benefits from a single-channel implantable stimulator. However, nearly half of all subjects required reimplantation as a result of electrode displacement or failure. Two multichannel implantable peroneal nerve stimulators have been evaluated in Europe. A dual-channel device developed by the University of Twente and Roessingh Research and Development (the Netherlands) stimulates the deep and superficial peroneal nerves for better control of ankle dorsiflexion, eversion, and inversion (Figure 21.7) (125). A four-channel device, developed at Aalborg University (Denmark), utilizes a nerve cuff with four tri-polar electrodes, oriented to activate different nerve fibers within the common peroneal nerve (126). Both devices have the Conformité Européene (CE) mark in Europe. Kottink et al. (127) reported specifically on the neuroprosthetic effect of an implantable PNS on walking speed in a RCT.

To address gait deviations due to deficits proximal to the ankle, several studies evaluated multichannel surface NMES systems (109–111). However, although these systems were clinically implemented as neuroprostheses, neuroprosthetic outcomes were not assessed. Instead, these studies focused on therapeutic or motor relearning effects and, therefore, were discussed in the earlier section on motor relearning.

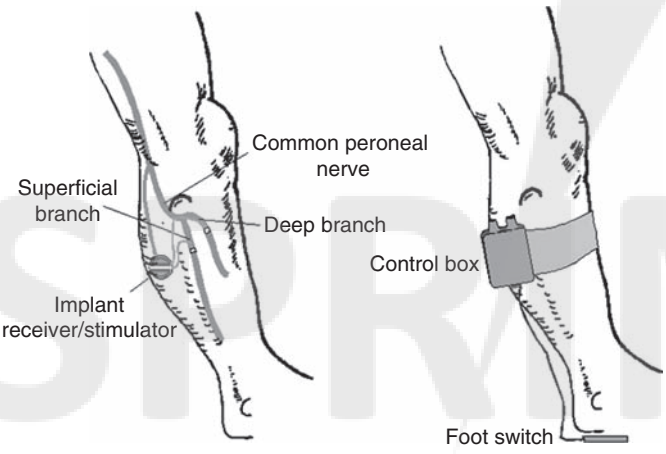

FIGURE 21.7 A two-channel implantable peroneal nerve stimulator (STIMuSTEP) allows individual stimulation of the deep and superficial branches of the common peroneal nerve for ankle dorsiflexion and eversion–inversion balance.

Summary, Clinical Considerations, and Future Directions

At present, a hand neuroprosthesis using surface electrodes may allow stroke survivors to complete a limited number of selected functional tasks. However, a clinically viable hand neuroprosthesis system that provides broad functional benefit is not yet available. The requirements for a clinically viable hand neuroprosthesis using either surface or implanted technology are significant. Because stroke survivors can perform most basic ADLs with the unaffected upper limb, an upper-extremity neuroprosthesis will provide clear value only if it can facilitate performance of bilateral upper tasks or more complex ADLs such that the need for assistance from a caregiver is decreased. An upper-extremity neuroprosthetic system must address both proximal and distal motor control (128) and have sufficient miniaturization to allow the user to perform functional tasks without impeding the function of the unaffected limb or interfering with mobility. Control paradigms are necessary to produce effortless movement of the impaired upper limb (129). Finally, the system must "turn off" overactive muscles to address the problems of spasticity, associated reactions, coactivations, co-contractions and delay in termination of muscle contractions (117).

Lower-limb neuroprostheses that use surface peroneal nerve stimulation are increasingly being prescribed as alternatives to ankle–foot orthoses in stroke survivors. However, clinical adoption likely will depend on whether there is any significant added value relative to an AFO. Implanted PNS devices are available in Europe and may be appropriate for stroke survivors who experience significant improvement in mobility with the surface system, but have difficulty with electrode placement, skin irritation, painful sensation of stimulation, or donning and doffing of the device. However, in view of limited data, more definitive recommendations must await additional studies and the emergence of additional clinical experience. At present, multichannel, multijoint systems are clinically less accessible and are limited to investigative purposes.

Although the clinical prevalence of a lower-limb neuroprosthesis for hemiplegia is greater than upper-limb neuroprosthetic systems, several issues remain to be elucidated. First, surface systems can be limited by discomfort and difficulty with electrode placement for reliable muscle contraction. Implanted systems may address these issues, but at present, implanted technology is only available in Europe and potential benefits would clearly have to be weighed against the risks and costs associated with an invasive procedure. Second, optimal functioning will require control of multiple joints.

Although available devices focus primarily on the ankle, most stroke survivors also have difficulty with hip and knee flexion during swing and knee control during stance. Clinical implementation of a complex multichannel surface electrode system will be challenging. A multichannel implanted system may be needed. Lastly, clinical relevance must be established in a controlled trial by comparing the effects of the intervention with the standard of care on mobility and quality of life.

CONCLUSIONS

The principal goal of rehabilitation management of persons with hemiparesis is to maximize motor ability and thus enhance both functional performance and quality of life. NMES systems bypass the injured central circuitry to activate neural tissue and contract muscles with the intent to both facilitate motor relearning as a therapeutic intervention and improve functional movement as a neuroprosthesis. Recent technological advances in clinical medicine and biomedical engineering make the clinical implementation of NMES systems in stroke survivors with hemiparesis much more feasible. NMES for motor relearning in hemiplegia is a promising application of goal-oriented repetitive movement therapy. Whereas additional rigorous multicenter clinical trials to confirm effectiveness and fundamental studies to elucidate mechanisms are still needed, the clinical implementation of these devices is appropriate. Presently, upper- and lower-extremity cyclic NMES, EMG-triggered NMES, and neuroprosthetic devices should be included reasonably in the broader clinical armamentarium of stroke rehabilitation professionals and considered judiciously for select stroke survivors.

After decades of development, the clinical utility of NMES systems is becoming realized. By necessity, scientists and clinicians must continue to explore new ideas and improve upon the present systems. Components will be smaller, more durable, and more reliable. The issues of cosmesis and ease of donning and doffing will be a factor in the evolution of devices. Control issues will remain central, and the implementation of cortical control will dictate the nature of future generations of neuroprosthesis systems. Future developments will be directed by consumers. In the present health care environment, in which cost is an overwhelming factor in the development and implementation of new technology, the consumer will become one of technology's greatest advocates. Finally, the usual drive toward greater complexity will be tempered by the practical issues of clinical implementation in which patient and clinician acceptances are often a function of a tenuous balance between the "burden and cost" associated with using a system and the perceived impact of that system on quality of life.

Robots in Stroke Rehabilitation

Joel Stein, Lauri Bishop, Sunil K. Agrawal, Susan E. Fasoli,
Hermano Igo Krebs, and Neville Hogan

In contemporary society, the adoption of new technologies often is viewed as an inevitable component of progress. Stroke rehabilitation has been slower to adopt new technologically based therapeutic tools than many other areas of medicine and has largely remained a "hands-on" field. There are, however, several arguments supporting broader incorporation of robots and other technologies into stroke rehabilitation. An economic case can be made that the field of stroke rehabilitation ought to take advantage of the potential labor-saving nature of these technologies. In an environment in which labor costs continue to rise and the costs of technology are falling, using robots to reduce the reliance on skilled human labor for stroke rehabilitation will undoubtedly be cost-effective in the long run. The need for more efficient delivery of exercise therapy is amplified by the growing evidence that more intensive exercise training is an important factor in enhancing motor recovery after stroke.

A second consideration in favor of increasing the adoption of robots in stroke rehabilitation is that these devices are able to provide treatments repetitively without risking therapist fatigue. This can easily be illustrated by analogy with the low-tech example of continuous passive motion (CPM) machines after total knee arthroplasty. These devices can provide many hours of slow, steady, passive range-of-motion exercises after surgery. Although a human therapist is capable of performing similar exercises, he or she would not be able to sustain this effort for many hours.

Certain therapies and treatments can be provided only through the use of technology. For example, the incorporation of computerized games into robotic exercise therapy allows patients to become more engaged in the required task, converting what might otherwise be a tedious and repetitive set of exercises into a form of entertainment. Robots in particular are well suited to assisting with movements in individuals too weak to complete these movements unassisted, thus allowing individuals to complete a prescribed exercise that would otherwise require the assistance of another individual.

Similarly, robotic devices appear particularly well suited to facilitating motor learning. Evidence continues to accumulate that motor-learning principles, such as task repetition and progression, are critical elements of exercise programs to stimulate brain plasticity and recovery of motor function. Advances in robotic technology are increasingly capable of providing a flexible, programmable platform to engage stroke survivors in a growing array of interactive motor-learning activities.

Lastly, many stroke rehabilitation centers are seeking ways to distinguish themselves in a competitive marketplace. Although this is not a strong argument for the adoption of new technologies, it is nonetheless likely a driving factor among some early adopters of new treatment technologies.

Robotic devices may have particular application to stroke rehabilitation. This chapter describes the potential applications of robots as aids for rehabilitation and recovery in stroke survivors and discusses several of the specific systems currently in use and the evidence supporting their clinical efficacy.

WHAT ARE ROBOTS AND WHY USE THEM IN STROKE REHABILITATION?

The boundaries of robot technology overlap other emerging therapeutic technologies such as electromechanical exercise devices and virtual reality therapy. Rehabilitation clinicians have employed electromechanical devices for decades. CPM devices, treadmills, and isokinetic exercise machines perform automatic functions and can be programmed in advance. These relatively simple machines have primarily been used for orthopedic and sports medicine applications. Although some might consider these simple robots, we have used a somewhat stricter definition in this chapter.

The American Heritage Dictionary defines a *robot* as "(a) A mechanical device that sometimes resembles a human and is capable of performing a variety of often complex human tasks on command or by being programmed in advance. (b) A machine or device that operates automatically or by remote control" (1). In practice, general-purpose, anthropomorphic (human-appearing) robots have found little practical application in medicine, although they continue to captivate the popular imagination. The robots developed for rehabilitation have been specialized devices that bear little or no resemblance to humans and are of varying sizes,

FIGURE 22.1 InMotion Shoulder-Elbow robot (Interactive Motion Technologies, Inc.), based on the MIT-Manus design, provides planar exercises for the upper limb involving shoulder and elbow movements. Shown here with the InMotion Hand robot module in use, instead of the wrist-hand splint used in the basic configuration.

shapes, and complexity (see Figure 22.1). They share an increasing level of sophistication, with increasing capabilities and programmability.

USES OF ROBOTS IN STROKE REHABILITATION

Although the potential uses of robots in stroke rehabilitation are broad, we divide potential applications into three major categories: exercise training, wearable functional orthoses, and as aids for activities of daily living (ADLs). The vast majority of the research in the use of robots for stroke rehabilitation has focused on their use as exercise training devices, and this will form the majority of the focus in this chapter. Some of these devices are wearable exoskeletons in design and are the devices most easily adapted to potential applications as wearable functional orthoses. This chapter provides an overview of the arguments for and against the incorporation of these technologies into stroke rehabilitation in these different roles and the various clinical circumstances in which they might prove useful. Clinical research results are reviewed, where applicable.

Robot-Aided Exercise

Exercise is one of the key therapeutic modalities in stroke rehabilitation. Exercise treatments are most commonly provided under the direct personal supervision of physical therapists, occupational therapists, exercise physiologists, athletic trainers, or other practitioners. In many cases, this direct supervision is gradually withdrawn in favor of intermittent supervision as the patient progresses, and the patient is encouraged to engage in an independent exercise program at home or in a gym. This model of care requires extensive personnel time and yet is often unsuccessful in its ultimate goal of having patients perform exercises independently without direct supervision. Achieving long-term compliance with exercise programs remains a challenge in this traditional model of care, with many patients discontinuing exercises because of limited functional gains or insufficient motivation.

The use of robots to assist in stroke rehabilitation has been proposed as a labor-saving approach for the provision of exercise therapy. Robot-guided exercise can, in principle, be substituted for exercise provided under the direct guidance of a therapist, or perhaps more importantly, to supplement this therapy to achieve a greater total amount of exercise. Models for incorporating these devices into an exercise program include (a) having a single therapist provide supervision to several patients working with training systems simultaneously, (b) having a patient work at home with a robot or virtual reality system with remote supervision from a therapist, or (c) having a patient work independently with a technology-based training system with periodic review and adjustment of the exercise program by a therapist. With the available technology, most robotic therapy is currently delivered with one-on-one supervision of a therapist or rehabilitation aide in an institutional setting. We expect this to shift gradually to models that allow greater patient autonomy and efficient staff utilization to achieve the ultimate labor-saving benefits that robots must produce to justify their use.

Ultimately, the use of robots might provide improved therapeutic outcomes compared with traditional exercise therapies. Whereas these benefits have not yet been demonstrated in a clinical trial comparing robotic therapy to dose-matched human-delivered therapy, we believe there are reasons to anticipate that improvements in robotic design will ultimately achieve this goal. Specifically, the programmable nature of computer-based training devices allows the health care provider to design and institute an exercise program that is specific to the patient's impairments, predictable, and well controlled. These devices can also be interactive and alter the therapy provided based on the patient's immediate reaction or response to treatment over time. The parameters of exercise that can be controlled through the use of robots include the nature of the exercise activity, the movement pattern, the number of repetitions, the forces exerted by the robot on the patient, and others. Thus, there is the potential to deliver exercise in a more consistent and evidence-based fashion with robot aids and perhaps to improve the ultimate results of treatment.

For individuals with weakness, robots can provide physical assistance for task completion. Thus, for a stroke patient with some active movement at the shoulder and elbow, but unable to achieve antigravity strength, a robot might assist with a reaching movement. This capability is

similar to that provided by a human therapist who provides individual treatment by facilitating/supporting movements in a weak patient, but can be sustained for longer duration and more repetitions. Potentially, robotic algorithms could be developed to optimize the amount and type of assistance provided to maximize motor outcomes, although we do not yet possess sufficient understanding of the ideal motor retraining parameters after stroke to create these algorithms at present.

Resistance training has been studied as a therapy for poststroke weakness (2,3) and can be incorporated into robotic exercise (4,5). Whereas the possible therapeutic advantages of resistance training for hemiparetic stroke survivors continue to be studied, the availability of this mode of training in robotic exercise devices is an important capability and might be expected to be beneficial in certain clinical circumstances. Robots also can be programmed to exert force on the patient's limb that induces adaptation on the patient's part to counter the force exerted by the robot. Thus, a patient working with a robot that applies a consistent force field in a particular direction may develop a compensatory adaptation, increasing the effort to move the limb in the opposite direction. When the robotic training session ends, this adaptation may persist, although any long-term functional impact of this adaptive response remains to be established.

Robots can be designed and programmed to make repetitive exercise more interesting and enjoyable for a patient. Computer-based video games can be integrated with the robot training to provide a more stimulating therapy environment for the patient. Even relatively simple computer games, such as a "Pong"-type game, can relieve the boredom many patients associate with repetitive exercises. This ability to provide an interesting and structured environment for the performance of an exercise program holds promise as a means of improving compliance with exercise prescriptions in the future. More elaborate virtual reality visual displays are also being developed, and continued convergence between the two approaches is likely.

Robots can collect data on exercise compliance and performance and allow the supervising practitioner to provide appropriate feedback to the patient regarding his or her exercise activities even when the practitioner is not physically present during the exercise session. This data can be stored electronically and reviewed at the convenience of the supervising therapist rather than at the time of the actual exercise. Compliance with prescribed exercise training can be directly measured rather than estimated from patient self-reports. From a research perspective, data obtained through robotic devices have provided insights into the mechanisms of recovery of motor control after stroke (6–8).

The number of robotic devices developed has burgeoned over the past 20 years since their introduction, and more than 60 clinical studies using these devices have been published (see summary in Lo (9)). Corporations, ranging from small start-ups to large multinational companies have become involved in rehabilitation robotics (10). As with any emerging technology, devices that have not yet been tested in clinical populations are under development. This chapter focuses primarily on devices for which there are published reports in patient populations or which are commercially available in the United States.

Workstation Exercise Robots

Upper-Limb Robotic Exercise Training

Robotic devices for therapeutic exercise have been tested clinically for patients with neurologic diagnoses, including stroke, traumatic brain injury (TBI), multiple sclerosis, and spinal cord injury (SCI). Neurologic rehabilitation has been a particularly fertile field for robotic applications. For persons with stroke, it has been demonstrated that highly repetitive, task-specific exercise training can facilitate neuroplastic changes in the brain, with concomitant improved motor abilities and enhanced functional activity performance (11,12). Robotic devices can provide such augmented exercise therapies in accurate and reproducible dosage. Furthermore, they hold promise to become an economical complement to traditional, labor- and time-intensive neurologic rehabilitation.

Several research groups have tested the treatment effects of robotic therapy for poststroke upper-limb motor recovery. The robots reported in these clinical studies range in complexity from unimanual, single-joint devices to bimanual devices with multiple degrees of freedom.

The MIT-Manus robot (InMotion2 robot, Interactive Motion Technologies, Inc., Watertown, MA; see Figure 22.1) has two *degrees of freedom* that provide shoulder and elbow exercises in the horizontal plane. The patient's forearm and hand are supported and attached to the robot manipulandum with a splint. The MIT-Manus robot can administer active–assistive or resistive exercises or be programmed into a "passive" mode that provides neither resistance nor assistance. The design of the robot allows patients with a broad range of motor impairment to use this device. Even patients with severe weakness who are incapable of completing constraint-induced movement therapy can successfully undergo exercise training with this robot. Training algorithms continue to be refined, and an adaptive active–assistive exercise mode that alters the amount of guidance or assistance provided to the patient based on his or her performance has been developed (13). An electromyographic (EMG) triggered mode in which the user's surface EMG activity is used to trigger the robotic assistance has been piloted (14). In all exercise modes, subjects attempt to move the robotic arm while guided by target images on a computer monitor. Several different screen displays and accompanying motor tasks have been developed, although the best-studied "game" involves radial movements of a cursor in each of eight evenly spaced directions.

The MIT-Manus robot has been studied in a randomized controlled trial (15–18) of 96 patients within 1 month of stroke. Subjects in the treatment group received one hour of active–assistive exercises with the robot for the paretic arm 5 times per week for 4 weeks, and control subjects received sham exercise (i.e., with the robot in "passive" mode) with the robot once

each week. The robotic therapy consisted of active–assistive reaching practice in the horizontal plane toward eight targets. All subjects received conventional rehabilitation therapy, per standard clinical practice, in addition to robotic therapy. At the end of treatment, the robot therapy subjects experienced significantly greater improvement in motor impairment measured on the Motor Status Scale (MSS) and the Medical Research Council Motor Power Scale (MRC) for shoulder and elbow motor function. These improvements were maintained at the time of a three-year follow-up study (19).

The MIT-Manus robot has also been tested in several trials for stroke survivors with chronic hemiparesis. In one study (20), 42 subjects received either active–assistive or progressive-resistive reaching training for 1-hour sessions, 3 times per week for 6 weeks. Subjects performed up to 18,000 point-to-point movements over the course of the trial. Subjects in the resistive and active–assistive treatment groups demonstrated significant impairment-level gains using several scales (Fugl-Meyer, MSS, MRC) that remained improved over baseline scores when measured at four-month follow-up evaluations. No differences in outcomes were detected between the resistance training and active–assistive training groups (4). The other studies of patients with chronic hemiparesis found similar improvements in motor function (21–24). Seventy-two subjects received active–assistive training using an adaptive training algorithm to adjust the amount of assistance to the person's movement ability using the MIT-Manus robot.

The benefits of robot-assisted upper-limb exercise therapy in these studies of MIT-Manus were seen primarily in shoulder and elbow movements, rather than in the wrist or hand. This is consistent with a specificity of training effect, because the robot provides exercise only to these portions of the upper limb and keeps the wrist and hand immobilized in a splint. The magnitude of the changes in motor impairment has been clinically significant but modest, but would be expected given the limited nature of the robotic exercise. The training effects appear to persist over time (25).

A series of related robot modules have been developed, including a wrist device that provides wrist flexion and extension, radial and ulnar deviation exercises; a linear reaching robot that can be positioned to provide upward reaching movements at the shoulder and elbow; and a hand module that addresses grasp and release. A clinical trial combining the use of these four devices (shoulder–elbow, wrist, reaching, and hand robots) compared robot-assisted therapy with therapist-provided exercises and a usual care group (26). Whereas clinically significant benefits of this combined robotic therapy were seen when compared with usual care, the magnitude of these improvements were in the same general range as those seen on studies of the more limited shoulder–elbow robot in prior studies. Other studies are underway to clarify if utilizing robotic modules serially for different limb segments (e.g., performing wrist exercises followed by shoulder/elbow exercises) is more or less efficient than combining modules in multisegment configurations (e.g., wrist and shoulder/elbow exercises simultaneously) in achieving improved motor control. In spite of the results of the study by Lo et al., the hypothesis that the combined effects of training with multiple devices for different upper-limb segments will provide a larger benefit of overall motor function in the upper limb remains attractive (27).

Reinkensmeyer and colleagues have developed a robot, the Assisted Rehabilitation and Measurement (ARM) guide, designed to administer active–assistive reaching practice in three dimensions (28). Although this robot provides only a single active degree of freedom, the linear track can be repositioned manually into different spatial orientations during the course of an exercise therapy session to allow a variety of movements. The patient's forearm and hand rest in a splint that attaches to a motorized, linear track, and the robot supports the arm against gravity and assists the patient to reach along the track. Visual feedback is provided through a computer monitor. Kahn and colleagues (29) tested the effects of the ARM guide on reaching performance for patients with chronic hemiparetic stroke. Seven subjects received 24 one-hour robotic therapy sessions over the course of 8 weeks, whereas another 7 subjects received an equivalent dose of unassisted, goal-oriented reaching exercise. All subjects practiced repetitive reaching in multiple directions and vertical levels. After the trial, results of impairment-level measures were mixed. Neither group demonstrated improvements in free-reaching distance, all subjects showed improved straightness of reaching paths, and only the robotic therapy group showed improved movement smoothness. A timed measure of functional activities, the functional test for the hemiparetic upper extremity, demonstrated significantly decreased performance times for the free-reach group and a trend toward improved performance for subjects who received robotic therapy. An important limitation of this study is the small number of movement repetitions per session (65 movement attempts per sessions)—substantially below the number provided in many other trials of robotic exercise, and perhaps insufficient to provide a therapeutic benefit. A robot with one degree of freedom and an adjustable track is available (30) (InMotion1 Linear Robot, Interactive Motion Technologies, Inc., Watertown, MA, www.interactive-motion.com).

One limitation of many of the earlier generation of rehabilitation robots is that they generally omitted or had limited hand robotic retraining capabilities. The InMotion Hand (Interactive Motion Technologies, Watertown, MA) provides a single degree of freedom robotic training system focusing on grasp-and-release. The Amadeo (Tyromotion, Graz, Austria; see Figure 22.2) has the ability to provide individualized training for each finger. A small uncontrolled pilot study of this device demonstrated good tolerability and suggested benefit, and larger controlled studies are in progress (31).

In contrast to this modular approach to upper-limb robotics, some groups have focused on incorporating multiple limb segment training into a single device. The ReoGo (Motorika, Caesarea, Israel) focuses on shoulder–elbow movements but adds an additional degree of freedom by incorporating a telescoping support from a pedestal base.

FIGURE 22.2 The Amadeo robot (Tyromotion, Inc., Graz, Austria) provides finger flexion and extension exercises.

Studies of this device have found reduced motor impairment, but large well-controlled trials have not been conducted thus far (32–34). The ARMin robot provides robotic assistance for movements at the shoulder, elbow, and wrist using an exoskeletal workstation design. Although only limited data on the clinical use of this device have been published (35,36), a commercial version, the ArmeoPower (Hocoma, Zurich) has recently been released (see Figure 22.3).

Bimanual robotic therapy using the nonparetic upper limb to help guide the movements of the paretic upper limb is another approach implanted in the mirror image movement enabler (MIME) robot and in the Bi-Manu-Track (Reha-Stim, Berlin). The MIME robot (see Figure 22.4) is a six degrees of freedom robot that can administer four distinct modes of upper-limb reaching exercise in three dimensions (5). Similar to the MIT-Manus robot, the patient's forearm and hand are supported and attached to the robot with a splint. Unimanual exercises include passive, active–assistive, and active–constrained movements. During active–constrained exercise, the MIME robot resists reaching movements toward a target with a viscous field and provides a spring-like assist to movements in all other directions. Bimanual exercise is performed while subjects attempt to move both arms in simultaneous reaching movements; the robot assists the paretic limb's movements, as necessary, to mirror the less-impaired limb.

FIGURE 22.3 Armeo Power robot (Hocoma, Inc.), based on ARMin robot, includes multiple degrees of freedom at the shoulder, elbow, and wrist.

FIGURE 22.4 MIME robot, an upper-limb robot with six *degrees of freedom*, designed to assist with reaching movements.

MIME robotic therapy has been compared to conventional neurodevelopmental technique-based therapy (NDT) in a study of 27 subjects with chronic hemiparesis after stroke in a randomized controlled trial (5). All subjects received 24 one-hour sessions over the course of 2 months. Subjects in the robotic treatment group repeatedly practiced 12 reaching movements in 4 directions and at 3 vertical levels. They received identical proportions of robot-guided passive and bimanual exercise and variable amounts of active–assistive and active–constrained exercise graded by individual motor ability. The NDT control group received exercises designed to facilitate a progression from mass upper-limb movement patterns to more isolated control, in the context of functional task performance. Immediate posttreatment results revealed that subjects in the robotic therapy group improved more than the control subjects for Fugl-Meyer Assessment scores (proximal section only), upper-limb strength measures, and free-reach distance. At the six-month follow-up evaluations, the Fugl-Meyer scores of the treatment group no longer were significantly different from those of the control group.

Hesse and colleagues tested a bimanual robotic therapy for its effects on distal motor impairment and function in a single-group exploratory study (37). This robotic arm trainer administered bimanual practice of wrist flexion/extension and forearm pronation/supination using active, passive, and resistive exercise. The robotic therapy was administered as an adjunct to a daily 45-minute comprehensive motor rehabilitation program. Twelve persons with chronic, hemiparetic stroke trained with the robot for fifteen 15-minute sessions over the course of 3 weeks. At the end of the robotic intervention, subjects showed reductions in wrist and finger spasticity as measured by the modified Ashworth test, but there was no significant improvement in performance of functional motor activities according to Rivermead Motor Assessment scores. Participants reported favorable impressions of the robotic therapy.

A second study by Hesse and colleagues (38) compared this bimanual robotic training device to EMG-initiated electrical stimulation of the paretic upper limb in hemiparetic individuals four to eight weeks after stroke. Individuals receiving robot-aided exercise showed significantly larger improvements in Fugl-Meyer motor scores. The authors speculate that the reason for the different outcomes in the two groups was that the robotic training group received a ten-fold increase in the number of repetitions compared to the EMG-triggered electrical stimulation group.

As robotic arm exoskeletons evolve, the devices face several challenges: (a) they are heavy compared to the weight of the human arm, thus significantly altering the moving inertia of the natural arm; (b) they require precise alignment between the exoskeleton and human joints—often impossible to achieve because human joint axes are formed by relative motion of complex bony segments; and (c) they require exoskeleton link lengths to be the same as human segments, requiring adjustable segments to accommodate users of varying limb lengths. A novel lightweight Cable-driven Arm Exoskeleton (CAREX) recently was developed as an alternative approach (see Figure 22.5). Instead of the rigid links and joints typically used in conventional exoskeletons, CAREX uses lightweight cuffs and tensioned cables (39). The weight of CAREX is approximately one-tenth that of conventional robotic exoskeletons and does not require joint alignment or link length adjustment. In addition, the weight of CAREX is supported by motors to minimize additional weight on the arm. Preliminary studies show that the "assist-as-needed" force field applied by CAREX helps healthy subjects and those with stroke to follow a desired path more accurately, with increased arm extension for the stroke subject. The data also demonstrate that the desired movements are accomplished with similar patterns of muscle activation at a reduced magnitude, suggesting that CAREX can facilitate physiological movement patterns with the arm in a relaxed state.

FIGURE 22.5 Prototype of CAREX, a cable-driven arm exoskeleton for training of stroke patients.

Lower-Extremity Robotic Exercise Training

Robots for lower-limb use in neurologic rehabilitation have been developed primarily as devices for administering partial

body-weight-supported treadmill gait training (BWST). BWST consists of partially unloading the weight of a neurologically impaired person suspended above a treadmill, while therapists manually assist the patient to step, shift weight, and maintain appropriate kinematic gait patterns during gait training. Several studies have reported improved gait performance after intensive BWST for persons with stroke (40), Parkinson's disease (41), and cerebral palsy (42), with inconclusive results after SCI (43,44). A large clinical trial recently found no benefit to BWST for stroke survivors (45), however. Thus, the rationale for developing robotic versions of this therapy has been seriously undermined.

Hesse and colleagues have developed a robotic device for gait training, including BWST, called the electromechanical gait trainer (EGT) (46). Resembling an elliptical exercise trainer, the EGT uses footplates that move alternately to simulate stance and swing phases of a physiological gait pattern. A harness suspends the patient above the footplates to provide for variable unweighting during gait training and reportedly serves to maintain the center of mass in a phase-dependent manner. Werner and colleagues (47) tested the EGT against conventional BWST in a randomized control trial involving 30 hemiparetic subjects who were 4 to 12 weeks poststroke. All subjects required at least some physical assistance (functional ambulation category [FAC] ≤2) for overground ambulation at baseline. Subjects were assigned to either an A-B-A or B-A-B crossover group. "A" consisted of two weeks of EGT therapy, and "B" consisted of two weeks of BWST therapy. They received experimental gait training 15 to 20 minutes daily in addition to conventional therapies for 6 weeks. At the end of treatment, both treatment groups demonstrated gains in FAC, gait velocity, and Rivermead Motor Assessment scores. The authors report that EMG measures of muscle activation patterns were similar for patients on both devices. The treatment group that received two-thirds epochs of EGT therapy had comparatively higher FAC scores, with more subjects able to ambulate independently, but this advantage was no longer evident six months after treatment. Differences were reported in the amount of therapist assistance required for each treatment. At baseline, most patients using the EGT required one therapist, but they required two therapists for assistance using BWST. By the end of treatment, most patients could use the EGT without therapist assistance, whereas most subjects needed assistance from one therapist while receiving BWST. The majority of subjects (23/30) reported that they preferred gait training with the EGT over the BWST.

A larger, multicenter study recently compared gait training with a combination of EGT plus conventional physical therapy with a group receiving conventional physical therapy alone in 155 subacute (average 4 to 5 weeks poststroke) subjects (48). The EGT group showed a greater improvement in gait and ADL measures, both clinically and statistically, than the control group over the course of the four-week treatment protocol. Improved gait ability was maintained at six-month follow-up, though the difference in ADL ability was no longer evident. Commercial versions of the EGT, the GT-1 (Reha-Stim, Berlin, Germany), and the G-EO (Figure 22.6; Reha Technologies, Olten, Switzerland) have been developed.

FIGURE 22.6 G-EO robot, an elliptical trainer-like gait robot that uses actuated footplates to guide and assist the user's gait.

Colombo and colleagues (49) have developed a lower-limb robot (driven gait orthosis [DGO]) for automated, intensive gait training. The DGO automates BWST by suspending two exoskeletal leg braces from a frame over a treadmill. Hip and knee motors in the exoskeletal braces are controlled by a computer to generate physiologically correct gait patterns for the patients who wear them. Ankle dorsiflexion is passively provided by elastic straps. The DGO requires a therapist operator but no direct human physical assistance while persons use the device for gait training. Studies examining the muscle activation patterns of subjects using the DGO compared with treadmill walking (50) and with manually assisted BWST (49,51,52) have reported conflicting results, and there is some evidence that users may reduce their effort during DGO assisted ambulation (52). A case series employing a DGO robot (Lokomat) (Hocoma AG, Volkestwil, Switzerland; see Figure 22.7) found gait improvement in patients with chronic incomplete SCI (43). Several studies comparing the Lokomat with conventional physical therapy have been published, with mixed and inconclusive results overall (53–55).

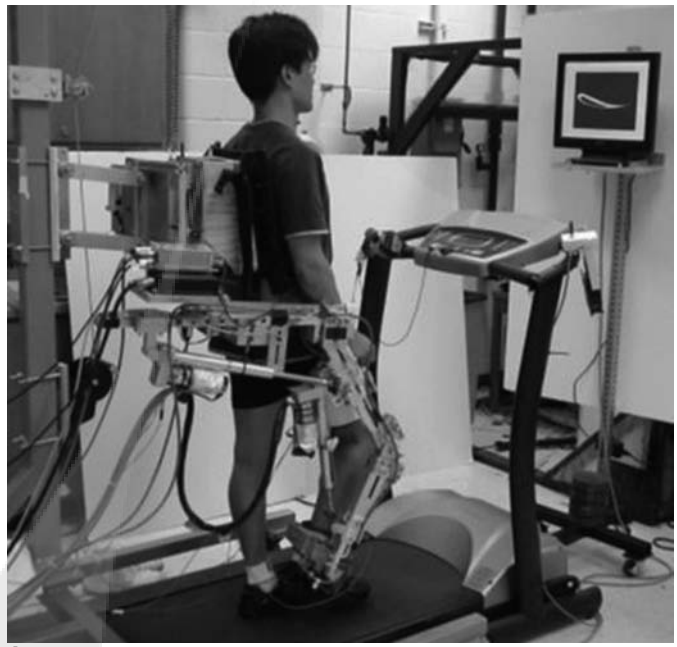
A *two active* degrees of freedom back-drivable robot for the ankle, the Anklebot, has been developed at MIT (Interactive Motion Technologies, Watertown, MA; see Figure 22.8). This tethered wearable device functions as a powered ankle–foot orthosis, with the ability to control and assist ankle dorsiflexion and plantarflexion as well as inversion and eversion.

FIGURE 22.7 Lokomat robot (Hocoma, Inc.) provides partial body-weight support during assisted treadmill training.

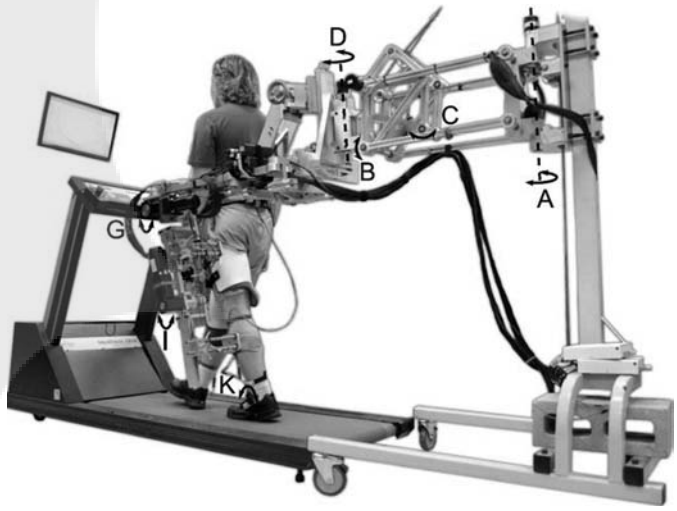
One study with chronic and another with subacute stroke found that training ankle movements in seated position with this device resulted in gait improvements (56).

A number of studies have been performed with Active Leg Exoskeletons (ALEX and ALEX II), shown in Figure 22.9, focused on the issues of design, human training, and optimal

FIGURE 22.8 Anklebot (Interactive Motion Technologies, Inc.) is designed to assist and train ankle movements during gait.



A



B

FIGURE 22.9 Gait training of healthy and stroke subjects using Active Leg Exoskeletons ALEX (A) and ALEX II (B).

haptic/feedback interface. ALEX has been used to study gait adaptation with "assist as needed" paradigm using healthy subjects and in a group of stroke patients (57–59). ALEX has also been used to study "error enhancement" paradigm in gait adaptation with healthy subjects and the role of feedback in human training and learning. ALEX is attached to a walker and strapped to a human subject on the trunk, upper- and lower-limb segments of the leg (see Figure 22.9). The attachment between the user's trunk and the device allows flexibility during walking. The hip segment of ALEX allows abduction and adduction with respect to the pelvis. The thigh and shank segments of the machine are telescopic to accommodate variability in leg geometry of users. The foot segment of the exoskeleton is a shoe insert. The orthosis has joint encoders

that record the movement of the trunk, hip, the sagittal plane motion of the leg, and the motion of the ankle. In addition, the exoskeleton has two 6-axis force-torque sensors that record the interaction force and torque between the machine segments and the corresponding segments on the human. The hip and the knee joints of ALEX are actuated by servo motors.

One of the significant aspects of ALEX is that its controller is designed to provide flexibility and maximize human learning. A virtual tunnel is created around a desired foot trajectory that is a function of subject size, age, and walking speed. Depending on the current position of the foot with respect to the tunnel, the controller can prescribe force on the foot—both normal and tangential to the desired foot trajectory (57–59). In the assist-as-needed paradigm, if the foot is within the tunnel, the normal force is close to zero while a tangential force guides the foot along the tunnel. As the foot goes outside the tunnel, the normal force brings the foot closer to the center line of the tunnel while the tangential force is kept small.

Wearable Robots/Robotic Orthoses

In contrast to the stationary exercise robots discussed so far, robots are also being developed that are "wearable," known as wearable exoskeletal robots or powered orthoses. Such robots may be useful to provide therapeutic exercise (similar to stationary exercise robots) and/or potentially as devices to help compensate for chronic weakness. Wearable exoskeletal robots are in an earlier phase of development than stationary robots, and the relative merits of wearable versus workstation robots remain largely unexplored. Potential advantages include the ability to move the location of therapy into a more "real-world" environment, including the patient's home, rather than confining treatment to a designated location in a health care facility.

FIGURE 22.10 Myopro (Myomo, Inc., Cambridge, MA) uses a custom-molded orthosis to provide actuated elbow flexion and extension movements using surface EMG control from the biceps and triceps muscles.

A small pilot study of a powered wearable elbow brace (see Figure 22.10; Myomo, Inc., Boston, MA, www.myomo.com) that uses surface EMG signals to control the level of torque provided found hemiparetic stroke survivors capable of using this device for exercise training (60). A small randomized controlled pilot study compared this device to conventional upper-limb exercise therapy and found that both were equally efficacious (61).

A wearable powered knee brace, called the AlterG Bionic Leg, is commercially available (see Figure 22.11; AlterG, Fremont, CA). This device uses a combination of sensors, including accelerometers and force transducers to determine the user's intended action and can infer whether the user is walking, ascending/descending stairs, or transferring from sit to stand. It then provides assistance to the user to achieve an idealized template pattern of movement. One small controlled study comparing this device with an exercise control intervention in chronic stable stroke survivors has been completed and found modest improvements in gait that were no different from the control intervention (62).

Several groups have developed bilateral wearable powered long-leg braces, including the ReWalk (Argo Medical Technologies, Ltd, Yokneam Ilit, Israel), Ekso (Ekso Bionics, Richmond, CA), and the Indego (Parker Hannifin,

FIGURE 22.11 AlterG Bionic Leg (AlterG, Fremont, CA) is a wearable powered knee brace.

Cleveland, OH). These devices seem useful most specifically for individuals with paraplegia due to SCI or other conditions, rather than stroke. Nonetheless, it is likely that selected stroke survivors may benefit from these devices. Further development and refinement may provide specific training options for the hemiparetic stroke survivor.

The use of wearable exoskeletal robots as compensatory aids has been proposed as a means of providing a "power assist" to chronically weak muscles. Such a robot might allow individuals to perform ADLs or ambulate independently despite severe weakness. Control and feedback mechanisms for this type of robot require further study and may vary with the nature and severity of weakness.

Potential Disadvantages and Limitations of Wearable Exoskeletal Robots

Wearable exoskeletal robots may be capable of providing a substantial number of clinically relevant degrees of freedom, although practical considerations, including the bulk and weight of the exoskeletal robot, may limit the actual number of degrees of freedom achievable. The ability to apply forces at multiple limb segments, rather than at a single point of contact, adds both complexity and sophistication.

Wearable exoskeletal robots must function in a much more varied and less controlled environment than workstation robots. Accordingly, they may expose the user to unanticipated risks because situations arise that are beyond the intended activities of the robot. For ambulatory patients, issues such as falls while using a wearable exoskeletal robot must be considered as a potential risk to both the user and the robotic device. The possibilities of striking oneself or being forced into an anatomically dangerous position are less easily prevented in a wearable exoskeletal robot design than in a workstation design. Another design concern is that a mismatch between the machine kinematics and those of the limb(s) to which it is attached could potentially generate forces large enough to cause injury. For certain movements, the bulkiness of the robot may reduce the usable range of motion. Issues of fit for individuals of varying size and shape also have to be considered. Slippage of the device on the limb so that the axis of rotation is no longer aligned with the target joint potentially could lead to injury with activation of the device. Donning and doffing a wearable exoskeletal brace also may pose challenges and require the supervision of a skilled therapist.

Technical issues, such as a lightweight, portable power supply and actuators for wearable exoskeletal robots, remain a work in progress. Some of these devices presently rely on external battery packs to provide enough power. Ideally, such robots would be lightweight, wearable devices that are as unobtrusive as possible. In reality, this goal has not yet been achieved. Actuators for wearable exoskeletal robots that are small, lightweight, durable, and generate sufficient force remain under development. Equally challenging is the need to develop effective and safe control systems for these devices. The use of surface or implantable EMG signals (63) or neural prostheses capable of capturing brain activity (64) all are under exploration and potentially could be applied to control powered orthoses.

Potential Disadvantages and Limitations of Robot-Aided Exercise

Both workstation and wearable robots are used predominantly for providing therapeutic exercise at present. There are many characteristics of the present technology and robot design that might limit the overall application of this type of therapeutic exercise. Generally speaking, existing robots are designed for very specific types of training and are limited in their degrees of freedom of motion. It is unclear whether this also is a clinical limitation, but there are different groups aiming at answering this research question (65,66). For example, the Bionic Leg is limited to actuation of flexion and extension at the knee joint, and does not provide actuators at the hip or ankle. The MIT-Manus robot provides only two degrees of freedom and is designed to provide reaching-type exercises for the shoulder and elbow (15). The MIME robot (5), although providing a larger number of degrees of freedom at the shoulder and elbow, does not include any robotic training for the wrist or hand. The ArmeoPower provides six degrees of freedom in the upper limb using an exoskeletal design, permitting actuated movements for the upper limb in a three-dimensional workspace, although it too lacks actuated hand movements. An alternative strategy is to combine the use of multiple mechanically simpler robotic modules sequentially, analogous to "circuit training" in a gym. This approach also has the advantage of allowing multiple patients to utilize the various devices simultaneously. As stated earlier, the clinical impact of this approach is still being evaluated (67).

Many existing upper-limb robots transmit force to the limb through a single point of contact in the distal limb, rather than exerting force at multiple more proximal limb segments (often termed "end-effector" robots). Examples of this include the MIT-Manus robot with a manipulandum centered at the user's hand, and the G-EO lower-limb robot with moving footplates as the point of contact. These are in contrast to exoskeletal robots that provide control of multiple limb segments, such as the ArmeoPower or Lokomat. Insufficient data exist to determine the relative utility of exoskeletal versus end-effector designs.

Several approaches have been used to assure the safety of robots for use in human exercise training, and a highly favorable safety record has been achieved. The InMotion shoulder–elbow robot uses an impedance-controlled, "back-drivable" system for generating force that provides a highly compliant machine–user interface that allows the user's limb to deviate from the intended movement path while providing a progressive amount of corrective force to help the user achieve the desired position. This approach limits the corrective force and may reduce the risk of injury. Other robots, such as the MIME robot, have used more conventional machine–user interfaces with padding and safety cut-offs. These devices generally are not back-drivable and have a less compliant interaction with the user. Although

not yet broadly used clinically, the robots being used to provide therapeutic exercise appear to have an excellent safety record. Whether such a record can be maintained outside of a carefully controlled research setting remains to be confirmed.

The development of training algorithms for robot-aided exercise remains in its early stages. Because of their programmable nature, there is no limit to the number of ways in which robot-assisted exercise can be designed. Questions remain regarding breaking down exercise tasks into simpler components versus performing more complex exercises, the importance of incorporating virtual environments, the most effective duration and frequency of training, the benefits of resistance training, and many other issues (68,69). Fortunately, the availability of robotic exercise devices provides the scientific tools to answer these questions in the coming years.

Overall, published research on the use of robot-aided exercise after stroke is encouraging but not yet definitive. Differences in robot design and training algorithms make it difficult to compare studies and likely account for the variable results. Training-specific effects on motor function are evident and may be dependent upon dose, device, and training algorithm. Further research should focus on expanding the scope of robot-aided exercise training to incorporate the entire upper limb, and on continuing the exploration of the best training regimens and algorithms based on the individual's movement abilities and goals.

FIGURE 22.12 JACO robot arm (Kinova, Inc.) is a wheelchair-mountable ADL robot arm that assists with reaching and grasping activities.

Robots for ADL Assistance

Computer-based technologic aids have become an important component of assistive technology for individuals with severe disabilities. These devices have been used to aid in communication, to assist with powered mobility, and to assist in ADLs. Appropriately designed robotic devices may be useful to help with manipulating objects in the environment that the user is incapable of manipulating independently.

The iARM robot (Exact Dynamics, Didam, the Netherlands, www.exactdynamics.nl) and the JACO (Kinova, Inc, Montreal, Canada; see Figure 22.12) are robotic arms that mount on a power wheelchair. These robots are controlled by a joystick, keypad, or sip-and-puff interface and can be used to pick up objects from the floor, open a refrigerator door and remove an item, and so on. This type of robotic device potentially is useful for individuals with large brainstem strokes with bilateral weakness, as well as nonstroke conditions such as spinal cord injuries, limb deficiencies, and neuromuscular conditions.

This type of robot arm has a substantial number of degrees of freedom, but accomplishing functional tasks may be slow and complex to master. The absence of proprioceptive feedback is compensated for by the use of visual monitoring of the robot's trajectory and target acquisition. The optimal terminal device (gripper) and force applied during robot grasp remain under study. Existing designs are capable of assisting in feeding, turning light switches on and off, and even opening doorknobs. The psychological benefits of improved ability to manipulate one's own environment appear considerable and are supported by case reports (70,71) and small case series (72). A study of one device found that users could rapidly learn to complete tasks, and an economic analysis suggested potential savings achieved through reduced caregiver hours (73). Novel control mechanisms, including brain–computer interfaces, are being studied in an effort to integrate these devices more closely with the central nervous system (74).

Potential Disadvantages and Limitations of ADL Robots

Technical issues include the absence of sensory feedback when using these devices, thus posing the risk of grasping an object too hard or not hard enough. These robot arm devices are slow and laborious to use and require patience, good perceptual abilities, and well-preserved cognitive abilities to master and use them appropriately. The risk of injury caused by misuse or errors appears small but has not been quantified.

The devices are designed for an intermediate degree of fine motor control. Tasks requiring very fine control, such as writing, or those that are bimanual in nature, are not feasible with the current generation of devices.

Cost is a major consideration for ADL robots, as discussed later (see "Economic Considerations" section). For example, the JACO robot arm costs more than $35,000—a price that places this device outside the affordable range for most patients unless a third-party funding source is available. In contrast to exercise robots, which are typically used for a limited period of time in a therapeutic environment, ADL robots are intended for long-term use in a home setting.

Robotic Walkers

Robotic walkers have been proposed both as therapy aids during gait training and as functional aids during independent ambulation. The Veterans Affairs Personal Adaptive Mobility Aid (VA-PAMAID) is under development as a navigation aid for elderly individuals (75). Successful implementation of this type of robot will have to address issues of cost, weight, complexity, and stability.

Another type of robotic walker has been developed to assist during gait training, the KineAssist (Kinea Design, Evanston, IL; see Figure 22.13). This robot is designed to assist a physical therapist during gait training by providing external stabilization for the patient. The robot does not provide therapy per se, but rather facilitates conventional physical therapy training and reduces the need for additional staff members to provide physical assistance to the patient for safety. The robot is designed for a therapeutic environment rather than for use in the community, although it can be used outdoors on smooth surfaces. Limitations include a large footprint, limiting use to relatively open areas, and cost. Clinical trials have not yet been conducted using this device. Tethered systems that support a user from a track above, such as the Zero-G (Aretech LLC, Ashburn, VA) are another approach to accomplish similar goals that may prove logistically easier.

FIGURE 22.13 KineAssist (Kinea, Inc.) is a mobile robot to assist with gait training. The ability of the device to support a patient when losing balance is shown.

ECONOMIC CONSIDERATIONS

In more developed countries, such as the United States, Japan, and Western Europe, there has been a steady downward trend in the cost of technology-based devices, while at the same time labor costs continue to rise. As a result, there has been an ongoing substitution of computer- and robotic-based devices for workers, whenever feasible. Examples of this substitution abound and include the ubiquitous use of automated teller machines instead of bank tellers, the growing use of check-in kiosks in airports rather than airline representatives, and the continued growth of industrial robots in manufacturing to reduce the number of assembly line workers. Medicine is not immune to these trends, although it has been slower to adopt this approach than many other fields. One example of automation is the use of pharmacy dispensing systems that are now widespread in hospitals and help reduce the manual labor involved in managing medication inventories.

This trend of reducing the number of skilled workers required in favor of technological substitutes shows no sign of abating, and the economic forces that drive it are likely to persist or even accelerate. The aging of the population is now a major challenge in Japan, and the shortage of workers to assist older individuals is stimulating Japanese companies to explore devices to help bathe and care for the elderly. The U.S. population is also aging, and shortages of nurses and personal care attendants already plague health care systems in many areas of the United States.

The incorporation of newer technologies in rehabilitation depends on the clinical evidence, their cost, and health insurance coverage for these devices. In particular, assistive technology often is not adequately or not at all reimbursed by third-party payers because of annual caps on payment for "durable medical equipment" or definitions of "medically necessary devices." Although an ADL robot may provide substantial improvements in independence, it is not intended to directly treat the patient's medical condition, and thus may not be considered "medically necessary."

Establishing proof of efficacy for robotic devices remains challenging. Large randomized clinical trials comparing robotic with present rehabilitation techniques and demonstrating clinically meaningful improvement will have to be completed before third-party payers will reimburse their costs. Unfortunately, companies bringing robotic devices to market in the United States and Europe face incentives that discourage the conduct of definitive clinical trials. In the United States, robotic devices have generally achieved FDA clearance using the 510(k) mechanism that permits the sale of these devices without demonstrating safety and efficacy in large controlled clinical trials. The availability of this mechanism, coupled with the limited financial rewards currently achievable in the marketplace from the sale of robotic devices, has prevented most companies from supporting these clinical trials. In the United States, the NIH and foundations typically do not fund these types of studies, leaving a vacuum for the support of definitive clinical trials. Comparative costs for these systems also must

fall substantially or else the economics of incorporating these technologies into rehabilitation will remain unfavorable, unless research demonstrates added value in using these systems over present rehabilitation techniques.

Because of the novelty of therapeutic robots and virtual reality systems, these still are commonly used with direct supervision by a skilled caregiver (typically a physical or occupational therapist). Thus, little of the opportunity for these devices to be truly labor-saving has yet been realized. Over time, it is reasonable to expect that greater familiarity with these devices and simplified user interfaces will allow more autonomous use of technology-aided exercise therapy. Therapy might be provided in a group setting in a "high-tech" gym with a therapy aide providing intermittent supervision or even in a home-based treatment program without the presence of a health care worker during treatment sessions.

The specialized design and limited range of activities that the current generation of devices provides, however, preclude using these devices as substitutes for human-provided therapy, even if they can be operated autonomously. As an example, an upper-limb exercise training robot cannot teach a stroke patient to dress herself or manage her hygiene as an occupational therapist would. Thus, in the intermediate term, the likely role of robots and virtual reality systems is as adjuncts to skilled therapists—perhaps more of a rehabilitation "aide" than "therapist." Genuine cost savings appear to be at least several years in the future, but seem inevitable as the efficiency of delivering these types of therapy improves. Although a preliminary study examining the cost of robotic therapy is encouraging (76), additional studies that are specifically designed to examine cost-effectiveness are needed to determine the appropriate utilization of these technologies.

RESEARCH FRONTIERS

Engineering advances in computer technology and in the implementation of clinical applications is proceeding at a rapid pace. Successful commercialization of one or more robotic and/or virtual reality devices is likely to enhance investment in industrial research and development and further accelerate the rate of change.

As Yogi Berra is alleged to have said, "It's tough to make predictions, especially about the future." Many technological advances in stroke rehabilitation are impossible to foresee at this time.

One key question is the role of complexity in further technology development. Many new consumer technologies have become increasingly complex as new capabilities are added. Stroke survivors often are coping with perceptual and cognitive impairments, and concerns exist regarding their ability to effectively use highly complex systems. Cost concerns also are important, as more complex systems are generally more expensive than simpler systems. Ultimately, clinical trials will be needed to compare different approaches to determine the most effective strategy.

Larger randomized controlled trials of the efficacy of these treatment approaches are needed to validate the preliminary evidence of efficacy seen in smaller studies. Research in the application of technologically based therapies will also have to clarify the relative efficacy and efficiency of strategies that seek to combine complex multiple-limb segment training in a single activity versus training systems that use a more modular approach for training individual limb segments and movements. For example, it is not yet clear if it is better to perform upper-limb exercises incorporating the shoulder, elbow, wrist, and hand in a single movement versus individual exercises for each of these joints. In addition, the relevance and generalizability of robot-trained movements to functional, daily life tasks has not been well addressed in previous studies. It is possible that "hybrid" therapies systematically combining robot-assisted therapies with therapist-generated intervention will prove more effective. Randomized clinical trials will have to demonstrate "clinically meaningful improvement" if robotic therapies are to be accepted and reimbursed as effective therapies.

CONCLUSION

Stroke rehabilitation robots are undergoing a phase of rapid development and testing and are likely to begin to appear in clinical settings on a regular basis within the next few years. Special-purpose devices are likely to remain the mainstay of stroke rehabilitation technology for years to come, given the extraordinary complexity of attempting to create general-purpose rehabilitation devices. Cost considerations and reimbursement issues are likely to grow in importance as the cost/benefit ratio of incorporating these technologies into stroke rehabilitation is debated.

Virtual Reality and Video Games for Stroke Rehabilitation

Judith E. Deutsch

The interest in and application of virtual reality (VR), using virtual environments (VE) and video games, for the examination and rehabilitation of individuals after stroke have grown steadily since the earliest papers published in 1997. A PubMed search (conducted in late 2013) using the terms *VR* and *stroke rehabilitation* yielded 227 references, with fewer than 5 publications per year until 2002, followed by triple that amount in 2006 (see Figure 23.1). This number is likely a slight underestimation, as not all papers on VR can be found in PubMed.

The appeal of VR augmented sensorimotor rehabilitation has been the promise of ecologically valid, intensive task-specific training (1), concurrent with multisensory training that would transfer from the virtual world to the real world (2). Additionally, some have suggested that VR could deliver training intensity (repetitions and duration) associated with neuroplasticity and positive behavioral adaptations (3) because it is particularly well suited to very high training doses (4,5). Relatively recent reviews of the field have shown that promise to have been partially met for recovery of upper-limb function in people after stroke (6,7), as did a more recent review (8) and meta-analysis that identified moderate improvements across the ICF domains for upper-limb function, walking, and balance for people after stroke (9).

VR augmented rehabilitation for people after stroke has been delivered using different technologies and for a range of purposes. Video games that are designed for entertainment, labeled either *commercial-off-the-shelf* (COTs) or *active video games* (AVGs), when applied to rehabilitation are often called VR. In this chapter, we describe VR systems (both customized and commercially available) and video games, and evaluate their application for sensorimotor rehabilitation of the upper-limb function and walking. We begin with relevant definitions of VR and an explanation of the VR delivery systems and conclude with the evidence to support their application.

IMPORTANT DEFINITIONS

Virtual Reality

VR has been defined as a computer-synthesized three-dimensional graphical environment created from numerical data (10) that is enhanced by visual, aural, and haptic devices, so that the human operator can experience the environment as real (11). From a rehabilitation perspective, it is the interactivity of the VR system that is important. A VR system consists of hardware and software. The hardware serves as an input, recording and transmitting movement into the VE that is animated by the software.

Simulation or VE or Game

Simulation or *VE* or *game* consists of task(s) performed by the user in the environment(s) with specific feedback. This could be knowledge of results or knowledge of performance (12). It occurs in the form of summary feedback at the end of the simulation, VE, or game. Research comparing the effects of training with a robot alone to those yielded by coupling the robot with VR demonstrated the latter to be far superior in transfer of training to over-ground walking (13). These findings underline the importance of the VE and its content as key elements in successful VR systems.

Avatar

An *avatar* is the graphical representation (often in three dimensions) of the person interacting with the VE, also called the user's *character* (14). The avatar can be customized to look like the user, creating a greater sense of agency or connection to the game. An avatar may be represented in a first- or third-person perspective. In the third-person perspective, one appears to be looking at oneself from the outside (either the front, back, or side). In the first-person perspective, one appears to be looking from the inside of the character; for example, users might see their feet stepping on a walkway, or their arms as they interact with objects in the VE.

Presence and Immersion

VEs are created to afford the user the sensation of being present and/or immersed in the environment. The term *(tele)-presence* was first used in this context by Minsky (15), who defined it as a sense of "being there." Minsky wondered

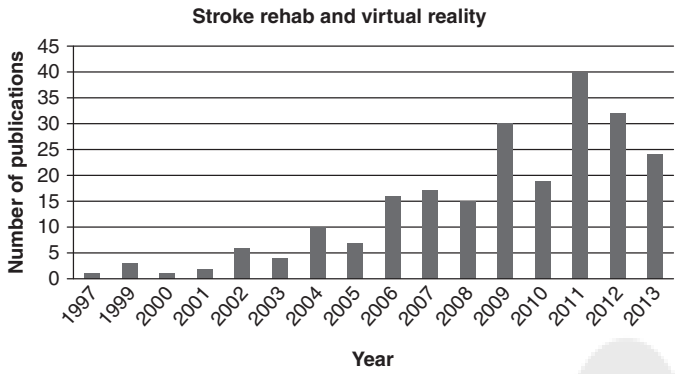

FIGURE 23.1 Number of publications on virutal reality and stroke organized by year.

whether tele-presence could be a true substitute for the real thing and if one could couple artificial devices naturally and comfortably to work together with the sensory mechanisms of human organisms (15). A more recent discussion by Lee (16) posited that presence is a psychological construct dealing with the perceptual process of technology-generated stimuli. He categorizes presence, based on the way humans experience the world in three domains, as physical, social, and self. It follows that users interact within virtual worlds through one or more of these domains. As a result, their experiences extend from their sense of presence as they relate to each of these domains. In the context of rehabilitation, Gaggoli and Riva describe presence as having two roles: locating the self in an external physical and/or cultural space and providing feedback to the self about the status of its activity (11, p. 8). This definition suggests that presence allows for interactivity and that action is more important than perception. Therefore, the well-designed VE makes a trade-off between perceptual realism and naturalness of interaction (11, p. 17).

From a practical standpoint, presence is a construct that can be measured. The experience and intensity of presence in a VE is a function of both individual differences and the characteristics of the VE. Thus, Witmer and Singer developed a Presence Questionnaire (PQ) and an Immersive Tendencies Questionnaire (ITQ) to address both the VE and user factors associated with presence (17). The PQ defines presence as a combination of immersion, a "psychological state in which you can interact with an environment that provides a constant stream of stimuli and experiences" (17, p. 227), and involvement, a "psychological state that is experienced as a consequence of focusing one's energy and attention on a coherent set of stimuli or meaningfully related activities and events" (17, p. 227). In other words, salience and interactivity are measures associated with presence.

Immersion

Immersion, defined as a state in which one can interact with an environment (17), is linearly related to presence. VR systems are described on a continuum of nonimmersive to highly immersive. Immersion is, in part, achieved by blocking out stimuli in the real world that may distract the user from interacting with the VE. Thus, hardware used to visualize the environment, such as a head-mounted display (HMD), would block the viewer's external view and be highly immersive, in contrast to a desktop computer display, where the viewer is looking into the environment, making the experience less immersive. Furthermore, the more natural the interface is with the VE, the more likely the user is to be immersed. Thus, one might hypothesize that a system that reads one's movement into a VE with great fidelity would be more immersive than one that distorts the movement.

The relevance of the VE, the specific hardware used to deliver the VE, and the user's personal qualities all interact to create a sense of presence and immersion. Rand and colleagues demonstrated that presence, for a group of healthy people ranging in age from 16 to 75 years, was an interaction between the simulation, the hardware used to deliver the VE, and the user's personal characteristics (18). Therefore, the degree of immersion based on the delivery method is only one important variable. Importantly, Rand's group also demonstrated that after stroke, individuals could be present in a VE, even when these environments would be defined as semi-immersive (19). From a rehabilitation perspective, we seek to have the user immersed and present in the environment.

VR TECHNOLOGY SYSTEMS

VR systems typically consist of hardware interfaced into the VE, equipment used to display the VE, and software that controls the system and creates the VE. The hardware interface collects movement data (the input into the system) using cameras, sensorized gloves, and/or robotic exoskeletons. The equipment used to present the visual information from the VE (outputs) can be (from less to more immersive) a desktop computer, television screen, a rear-projected single or multiple screens, or a HMD. The sensation of touch (haptic) that augments the visual and auditory stimuli is delivered using an exoskeleton, or a robotic interface, or (in the case of a mixed reality system), a real-world object. The sense of touch facilitates the addition of physical task parameters, such as rendering of environmental obstacles as well as provision of global forces such as gravity. Haptics also provide forces that produce biomechanical and neuromuscular interactions in the VE that approximate real-world movements better than the visual information alone (4). Finally, the simulation or VE is typically a three-dimensional animation that requires user interaction. For sensorimotor rehabilitation, the interaction requires the user's head, limb, or total body movements; for cognitive tasks, the interaction may be achieved with a keyboard or a joystick interface. For additional information on VR augmented sensorimotor systems, the reader is referred to references (5) and (20).

Systems are often categorized by their sensing elements. These may be grouped into two large categories: camera-based and sensor-based (with or without haptics) systems.

Camera-Based Systems

Camera-based systems are referred to as *motion* or *video capture systems*. They capture motion using a single camera or multiple cameras. They detect motion by color, markers, or the outline of the human body and then reconstruct the images and represent them with an avatar, or capture the user's image and place the person in the environment. The system first developed for rehabilitation was GestureTek's IREX (see Figure 23.2). It uses a chroma key background, and the user's image is placed into a VE facing out. The user then watches his or her own image as he or she interacts with the VE. Weiss and colleagues reviewed the history of this system and the PS2™ (described in the following text) and their application in rehabilitation (21). The CAREN is an eight-camera system that tracks motion and displays the VE on a large rear-projected screen using the first-person perspective (see Figure 23.3). This system integrates motion capability by using a treadmill. Both of these systems are commercially available.

In addition to commercially available systems like the IREX and the CAREN, researchers have designed other systems for rehabilitation of people after stroke. Jaffee and Brown, for example, used a camera to track lower-extremity movements and display them to the user in a sagittal view on a HMD (see Figure 23.4) (22). There are also several variations of the treadmill systems to promote ambulation, which have environments rear-projected on three screens (23) or tracked by a head marker and displayed on a television screen (24).

FIGURE 23.3 CAREN system with a rear-projected environment on a curved screen. Participants ambulate on the treadmill and are detected by the cameras. In this simulation the participants have a first-person perspective.

Sensor-Based (Haptic) Systems

Sensor-based (haptic) systems use an exoskeleton or an instrumented robotic interface to sense motion and represent it in the VE. These systems can incorporate the sense of touch (haptics), further augmenting visual and auditory feedback. Commercially available systems that use endpoint control such as the Haptic Master have been incorporated into VE systems targeting the upper limb (see Figure 23.5). Other systems use robotic exoskeletons, one for locomotion (Lokomat) and the other for upper-limb movement (Armeo), and have interfaced their systems with VE (see Chapter 22 on robotics). A glove with sensing capabilities can be used to reproduce hand motions, such as illustrated in Figure 23.6 with a piano-playing simulation. An instrumented steward platform has been used to sense ankle and foot motion in the Rutgers Ankle Rehabilitation System (see Figure 23.7).

COMMERCIAL OFF-THE-SHELF VIDEO GAMES (COTS)

Motion-sensing video game consoles transformed video game play and have provided a low-cost option for introducing VR into the clinical environment. Using technology identical to the IREX system but at a much lower cost, the earliest COT video capture system was the Sony PlayStation 2™ with its camera the EyeToy™ (see Figure 23.8). Similar to the IREX, the user sees his or her image in the VE and can interact with virtual objects. The first studies that evaluated the feasibility of using video games for stroke rehabilitation were performed with the PlayStation 2™ and the EyeToy™ camera (19,25–27). Participants' engagement was measured and found to be positive (25); a single patient was able to use it for upper-limb and balance rehab in her home (26). Additionally, individuals in the chronic phase after stroke who were at a higher functional level had more meaningful game play than those in the subacute phase (19); however, subacute patients benefited from the addition of the games for their upper-limb movement and self-care, compared to a group of patients who just watched the EyeToy™ games (27). These early papers were met with

mixed reviews. The main complaint was the lack of control over the game play, which differs from that afforded by systems designed for rehabilitation (21).

The introduction of the Nintendo Wii™ console and Wii Sports™ games in 2007 provided motion-sensing capabilities similar to haptic-based interfaces (Figure 23.9). The controller or Wiimote™ is instrumented with an accelerometer that reads the upper-limb gross movements. A vibratory element in the Wiimote™ provides a haptic sensation when an object is contacted. The Wii-Fit™, introduced in 2009, added a force platform as a user interface. Validation of that platform's (28,29) measurement capabilities and software to track improvements made it an appealing tool for rehabilitation of balance.

The Microsoft Xbox™ with its Kinect™ motion-tracking sensor, released in 2010, is the most recent motion-sensing console used for rehabilitation (30). The system uses an infrared projector, camera, and a special chip to track the movement of objects and individuals in three dimensions (31). It has been reported to have greater precision than the PS2™ and offers a variety of games such as Kinect Adventures!™ and Kinect Sports™ that may be applied to rehabilitation.

UPPER-LIMB SENSORIMOTOR REHABILITATION

Customized VR Systems

Both upper-limb specific (4,7,32) and field overview reviews (8,9) have summarized the state of the field. The early reviews primarily included pre- and posttest single group studies that documented both motor impairment and motor function improvements with both camera-based and haptic-sensor-based systems (7). More recent work on comparative efficacy studies (6,8,9) finds a consistent but modest benefit of VR over standard of care.

Camera-based motion studies of the upper limb used commercial systems like the IREX and CAREN (33,34). Sensor-based motion capture systems of the upper limb used commercially available hardware like the phantom (35), Amadeo (36), and the Armeo (37,38), as well as many customized systems that used magnetic trackers (39–43); and pneumatic gloves as inputs into the VE (44). Haptics have been incorporated into several of the sensor-based motion capture systems (35,36,38,43,44). Mixed reality systems incorporated use of real-world objects (39–41).

The types of tasks used by the investigators studying upper-limb movements involved reaching, transport, and, in some cases, selective finger movement (36,45). Simulations consist of real-world tasks and game-based activities. Examples of real-world tasks included putting envelopes in a mailbox, or breaking eggs (40), or reaching for objects in a virtual supermarket (34). Examples of game-based tasks included intercepting flying spheres (43).

The findings across all of these studies is that VR augmented systems have a modestly positive outcome when compared to standard of care (6,9). The participants are predominantly in the chronic phase after stroke (more than six months), with a few exceptions for work with acute and subacute (less than three months) participants (43) (33,36). The predominance of positive outcomes is at the body function and activity level, with little or nothing reported on participation (9).

Fluet and Deutsch (8) synthesized the controlled trials on upper-limb studies that were published after the VR Cochrane review (6) and made several interesting observations. In the eight studies the authors analyzed, they found that reaching simulations consistently improved reaching, and game-based simulations produced less specific outcomes. This suggests that specificity of training is relevant in VEs. For studies that compared training with and without haptics (38,44), there was only a small additive effect of having the haptics. Thus, the value of adding haptics, with all the technical challenges it involves, remains an unanswered question in the field (8). Widespread adoption of these systems is also currently not possible because many of them are not commercially available.

Commercial Off-the-Shelf (COTs)

The low cost of the COTs makes them appealing as alternatives to the custom VR systems. All three consoles, the PS2™ with the EyeToy™ camera, the Nintendo Wii Sports™, and the Xbox Kinect™, have been used in upper-limb rehabilitation. The early work with PS2™ included a randomized controlled trial by Yavuzer (27) in which playing PS2™ games was compared to watching PS2™ games for people with motor recovery of Brunnstrom Stage II. The PS2™ was played for 30 minutes, 5 times a week, in addition to the

standard of care which ranged between 2 to 5 hours, 5 days a week. Outcomes measured by the self-care items of the FIM showed significantly better scores both at pretest and at follow-up for the group that played the games.

Several investigators have used the Wii for upper-limb poststroke rehabilitation, both with acute (46,47) and chronic (48) participants with moderate motor control. The study with the highest level of evidence (2b on the Oxford Center for Evidence Based Medicine; CEBM) compared playing table-top games that involved upper-limb use such as playing cards to Wii-based games. Both groups were seen in recreational therapy for 60 minutes, once a day, over 2 weeks. Both groups improved on the Wolf-Motor Function (WMFT) test at posttest and follow up. There were, however, no significant differences between the groups (47). The other two studies measured improvements in upper-limb function on the Fugl-Meyer (FM) scores and WMFT, but they had a lower level of evidence (CEBM 4) (46,48).

Two recently published trials by the same group of investigators (49,50) examined the Kinect™ games applied to upper-limb rehabilitation and ADLs. They showed that the addition of the Sports and Adventures! games to standard of care, during a six-week intervention, for individuals on an average seven months after stroke, was superior to standard of care alone in improving upper-extremity FM score, performance on the Box and Blocks, and active range of motion of proximal joints (50). Regrettably, both studies compared the addition of the Kinect games to standard of care, resulting in greater treatment time for the experimental group. However, their findings do suggest a specificity of training, with results seen primarily for the gross movements of the upper limb and not more selective distal movements or ADL.

In addition to the feasibility studies, two validation studies on the use of the video games have shed some light on the promise of exercise intensity relative to standard of care. First, the amount of upper-limb use by people after stroke was compared while they played with the Wii™ and the PS2™, with significantly greater movement reported for the PS2™. The PlayStation 2™ EyeToy™ group produced an average of 302.5 (228.1) upper-extremity active movements and 189.3 (98.3) weight shifts, significantly higher than the Nintendo Wii™ group, which produced an average of 61.9 (65.7) upper-extremity active movements and 109.7 (78.5) weight shifts. No significant differences were found in steps and other lower-extremity active movements between the two systems (51). In the second, Rand and colleagues (52) reported that the number of repetitions of purposeful movement with the Kinect group (median 271) compared to a standard-of-care group (48 repetitions) was more than five times greater. Further, these movements were tracked with a three-dimensional accelerometer and the game was played at a higher velocity, which the researchers interpreted as being of greater intensity (52). Motion capture systems, like the PS2™ and the Kinect™, appear to promote greater activity than the Nintendo Wii™ sensor-based haptics games that use a handheld controller.

To summarize: There is modest evidence (2b-4) that COTs are effective in improving limb function for people after stroke, but they are not superior to standard of care. The most robust findings were for people with acute (47) and subacute (27) strokes. Most participants presented with low levels of motor control. The addition of playing video games targeted at joint motion on the PS2™, Wii™, and Kinect™ between 8 to 10 hours, in addition to rehabilitation, improved upper-limb activity. Given their high levels of activity, individuals with mild impairment appear to generate sufficient movement with high acceleration that may be beneficial for upper-limb recovery (52).

WALKING AND BALANCE REHABILITATION

VR Systems

Use of customized VEs for walking recovery and balance has been reported in several topic-specific reviews (53–55) as well as in overview reviews (6,8,9). The volume of work is more modest compared to the upper-limb VR work. This may in part be explained by the physical and safety challenges of building walking systems, as well as the fact that most people after stroke recover walking to a greater extent than their upper-limb control. Most of the studies have involved the use of a treadmill augmented with the VE, or a real-world video recording (56), typically displayed on one (57) or several rear-projected screens (23) or on a television screen (24). Two groups used a HMD for their display (22,58). The remaining studies trained gait-related activities using either the IREX motion capture system (59–61), a standing frame both in the clinic and at home (62), or a lower-extremity robot interfaced with a VE displayed on a computer screen (13,63).

What the research has in common is that the simulations have rich feedback, and generally positive outcomes are being reported. In a motor learning review by Imam and Juras (55), the authors reported that lower-extremity studies provided external focus of attention, with variable and unpredictable practice. The outcomes are typically gait speed, balance, and balance confidence measures. The positive walking and balance outcomes represent a transfer of training in VR to walking. For the studies that are not task-specific, the investigators did not train gait directly (13,59), and the doses (repetitions) are much higher than for the task-specific training. Four of the studies (57,59–61) used commercially available technology, though the remaining research groups developed their own systems. One group demonstrated the feasibility of training both in the clinics and at home using tele-rehabiliation (62). Cost and system availability are barriers to the positive transfer of training from VR to walking and, consequently, translation of real-world findings into clinical practice. This has prompted the exploration of COTs as an alternative to VR systems.

COTs for Balance and Mobility

Very few studies have employed COTs for balance and mobility training of people after stroke. Several case reports of people with chronic symptoms after stroke report

positive outcomes of balance and mobility training (26,64). Four pilot trials have been reported in this area, three for people in the chronic phase (65–67) and the other for people in the acute phase (68). Studies were executed primarily with the Nintendo Wii™, using the Fit™ games, although one study used both the Wii™ and the PS2™ (66).

Two of the trials had active control groups (65,68). Bower and colleagues (68) reported trends toward improved balance in the Wii Fit Plus balance group while no changes were observed in the control group, who played Wii-Resort games in sitting. In contrast, Deutsch and colleagues (65) reported no between-group differences, but a greater number of within-group improvements for balance and mobility measures for people in the standard-of-care group.

The importance of these two trials is the care taken in designing the control groups. Bower and colleagues had a game control group, so it was easier to isolate the specific effects of the type of game. Deutsch and colleagues ensured that comparable categories of exercise—warm-up, sitting, and standing balance and choice of games or tasks—organized the therapy in each group. They found, however, that the video game group had a limited selection of games that might have addressed their primary therapeutic goals. Customization of the plan of care was easier in the standard-of-care group. Although it is likely that video games will not be found superior to standard of care, the question of how best to incorporate them remains.

ACTIVITY PROMOTION

Implementation of movement-based VR systems has focused on sensorimotor rehabilitation, but there is an emerging application to fitness promotion in persons with disability secondary to stroke. Given the importance of physical activity (69) and the barriers to exercise encountered by people after stroke (70), VR is proposed as a facilitator of activity. There is a customized VR augmented cycling system that uses heart as an input to the VE. The Virtual Reality Augmented Cycling Kit (VRACK) is designed to convert any bicycle into a VR augmented system (71) (see Figure 23.10). Preliminary findings indicate that people after stroke (n = 4), who used the system for one hour, two times a week for eight weeks, demonstrated significant improvements in VO_2 max and mobility outcomes (72). Although the treadmill-based VR systems used to improve walking did not assess cardiorespiratory improvements, this is a possible future application.

In addition to their use as movement re-education tools, the games' activity-promoting capabilities have been explored for people after stroke. COTs that are designed to promote activity are called AVGs. Hurkmans characterized two predominantly upper-limb Wii games (tennis and boxing) and reported that they produced moderate exercise intensity (73). Kafri and colleagues, in a case-control series, compared the energy expenditure and exercise intensity between individuals after stroke with moderate deficits to semi-active healthy matched controls, while playing both Kinect and Wii games in sitting and standing positions (74). The games were selected hierarchically from least effort required from a standing balance task to upper-limb predominant (boxing) and lower-limb predominant (running). Generally, individuals after stroke had lower energy expenditure (at the low end of moderate) compared to the healthy controls (moderate to low end of vigorous), at similar exercise intensity. It appears that individuals after stroke are unable to expend as much energy, possibly due to lower muscle mass and incoordination to sustain the movements. Interestingly, when compared by the matched activities typically performed in therapy (such as a standing reaching task with the standing balance Penguin game), the games had lower energy expenditure. However, the games may be a tool for activity promotion, given their potential to increase motivation for exercise and to promote adherence.

CONCLUSIONS

The use of VR systems for sensorimotor rehabilitation and fitness promotion has grown from a novelty to a partial reality. Generally positive outcomes are reported for the custom VR systems at the body-function and activity levels. The quantity of the evidence is smaller for COTs and the findings for efficacy less robust. However, their low-cost makes them appealing. All systems have the provision of feedback and multisensory stimuli. The participant profile, dose, addition of haptics, superiority of customized systems compared to video games, fidelity of movements in the VE compared to real-world

movements, and the degree of immersion needed to produce positive outcomes remain unresolved questions in the field. Recent events, such as the purchase of Oculus Rift, a HMD that projects VEs, by Facebook, may reduce the cost of technology and allow for quicker translation of the technology into practice. In addition, the efforts to build games for rehabilitation for the commercially available consoles may bring the application of VR technology into the forefront of stroke rehabilitation.

ACKNOWLEDGMENTS

Thanks to my colleagues, Gerard Fluet PT, DPT, PhD; and Phyllis Bowlby, PT, EdD, PCS, for their careful reading of and thoughtful comments on the manuscript. Thanks as well to Chintan Patel for editorial assistance.
