Walking Recovery and Rehabilitation After Stroke

Sara J. Mulroy, Steven A. Kautz, and Katherine J. Sullivan

Motor control deficits are a common manifestation of and a major contributor to walking disability after stroke. As a result, limitations in mobility related to walking are evident in 75% of individuals who sustain a stroke (1). During the first 6 weeks after stroke, the majority of stroke survivors will regain some ability to walk; however, 40% will have severe motor impairment that restricts functional walking to household ambulation. For those with mild to moderate motor impairment, independent walking ability is likely, but of those who achieve physical independence in walking, 60% will be limited to community ambulation (2). Furthermore, motor impairments that limit walking ability contribute to balance deficits after stroke (see Chapter 25). Individuals who have mild to moderate motor impairment and are functional ambulators after stroke have a 73% incidence of falls within the first 6 months after stroke (3,4). This culminates in a fourfold increase in falls risk after stroke and among those who fall, a tenfold increase in hip fracture.

The greatest predictor of community ambulation and participation in home and community mobility is walking speed (5). Perry et al. conducted a cross-sectional study of individuals with gait impairments after chronic stroke and classified them into one of six functional walking categories based on the degree of community ambulation and social interaction (5). The most significant difference between groups was preferred walking speed, with mean speeds ranging from slower than 0.4 m/s for household walkers, 0.4 to 0.8 m/s for limited community walkers, and faster than 0.8 m/s for unlimited community walkers. As expected, the higher the amount of community ambulation ability, the more likely one was to participate in social activities such as family outings, grocery shopping, going to church, and so on. However, achieving the break point of faster than 0.8 m/s (1.8 mph) in walking speed only represents 60% of what is normal for most healthy adults (6). Thus, the functional impact of walking impairment after stroke is significant. Activity outcome measures of walking function such as the Barthel index (BI) (7) or the functional independence measure (FIM) (7) are poor indicators of community mobility and participation after stroke because the majority of stroke survivors can achieve high BI or FIM scores (i.e., independent walking 10 meters or less) without any consideration of walking speed (8).

The impact of motor control impairments and walking disability extends beyond the acute and subacute phases to the chronic phase after stroke. Poststroke, lower-extremity, motor control deficits contribute to specific lower-extremity primary and secondary motor impairments and activity restrictions that impact balance ability and walking skills and increase the risk of secondary complications related to impaired walking ability such as an increased risk of falls and hip fracture, and, ultimately, mobility limitations that restrict participation across the lifespan for an individual after stroke. Walking recovery and rehabilitation after stroke includes therapeutic strategies that are designed to address the complicated and multivariate predictors of walking function. The overall purpose of this chapter is to describe all of the following:

1. Biomechanical features of poststroke walking impairment
2. Primary and secondary motor impairments and recovery factors that contribute to activity restrictions in the acute and chronic phases after stroke
3. Effects of stroke severity (i.e., severe compared to mild–moderate sensorimotor impairment) and secondary impairments on walking outcomes
4. Rehabilitation interventions for poststroke walking recovery that are currently being used in practice to address the sensorimotor sequelae of stroke

BIOMECHANICS OF POSTSTROKE GAIT

Stroke results in a constellation of sensorimotor impairments such as weakness, impaired selective motor control, spasticity, and proprioceptive deficits that interfere with the typically invariant features of normal adult gait. There is a wide range of walking ability after stroke that depends on the severity of these sensorimotor impairments. After stroke, there are obvious gait deviations apparent during observational gait analysis. Biomechanical gait characteristics such as spatiotemporal features (i.e., interlimb symmetry), kinematics (i.e., joint motion relationships within and between limbs), and kinetics (i.e., forces required for stance and forward progression) can be quantified in an appropriately instrumented gait lab. This section describes the biomechanical features of

poststroke gait because biomechanical analysis is an essential element for understanding the mechanisms of walking recovery and responsiveness to specific walking rehabilitation interventions.

Changes in Temporal Gait Characteristics

Although asymmetry is a dominant characteristic of hemiparetic walking, the heterogeneity of the hemiparetic population has made it difficult to develop an integrative understanding of how spatiotemporal asymmetry is related to the underlying impairments. There are a multitude of variables that have been used to quantify spatiotemporal asymmetry, and inconsistent reporting of important variables has limited our understanding of the basis of asymmetry. For example, temporal asymmetry is often reported, whereas spatial asymmetry is not (or vice versa), with few studies reporting both variables in detail. Additionally, the general speed dependence of spatiotemporal characteristics must also be considered when interpreting hemiparetic spatiotemporal data (9) because most persons with hemiparesis walk slowly with an altered stride length and/or cadence. Despite all of the complications that have limited a more detailed understanding of hemiparetic spatiotemporal asymmetry, some general relationships are beginning to emerge.

For example, walking speed is determined by a combination of cadence and stride length (distance between consecutive foot placements of the same foot in the direction of progression). Although both are reduced in hemiparetic walking when compared to nonimpaired persons walking at their self-selected speed (10), neither appears to be consistently different when compared to nonimpaired persons walking at the same speed (9). This is likely explained by the mechanical constraints of walking and the required symmetry imposed by the definition of stride length and cadence. Hemiparetic subjects differ most dramatically from nonimpaired individuals walking at the same speed in the spatiotemporal measures that indicate interlimb asymmetry.

There are two main temporal asymmetries in hemiparetic walking. First, it has been consistently reported that persons with hemiparesis spend significantly more time in stance phase on the nonparetic leg (non-PP) than on the PP (10,11). Note that this also requires that they spend significantly more time in swing phase on the PP than on the non-PP. Second, it has been somewhat less consistently reported that the double support phase preceding PP foot-off (which we will define as paretic preswing) is longer in duration than is the initial PP double support phase (which we will define as paretic weight acceptance). Olney et al. found an average increase in duration for 32 persons (25% vs. 20% of the gait cycle) (12). Similarly, de Quervain et al. also found that the paretic pre-swing phase was prolonged for 18 persons (13). However, Goldie et al. reported no significant differences in the duration of the two double support phases in a group of 42 persons (9).

The main spatial asymmetry of hemiparetic walking is characterized by differences in the paretic and nonparetic step length (i.e., paretic step length is the distance in the direction of progression that the paretic foot is placed in front of the non-PP, and vice versa for nonparetic step length). Although many studies have reported that on average the paretic step length is longer than the nonparetic step length, these studies typically find substantial variability in that some persons with hemiparesis exhibit substantial asymmetry in the opposite direction. Until recently there has been no mechanistic explanation advanced to explain this variability.

In a recent study, Balasubramanian et al. found that step length asymmetry was related to propulsive force generation during hemiparetic walking (14). Propulsive force generation was quantified from the forward directed component of the horizontal ground reaction forces (GRFs) by the time integral of the propulsive GRF (positive area under the GRF versus time curve), because it is that impulse that acts to accelerate the body forward. Paretic propulsion in particular is defined as the proportion of the total propulsive impulse produced by the PP (i.e., impulse of PP divided by sum of the impulses of the paretic and non-PPs). Paretic step ratio is used to quantify step-length asymmetry and is similarly defined as step length of the PP divided by sum of the step lengths of the PPs and non-PPs. Specifically, these authors found that the subjects who generated the least paretic propulsion walked with relatively longer paretic steps, suggesting that increased propulsion by the non-PP may be one mechanism contributing to production of a longer paretic step (Figure 24.1). Further, those with more severe hemiparesis (those dependent on abnormal flexor and extensor synergies) walk with the longest paretic steps

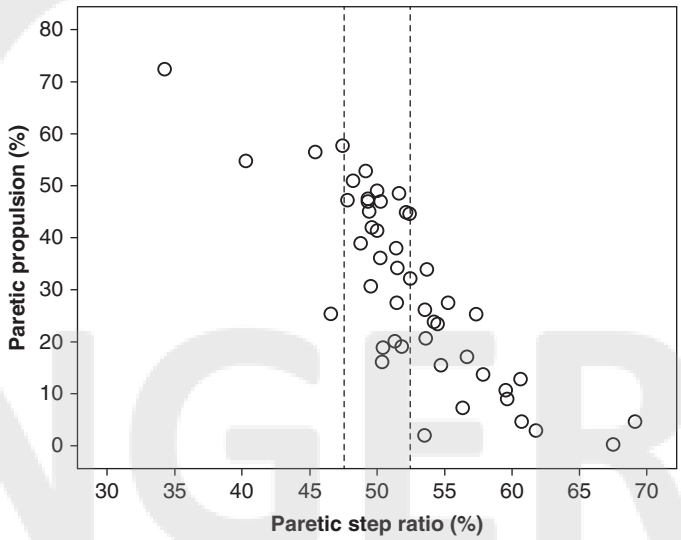

FIGURE 24.1 There is a strong relationship between step length asymmetry and paretic propulsion ($r = –0.83$, $P = .001$). Subjects with a longer paretic step generate less propulsion with their PP.

Source: Modified from Ref. (14). Balasubramanian CK, Bowden MG, Neptune RR, et al. Relationship between step length asymmetry and walking performance in subjects with chronic hemiparesis. *Arch Phys Med Rehabil*. 2007;88:43–49.

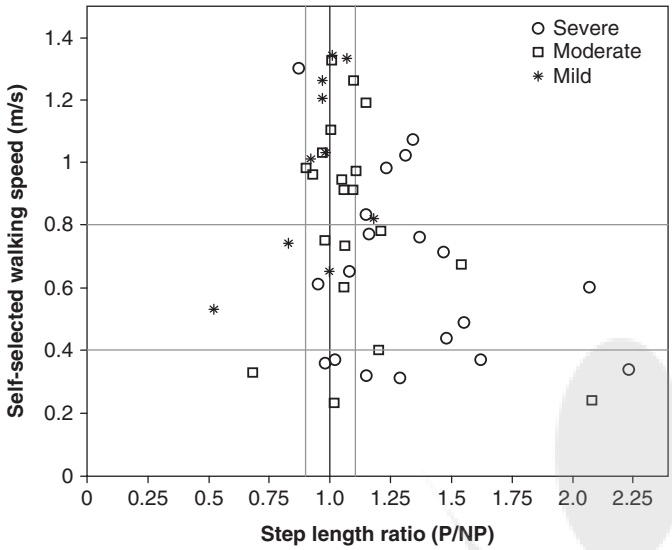

FIGURE 24.2 Relationship between step length asymmetry, walking speed, and hemiparetic severity. The solid black vertical line indicates symmetric steps (SLR), vertical gray lines indicate the SLR subdivisions at SLR = 0.9 and SLR = 1.1. Horizontal lines indicate subdivisions of walking speeds (< 0.4 m/s, house hold walkers; 0.4–0.8 m/s, limited community walkers; > 0.8 m/s, community walkers). Note that subjects with different SLR walk at all levels of walking speeds, yet the majority of those with severe hemiparesis walk asymmetrically at SLR greater than 1.1.

Source: From Ref. (14). Balasubramanian CK, Bowden MG, Neptune RR, et al. Relationship between step length asymmetry and walking performance in subjects with chronic hemiparesis. *Arch Phys Med Rehabil.* 2007;88:43–49.

relative to nonparetic (Figure 24.2). However, these results indicated that asymmetrical step lengths do not necessarily limit the self-selected walking speed (i.e., some subjects with longer paretic steps walk faster), likely because there is compensatory generation of propulsion by the non-PP.

Changes in Kinematic Parameters

The kinematics of hemiparetic walking are altered in both legs relative to healthy walking, with the changes being necessarily consistent with the slower speed, slower cadence, and greater asymmetry of hemiparetic walking. Paretic hip motion becomes more abnormal during preswing as self-selected walking speed declines (13). De Quervain et al. found that of 12 subjects studied after stroke, seven with severe hemiparesis did not begin hip flexion until toe-off, five more did not begin hip flexion until the last third of preswing, and in the subjects with moderate hemiparesis, beginning hip flexion occurred at the midpoint of preswing (13). In contrast, the timing of nonparetic hip flexion was normal in even the slowest walkers. Ankle kinematics may also be important for the performance of paretic preswing because peak plantarflexion is less than in normal walking, even when the ankle is in a more plantarflexed (i.e., equinus) position throughout much of stance (13). Nine of twelve subjects with severe hemiparesis were found to have little or no plantarflexion in preswing (13).

Two studies performed detailed analyses in persons very early in the recovery phase (13,15). Using the kinematic data, both studies classified subgroups of hemiparetic subjects with similar characteristics. Based on visual identification of common patterns of knee and ankle motion coupling, De Quervain et al. classified 18 subjects into four groups (13). Mulroy et al. used a nonhierarchical cluster analysis based on spatiotemporal characteristics and peak sagittal plane joint angles for each gait cycle phase and classified 47 subjects into four groups (15).

Subjects with slow walking speeds (i.e., severe hemiparesis) demonstrated more variable kinematics; however, similar kinematic patterns are described in the two studies. The "extension thrust" pattern described by De Quervain et al. was very similar to the "extended" pattern described by Mulroy et al. with increased ankle plantarflexion and knee hyperextension throughout stance, inadequate ankle dorsiflexion in preswing, and inadequate knee flexion in swing. Similarly, the "buckling-knee" pattern described by De Quervain et al. was similar to the "flexed" pattern described by Mulroy et al. with greatly increased ankle dorsiflexion and knee flexion throughout stance, decreased thigh extension in preswing, and decreased ankle dorsiflexion in swing. De Quervain et al. also described a "stiff-knee" pattern in which knee flexion remained constant throughout the stance at an angle of 20° to 30° of flexion in combination with decreased ankle dorsiflexion. Mulroy et al. did not identify any subjects who exhibited a similar "stiff-knee" pattern in the acute poststroke phase. Neither study identified a group of subjects with a fixed equinus deformity at this early stage of recovery, although others have reported it to be a major impairment during the later phases of recovery (16).

The kinematics of subjects who exhibit moderate to fast walking speeds (i.e., moderate to mild severity) tend to be more similar to those of nondisabled walkers, although some who are classified as the "extended" or "flexed" groups by Mulroy et al. are able to walk at these higher speeds. Mulroy et al. classified subjects into a "moderate" and "fast" group within this range, with the main difference being increased knee flexion in stance and decreased thigh extension and plantarflexion in preswing for the "moderate" group as compared to the "fast" group. De Quervain et al. appear to have combined these two groups into a single group, with intermediate characteristics.

The kinematics of the non-PP differ from the normal in a much more consistent fashion than did those of the PP. Hip angles seem generally consistent with nondisabled walking at slower speeds with a shorter stride (13,17). Those walking slowly tended to show the biggest differences at the ankle, where dorsiflexion in late stance is increased and the ankle plantarflexion in preswing is decreased or absent.

Changes in Kinetic Parameters

Generally, the GRFs and joint kinetics in hemiparetic walking are infrequently reported. This is beginning to change as

instrumented treadmills become more common and available for stroke research. An instrumented treadmill provides exceptional benefits for understanding of hemiparetic walking, such as the ability to measure bilateral kinesiological information for a large number of consecutive cycles in order to quantify both the step-to-step variability and the steady-state walking pattern. Supporting the use of instrumented treadmills to study hemiparetic walking, a large study (n = 56 persons with hemiparesis), compared overground and treadmill walking and concluded that treadmill walking was a valid method for determining poststroke motor control deficits and walking impairments (18). Kautz et al. (18) demonstrated that persons with hemiparesis do not demonstrate immediate improvements in symmetry (neither temporal nor spatial) when they walk on a treadmill without support (either a hand rail to hold or body weight support). Instead, treadmill walking increased step length asymmetry, which reflected a similar asymmetry seen when the same persons were asked to walk as fast as possible overground. This was interpreted as treadmill walking providing a challenge and exacerbating the hemiparetic participant's existing motor control deficit. The differences observed between treadmill and overground walking, primarily were manifest as differences in spatiotemporal measures (and the associated kinematics that accompany slower walking speed and shorter strides), and not changes in key kinematic and EMG measures that reflect motor control deficits.

Vertical forces have been investigated predominantly to determine symmetry of weight bearing. Three different patterns of vertical GRF are typically observed in the PP: double-peaked with early and late peaks (similar to normal), one single peak in midstance, and a plateau with no discernable peak (19). Kim and Eng investigated 28 hemiparetic subjects of varying ambulatory ability and found that all but three had reduced vertical GRFs in the PP and that symmetric weight distribution between the legs was related to increased temporal symmetry but not spatial symmetry during walking (20). Raja et al. (investigated PP loading in 44 subjects and found that the magnitude (average vertical force) was reduced and the duration (time to load the leg to 50% of body weight) was increased compared with the non-PP and nondisabled controls walking at matched speeds (21). Additionally, they found that both loading and unloading of the PP was significantly correlated with average leg angle, whereas the non-PP significantly correlated with average knee angle. Also, abnormalities in PP loading increased with increased lateral placement of the paretic foot and slower walking speed.

Bowden et al. used the propulsion force as a performance measure to quantify the contribution of the PP to hemiparetic walking (22). Lacking such a performance measure has been a significant barrier to understanding PP motor performance during walking. Measures have typically focused on bilateral gait-related outcomes such as walking speed, over-ground ambulatory capacity, endurance, and balance. The biomechanical and mechanistic contributions of the PP to such measures are not unique. For example, the same gait speed can be achieved with many levels of coordination of the PP if the non-PP provides different levels of compensatory output. Previously, estimates based on mechanical work calculations had suggested that the PP does 30% to 40% of the total mechanical work over the gait cycle, regardless of hemiparetic severity (17). However, these work estimates could be flawed because they may be dominated by the support of body weight and not a unique contribution of each leg to forward propulsion, this being a critical component of walking performance.

The purpose of the Bowden et al. study was to establish a quantifiable link between hemiparetic severity and PP contribution to propulsion during walking using a measure based on the anterior-posterior (A-P) GRF (22). In particular, the measure defined the proportion of the summed propulsion from both legs generated by the PP. Total body forward propulsion by a leg is calculated by integrating over time (e.g., stance) the forward propulsion produced by that leg. PP is the ratio (in percent) of the total body forward propulsion produced by the PP to the summed forward propulsion by both legs. Forty-seven participants with chronic hemiparesis walked at self-selected speeds. Spatiotemporal parameters and GRFs were collected. A-P GRF measures were correlated with both walking speed and hemiparetic severity (Figure 24.3). The percentage of propulsion generated by the PP was found to be 16%, 36%, and 49% for those with severe, moderate, and mild hemiparesis (as assessed by Brunnstrom stages (23), respectively (Figure 24.4). Thus, PP provided a quantitative measure of the coordinated output of the PP that indicates that the motor performance of the PP can be assessed independently and corresponds to the severity of hemiparesis.

Subsequently, additional studies successfully used propulsion based measures to explain step length asymmetry (14) and the consequences of abnormal electromyographic (EMG) timing (24) to assess the contribution of the PP to hemiparetic walking. Forward body propulsion by a leg at any instant is defined as the force that acts on the body to accelerate it forward (represented by the red vector at the hip in Figure 24.5A), which results from the anteriorly directed, forward GRF (red vector parallel to the ground in Figure 24.5A) acting on the leg at that instant.

PP is sensitive to differences in motor control not captured by multi-construct measures such as gait speed, and therefore it may be an effective tool for distinguishing functional compensation by the non-PP from physiological restitution of PP performance. Quantifying forward propulsion provides great insight into overall PP performance because it measures both the active generation of propulsive forces by muscles (e.g., plantarflexors) and the indirect contribution of other muscle activity (e.g., hip and knee flexors) through their influence on walking mechanics. For example, in terminal stance, or preswing, of normal walking, the heel rises and the forefoot acts as a "rocker" that allows body forward progression (Figure 24.5A). An inverted pendulum representation of walking illustrates this contribution to propulsion because the resultant GRF acts along the axis of the leg (blue vector), which results in an anteriorly directed component

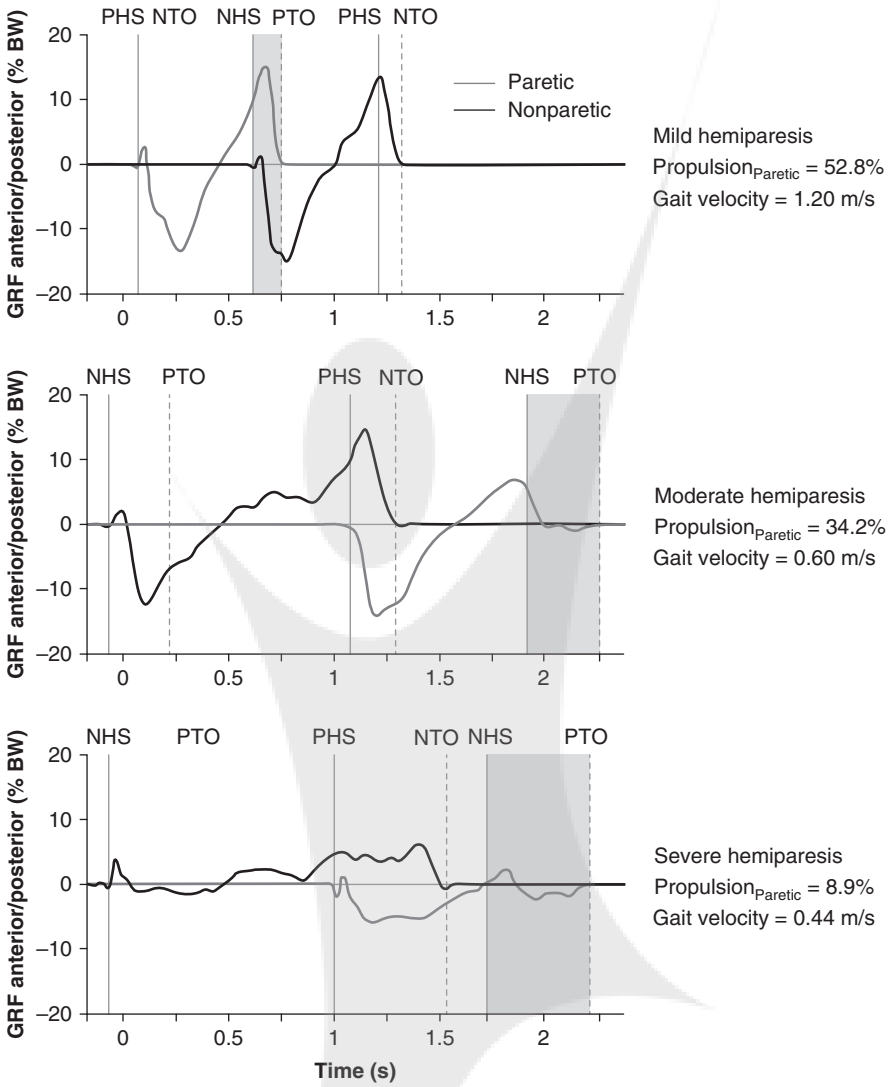

FIGURE 24.3 A-P GRFs for three subjects of differing hemiparetic severity. Positive values represent propulsion, and the positive area under the curve is the propulsive impulse. Increased hemiparetic severity was associated with decreased PP and decreases in self-selected walking speed.

Abbreviations: NHS, nonparetic heel strike; NTO, nonparetic toe off; PHS, paretic heel strike; PTO, paretic toe off.

(red vector parallel to the ground) of a particular magnitude in direct relation to those walking mechanics. Thus, reduced propulsion will occur as a result of walking mechanics per se should early initiation of leg flexion prevent the foot from moving sufficiently posteriorly relative to the pelvis (i.e., should the hip not extend sufficiently; Figure 24.5B).

As would be expected during slow hemiparetic walking, joint moments and powers are greatly reduced when compared to nondisabled subjects walking at their self-selected speed. However, the differences are much reduced when compared with walking at a matched speed. In fact, it is remarkable the extent to which the PP moment and power profiles are similar in pattern but reduced in amplitude in comparison to the non-PPs, which are mostly similar to those of matched speed control subjects (17). Thus, the main power generation bursts in hemiparetic walking are the same as that in nondisabled walking. There are the power generation bursts associated with the ankle plantarflexor moment in preswing (commonly referred to as A2, as by Olney et al.) (17), the hip extension moment during initial double support (H1), and the hip flexion moment during preswing (H3). The A2 positive power burst associated with the ankle plantarflexor moment in preswing is usually greatly reduced on the paretic side. H3 has also been found to be reduced in some subjects, especially those who walk most slowly, although it has been hypothesized for

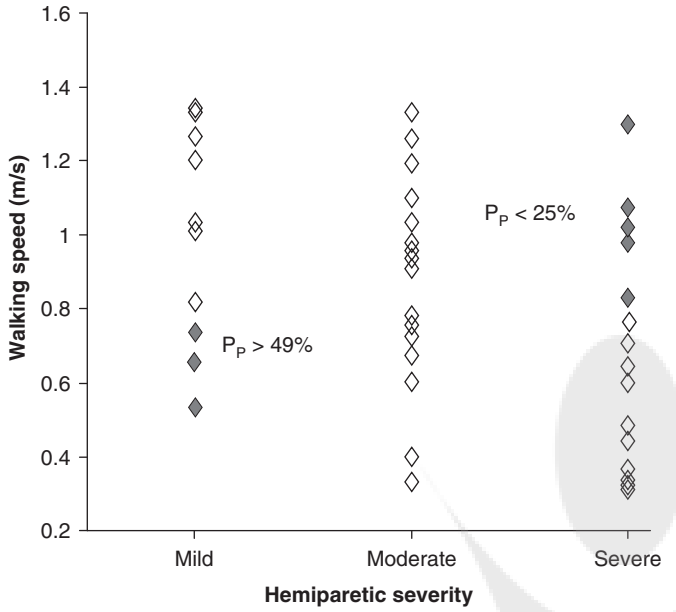

FIGURE 24.4 Individual walking speed data show that there is substantial variability in the weak relationship between walking speed and severity. Note, however, that PP helps explain much of this variation, as the five participants with severe hemiparesis who achieve faster walking speeds (> 0.8 m/s) all demonstrate substantial decreases in PP, whereas the three participants with mild hemiparesis who walked > 0.8 m/s have normal PP (> 49%).

FIGURE 24.5 Illustration of the potential contribution of mechanics to the propulsive GRF for two leg configurations in preswing. Reduced hip extension would result in decreased contribution to forward propulsion from walking mechanics.

some subjects that H3 compensates for the absence of ankle plantarflexor power.

Ankle joint plantarflexor power (A2) was barely evident in the PP in a group of 10 household walkers (17). In addition, when ankle moments during gait were compared with maximum isometric moments, it was suggested that the walking speed of 10 of 17 hemiparetic subjects was limited by plantarflexor weakness (although the four fastest walkers in that group appeared to compensate by increasing hip flexor moment) (25). Ankle moments are also substantially reduced in hemiparetic persons in comparison to slow walking controls, with household walkers having reduced moments compared to limited community walkers (17). In contrast to the PP, the non-PP A2 power generation is equal to or greater than speed matched control subjects, as the A2 power bursts supply about half of the positive work generated by the joint moments (26).

Increased pre-swing hip flexor moments and powers would appear to be able to compensate for plantarflexor weakness and produce faster walking speeds in some faster walkers (27). Hip flexor moments and powers seem to be reduced for slow walkers and increased for fast walkers with respect to healthy controls (11,17). Because hip flexion abnormalities during preswing differentiated the functional walking groups, De Quervain et al. concluded that "insufficient power and inappropriate initiation of flexion of the hip must be assumed to be the cause, as no activity was noted in the extensor muscles" (13). Although the H3 burst may be greater in the non-PP in some subjects, this nonparetic burst does not seem to be used to produce substantial amounts of compensatory positive work as does the nonparetic A2 burst.

The other potential mechanism for increased positive power generation is the hip extensor burst in initial double support (H1). Although H1 has a positive relationship with speed across different subjects (17) and a positive relationship with change in speed after rehabilitation (26), it produces less overall work than the other two bursts. Interestingly, the non-PP H1 appears to produce some compensation as it is increased in slow walking subjects (17).

There is also an important nonsagittal plane power burst at the hip that is seen in persons with hemiparesis; a study found the hip abductor moment is prolonged in hemiparetic walking in more than half of the subjects (20). Because it is seen most often in the faster walking subjects, Kim and Eng suggest that it is a compensatory mechanism for poor dorsiflexion and knee flexion during swing (20). This finding challenges the notion that treatment approaches should be directed toward restoring "normal" kinematic and kinetic patterns of walking if the goal is to achieve optimal functional performance rather than an aesthetic one.

Thus, kinetic measures such as GRFs and joint moments can provide much insight into the impaired mechanics of walking after stroke. Propulsion is a crucial task during

walking, and new biomechanical measures based on the anteriorly directed GRF provide a measure to quantify the contribution of the PP to walking and offer great potential for distinguishing compensation from recovery in the PP performance. Furthermore, the ankle plantarflexors during push off, the hip flexors during pull off, and the hip extensors during weight acceptance have been identified as the primary sources of power generation during normal and hemiparetic walking, with ankle plantarflexor power generation being particularly impaired in hemiparetic walking.

EARLY POSTSTROKE PATTERNS OF RECOVERY

Immediately following stroke, the most common feature of motor impairment is either paresis or paralysis, partial reduction or complete loss of the ability to generate force in the muscles of the extremities contralateral to the stroke (28). At this time point after stroke, the primary contributors to contralateral paresis are disruption of the motor neural pathways leading to reduced motor recruitment (29) and disuse atrophy (30). Consequently, in the early poststroke phase the characteristic asymmetrical gait results primarily from inadequate muscle force generation (31).

Abnormal Motor Unit Recruitment and Muscle Weakness

Paresis in the lower extremity can impair both the ability to advance the limb for swing and to support body weight during stance (6,11,20). Support of body weight can be compromised by inadequate activation of the ankle plantar flexors, knee extensors, or hip extensors (32). Paresis of the ankle dorsiflexors may result in poor foot clearance in swing (31). If the hip flexors are also weak, inability to compensate by lifting the limb results in a toe drag and limited step length.

Alterations in EMG timing and intensity during walking result from both reduced activation and from compensations for loss of force (15,31). Few studies have described muscle activity patterns in the early poststroke phase (13,15,31,33). The impact of reduced muscle activation and resultant weakness on the characteristic patterns of walking after stroke was identified in 47 individuals at admission to acute rehabilitation and again at 6 months after stroke (15). Four distinct gait patterns were discerned. Those subjects in the two groups with greater walking impairment walked at just 10% to 11% of normal velocity, and lower-extremity muscle strength ranged from 17% to 36% of the normal with weakness most severe at the ankle. In both of the slower groups, marked paresis of the ankle plantar flexor muscles removed the normal restraint of the tibia in stance. The pattern of walking compensation adopted initially was reflected in the knee position in mid-stance. The relative strength of the proximal muscles in the PP was the factor that determined which compensatory pattern was adopted. In those individuals with greater extensor muscle strength at the knee than at the hip, the knee collapsed into flexion with the demand shifted to the quadriceps (flexed group). In contrast, subjects with stronger hip extensors and weaker quadriceps thrust into hyperextension at the knee (extended group) relying on passive stability at the knee and increased activation of the hip extensors for stance control and progression of body weight.

In the two faster groups (fast and moderate), walking velocity was 44% and 21% of normal, respectively (15). Ankle plantar flexion strength was less than normal (53% and 38% of normal), but not as markedly reduced as in the two slower groups (flexed and extended). This greater residual plantar flexion strength resulted in only mildly excessive knee flexion in stance for the moderate group and normal extension in the group with the least walking impairment (fast). Moreover, activation intensity was *greater than normal* at admission for the two faster groups in vastus intermedius and gluteus maximus, indicating increased proximal activity in stance as a substitution for reduced distal control (Table 24.1). The significant impact of reduced activation of the calf muscles on walking function in the acute poststroke phase was confirmed by Lamontagne and colleagues, who documented that gastrocnemius EMG intensity during gait explained a full 52% of the variance in walking speed in the early poststroke phase (31).

The swing-phase movement pattern in the acute phase was characterized by the amount of dorsiflexion achieved in mid-swing (15). The decreased activation of anterior tibialis in both of the two slower groups produced inadequate dorsiflexion in mid-swing (Table 24.1). Although volitional ankle dorsiflexion strength was also less than normal in the two faster groups, the muscle response was adequate to achieve at least a neutral ankle in swing.

In addition to reduced EMG intensity, alterations in the timing of muscle activity have been identified during walking (13,15,33). In our study of walking recovery (15), at the early poststroke assessment, onsets of muscle activity were delayed in the two groups with the slowest velocities for all hip and knee extensors that have a typical onset in mid- or terminal swing (gluteus maximus, gluteus medius, semimembranosus, biceps femoris, and vastus intermedius). This finding is indicative of a reduced need for limb deceleration in swing because of the subjects' very slow velocities. In contrast, EMG onsets for the faster subjects were premature in vastus intermedius and adductor longus, indicating that these subjects had the capacity to activate the muscles, but the decreased muscle force output required an early onset to achieve the desired swing-phase motions. Muscle activity was prolonged with cessations in mid-stance for the hamstrings and in terminal stance for gluteus maximus and vastus intermedius for subjects in all groups, indicating the need for increased proximal stability in stance to substitute for the reduced plantar flexor activity distally. Rectus femoris activity was prolonged through swing for both fast and slow velocity groups, which may indicate either spasticity or the increased need for hip flexor force in swing. Because of its insertion below the knee, however, prolonged rectus femoris activity results in inhibition of the necessary knee flexion required for foot clearance and limb advancement.

TABLE 24.1 Mean EMG Intensity During Walking at Admission to Rehabilitation and Six Months After Stroke

		EMG INTENSITY (% MAX MMT)			
		STROKE—ADMISSION		STROKE—SIX MONTHS	
	ABLE-BODIED	SLOW	FAST	SLOW	FAST
SMEMB	20	12 ± 11	18 ± 8	17 ± 10	21 ± 9
BF long	13	11 ± 9	13 ± 10	16 ± 14	17 ± 8
GMAX	18	17 ± 9	23 ± 9	21 ± 11	20 ± 8
VI	13	15 ± 9	29 ± 15	24 ± 16[a]	29 ± 17[a]
SOL	35	17 ± 13	30 ± 20	27 ± 19[a,b]	36 ± 15[a,b]
PB	20	5 ± 12	10 ± 8	7 ± 9[a,b]	18 ± 17[a,b]
ADL	14	9 ± 8	12 ± 7	15 ± 7[a,b]	26 ± 11[a,b]
RF	15	8 ± 7	12 ± 12	14 ± 10[b]	17 ± 11[b]
AT	25	10 ± 6	26 ± 18	20 ± 11[a]	28 ± 16[a]

[a]Significantly greater in fast than in slow.
[b]Significantly greater at six months than at admission.

Abbreviations: ADL, adductor longus; AT, anterior tibialis; BF long, long head of biceps femoris; GMAX, gluteus maximus; PB, peroneus brevis; RF, rectus femoris; SMEMB, semimembranosus; SOL, soleus; VI, vastus intermedius.

These results are consistent with those of den Otter and colleagues, who identified premature onset of gastrocnemius and prolonged activity through stance in biceps femoris and rectus femoris (33,34). As they utilized surface electrodes to record EMG activity, the rectus femoris recording likely also reflects activity from the underlying vasti.

CHRONIC POSTSTROKE PATTERNS OF RECOVERY

As time following stroke progresses, muscle strength, activation, and walking ability begin to improve (15,35,36). Incomplete recovery and development of additional impairments, however, can contribute to continued gait dysfunction (11,13,20,37). Spasticity or contracture of the ankle plantar flexors can cause excessive plantar flexion and toe drag in swing and impede forward progression during stance (31,37). Knee extensor or hamstring spasticity can inhibit limb advancement in swing (38). In the chronic poststroke phase, disuse muscular atrophy compounds the initial neurologic injury, and consequently, muscle weakness remains prevalent despite the functional recovery during the acute phase (39). The relative contributions of reduced activation and atrophy to poststroke muscle weakness vary between individuals and muscle groups. A recent study of contributors to ankle plantar flexion weakness after stroke determined that reduction in voluntary activation (measured by supramaximal interpolated twitch) was the primary factor related to maximal torque production whereas muscle atrophy and antagonist coactivation had less influence on muscle strength (40). In contrast, both activation and atrophy were identified as significant causes of reduced muscle force production for the quadriceps and hamstrings in the PP (41). Decreases in activity level contribute to reduced cardiovascular fitness and endurance across the chronic phase after stroke (42) (see Chapter 27 for more information).

Abnormal Motor Unit Recruitment

In the study of walking recovery at six months after stroke, consistent with improvement in walking speed, lower-extremity muscles, particularly distal ones, demonstrated increased activation intensity during walking compared to the early poststroke phase (15). Improved walking speed was associated most strongly with increased activation in soleus and adductor longus. Anterior tibialis intensity increased at the six-month assessment for subjects in the slow groups, whereas it remained unchanged for those in the faster groups at levels similar to those exhibited by able-bodied subjects. Subjects in the two faster groups exhibited a greater-than-normal intensity in both vastus intermedius and adductor longus in this later assessment. Those in the slow groups had greater than normal intensity only in vastus intermedius (Table 24.1). Thus, the increase in soleus activation intensity seen for all walking speed groups represents partial recovery of initially impaired plantar flexor function, whereas increase in adductor longus activation, primarily in the faster walkers, represents compensation to increase hip flexor power generation to substitute for the remaining residual reduction in ankle plantar flexor power generation.

Timing of muscle activity also improves with recovery but remains altered compared to normal phasing for most individuals (15,33,34,43). The hip and knee extensors, which initially displayed a delayed onset late in terminal swing, began earlier in swing as recovery progressed at six months. Onsets were premature compared to normal timing for semimembranosus, vastus intermedius, and soleus. These premature onsets can interfere with the flexion necessary

for limb advancement in swing. The swing-phase muscles—adductor longus, rectus femoris, and anterior tibialis—also displayed earlier onsets at six months after stroke, resulting in premature activation.

The swing-phase movement pattern at six months was more influenced by the magnitude of knee flexion than ankle dorsiflexion, consistent with the improved anterior tibialis activity exhibited by subjects with slower initial walking speed (15). Those subjects who retained the extended pattern developed a stiff-knee gait with severely decreased knee flexion in swing. All four subject groups (e.g., fast, moderate; flexed, extended) demonstrated excessively prolonged activity of rectus femoris throughout swing, which would inhibit knee flexion. Only the intensity of adductor longus activity (a hip flexor in gait) differentiated those who displayed markedly reduced knee flexion in swing. It appears that individuals with sufficient activity in adductor longus were able to overcome the knee extension force from excessive activity of rectus femoris by generating a strong hip flexion force from adductor longus, resulting in thigh flexion and secondary knee flexion. Thus, restoration of the walking function in the sub-acute poststroke phase is accomplished both by restitution of distal muscle activation and greater than normal proximal muscle activity (see Chapter 19 for a similar discussion).

Muscle Weakness

Although muscle strength improves from the acute to the chronic poststroke phase (after six months), for most individuals, strength remains less than normal in the muscles of the lower extremity contralateral to the side of the stroke (15,35,44). Ankle plantar flexion and dorsiflexion weakness still dominate in the slowest individuals. Neckel et al. documented greater than normal knee extension strength in a group of individuals at least one year after stroke (44). They postulated that knee extensor muscles may have been strengthened from increased activity during walking as part of a compensatory strategy. This is consistent with the finding of a greater-than-normal intensity of vastus intermedius activity (15).

Musculoskeletal models of walking have identified the function of muscle activity in normal walking and predicted the impact of paresis in individual muscles for subjects with pathology (45,46). The results of these studies can increase our understanding of the consequences of poststroke muscle weakness. In walking at self-selected speed by able-bodied adults, a model of walking demonstrated that force production by plantar flexors in terminal stance and preswing is critical to forward progression of the trunk, swing initiation, and power generation (46). This is consistent with the robust finding of reduced ankle joint power that is strongly related to walking velocity after stroke (12,25,47).

Compensatory strategies to substitute for distal muscle weakness have been identified in the proximal musculature of the PP as well as in muscles of the nonparetic limb (32,45,48,49). Increased distal muscle coactivation in the non-PP during the double-limb support phases was documented as a compensatory mechanism in subjects with more severe motor impairments (31,49). Musculoskeletal modeling demonstrated that an individual with severe plantar flexion weakness and the flexed-knee poststroke walking pattern would exhibit increased contributions from the paretic hip and knee extensor muscles in single-limb stance as an alternate source of stability confirming the experimental EMG evidence (32,45). Later in the stance phase, the model also identified that increased hip flexor activity can compensate for plantarflexor weakness and produce faster walking speeds (32) (see Chapter 19 for more information on the relationship between proximal and distal power strategies during walking).

Abnormal Muscle Synergies

Clinical observations of volitional movement patterns in both the upper and lower extremities following stroke have been described as abnormal muscle synergies that are stereotypical combinations of secondary, unwanted motions that accompany the primary desired motion (23,28,31). During attempts of isolated, volitional joint movement, lower-extremity abnormal synergistic movement combinations have been described as massed extension of the entire limb with adduction and internal rotation and massed flexion with abduction and external rotation. Measurement of secondary torques during isolated, isometric contractions in subjects with stroke, however, did not confirm the patterns observed during the attempted dynamic movements (44). Individuals who have impaired selective movement control can utilize these mass extension and flexion patterns of the lower extremity for stance and limb advancement during walking. The extent of dependence on the abnormal synergy patterns and the strength of the patterns during walking vary greatly among individuals such that the subjects that depend on abnormal movement patterns for walking have greater functional impairment (50). The mass extension pattern utilized in the stance phase does not have the normal graduated increases in muscle activation necessary for controlled knee flexion in initial double-limb support or ankle dorsiflexion in single-limb stance. The flexion pattern for swing limb advancement can limit stride length when knee extension in terminal swing is incomplete with continued hip and knee flexion. Excessive, premature ankle plantar flexion and hip extension in late swing often accompany attempted knee extension, which also impedes limb advancement and reduces stride length. Abnormally increased heteronymous facilitation has been implicated in the extensor synergy in persons after stroke with early activation of soleus identified during periods of typical quadriceps activity (51). This premature facilitation of soleus during quadriceps activation is consistent with the high intensity plantar flexor activity seen in loading response and premature plantar flexion in terminal swing in persons who exhibit an extensor synergy during walking. Abnormal activation of soleus during knee extension efforts was inversely related to walking speed.

TABLE 24.2 Duration of EMG Activity Following Rapid Stretching at Admission to Rehabilitation and Six Months After Stroke

	ADMISSION					SIX MONTHS				
	% < 1 SEC	% 1–3 SEC	% > 3 SEC	MEAN SEC	MEDIAN SEC	% < 1 SEC	% 1–3 SEC	% > 3 SEC	MEAN SEC	MEDIAN SEC
Gluteus maximus	90	6	4	0.44	0.12	90	8	2	0.33	0.10
Semimemb	45	15	40	2.03	1.14	32	19	49	2.49	2.96
Biceps femoris	63	10	27	1.5	0.32	59	8	33	1.65	0.26
Adductor longus	11	6	83	3.77	4.24	8	6	86	3.80	4.20
Rectus femoris	65	14	21	1.25	0.36	53	10	37	1.94	0.84
Vastus intermedius	76	10	14	0.98	0.24	74	13	13	0.97	0.38
Soleus	60	13	27	1.42	0.16	79	3	18	1.01	0.10
Anterior tibialis	94	2	4	0.28	0.06	89	8	3	0.35	0.04

Reliance on muscle synergies during walking can be quantified by analyzing EMG activity to determine the number of independent patterns of muscle coexcitation. Using factor analysis techniques to analyze the EMGs recorded from healthy individuals, Clark et al. (52) found that four independently timed patterns of muscle coexcitation accounted for muscle activity in eight muscles over a wide range of walking speeds. They hypothesized that the health of the poststroke locomotor control system depends on the number of coexcitation patterns needed to account for the EMG signals and found that lower-extremity muscle activity in most persons with poststroke paresis could be accounted for with only two or three independent patterns compared to that in nondisabled individuals where four independent patterns were needed. This reduced independence of muscle excitation was associated with poorer walking performance, including decreases in speed, step length symmetry, propulsive force symmetry and speed adaptability (fastest minus self-selected speed). Thus, factor analysis techniques provide compelling evidence for locomotor control after stroke ranging from massed flexion and extension patterns to more selective control of individual muscle groups. The number of independent patterns of muscle coexcitation that exists was also found to be a superior predictor of walking performance than the lower-extremity Fugl-Meyer (LEFM) assessment (53).

Spasticity

In his classic descriptive study of recovery after stroke, Twitchell described the timing and pattern of the onset of spasticity (28). He noted that spasticity began between 2 and 20 days after stroke and was most common for the lower extremity in the ankle plantar flexors. Clinical measures of spasticity are related to both the intensity and duration of EMG activity elicited during passive stretching of the muscle (54).

In a study of walking recovery after stroke, the duration of EMG responses to a manual quick stretch was recorded as an indicator of spasticity at an average of 21 days after stroke and again at 6 months after stroke (Table 24.2) (15). A normal EMG response to quick stretch lasts for less than 0.10 seconds. At both time periods adductor longus was the muscle that most frequently exhibited a prolonged response to quick stretch (greater than 3.0 seconds in over 80% of subjects). This excessive stretch sensitivity, however, was not related to increased functional deficits in walking. In fact, greater adductor longus activity during gait was associated with greater (more normal) swing-phase knee flexion despite prolonged activation in rectus femoris. One-third to one-half of subjects exhibited prolonged responses to quick stretch in the hamstrings (semimembranosus and biceps femoris long head), rectus femoris, and soleus. Though less frequent, the impact of severe spasticity in these muscles on walking was greater than that of the adductor longus.

Spasticity of the hamstrings can limit knee extension in terminal swing and inhibit thigh flexion in initial swing with secondary decrease in peak swing knee flexion (38). Rectus femoris spasticity is a common contributor to reduced knee flexion in swing (38), and soleus spasticity can contribute to equinovarus, which can impair forward progression of body weight over the ankle in stance and impact foot clearance in swing (37). Both semimembranosus and rectus femoris demonstrated increased spasticity at the six-month test compared to the earlier evaluation, which corresponded with greater impairment in swing phase knee flexion.

Although anterior tibialis does not often demonstrate increased response to passive stretch, excessive or continuous activity during walking is a common contributor to excessive subtalar joint varus (55). Although spasticity is not a strong determinant of walking function for the majority of individuals following stroke (56,57), for those who do exhibit obstructive spasticity, both surgical interventions and anti-spasticity medication can produce increases in walking speed and reduce gait deviations at both the ankle and knee joints (37,38,58) (see Chapter 29 for more information).

Joint Contractures

After stroke, longstanding weakness in a muscle group or spasticity in the antagonist group can result in increased passive stiffness and joint contractures (31,54,59). In the lower

extremity the ankle plantar flexion contractures are the most common site for restrictions of joint motion, although inversion contractures are also common, and flexion contractures at the knee and hip joints develop occasionally, particularly in individuals with limited standing and walking function (37,55,60). Adequate passive joint mobility is necessary to obtain a stable passive alignment during the stance phase of gait.

Using a mechanical modeling simulation, Kagaya and colleagues (61) confirmed the clinical impression of the lower-extremity postures that produce maximal passive stability during stance, which comprised 5° of dorsiflexion at the ankle, 0° flexion at the knee, and 15° of extension at the hip (61,62). The model predicted significant increases in muscle demand for postures at or greater than 6° of plantar flexion and 20° of flexion at the knee or hip joints. In a subsequent mechanical modeling simulation, hip or knee flexion contractures of no greater than 15° or ankle plantar flexion contractures of less than 0° were required to maintain positive step length and forward movement of the center of gravity (61,63). These theoretical models indicate that, although moderate to severe contractures are destabilizing, mild contractures may be accommodated, and in fact, mild ankle plantar flexion tightness (0°–5° of dorsiflexion) can augment support for weak calf muscles in stance (6,49).

Proprioception

The influence of impaired joint position sense has proved to be more of a "yes/no" threshold rather than a scalar determinant of gait quality (4,5). No significant difference in proprioceptive ability was identified between poor and good hemiparetic walkers (5,20). Proprioception loss in the lower extremity tends to be more severe distally.

Absence or impaired proprioception in the ankle joint can be controlled with an ankle-foot orthosis that limits available motion at the ankle. If lack of proprioception extends to the knee joint, a knee-ankle-foot orthosis (KAFO) may be required to stabilize the knee in stance. If proprioception at the knee is impaired, but not absent, an unlocked KAFO may provide sufficient sensory input, but if joint position sense is absent at the knee, a locked KAFO is usually required for stability in stance. This is important for safety during walking because absent proprioception in the knee is related to the risk of frequent falls (64). The weight of the orthosis and increased energy cost of walking with an extended knee in swing typically result in KAFO use for household or exercise use only. If proprioception loss extends to the hip, potential for functional ambulation is typically limited (see Chapter 36 for more detailed description of indicators for orthotic prescription).

Non-PP Leg Motor Patterns

A recent study (65) analyzed non-PP EMG patterns in a large group of subjects after stroke (n = 60) to identify compensatory patterns. They defined two types of compensations: *expected compensations*—increased activity during regions typically active in walking in healthy persons, presumably to increase the contribution to a muscle's usual biomechanical function—and *novel compensations*—increased activity in regions in which a muscle is typically off or active at a low level that results in either a new biomechanical function being performed or the same function being performed at a different time. Expected compensations included increased activity in hamstrings in early stance and plantarflexors in late stance and novel compensations included plantarflexors in early stance, vastus medialis and rectus femoris in early single leg stance, and hamstrings and rectus femoris in preswing. Most of these compensations were considered likely to contribute to increased propulsion to make up for the decreased propulsion by the PP.

POSTSTROKE WALKING REHABILITATION

Customary walking speed has been identified as the primary indicator of overall functional locomotor ability after stroke (5,20). Moreover, improvements in walking speed categories following rehabilitation have been related to significant improvements in quality of life, confirming the impact that reduced walking speed has on functional mobility (66). Thus, the primary goals of walking rehabilitation programs are to develop walking ability at speeds and distances that are functionally significant for community ambulation (see Chapter 19 for further discussion of walking speed as a global indicator of locomotor ability after stroke).

In addition to gait training, walking rehabilitation programs address the various residual motor impairments identified as significant predictors of walking speed after stroke. Physical contributors to walking deficits after stroke include selective motor control (i.e., synergy stage), muscle strength, balance, and aerobic capacity (20,56,64,67–73). It is beyond the scope of this chapter to address all physical rehabilitation interventions that may contribute to walking recovery. We focus, rather, on the main predictors of walking recovery and best-practice strategies based on current evidence as guides for the clinician in developing effective walking rehabilitation programs for their patients with stroke.

Predictors of Walking Recovery and Responsiveness to Rehabilitation Interventions

Improvement in walking after stroke is accomplished by a combination of natural recovery and rehabilitation intervention (74). Premorbid factors as well as stroke-related variables can impact an individual's ability to respond to intervention. Both older age and greater initial severity of stroke have been found to be predictors of poor outcome following rehabilitation (75,76). This finding may give the erroneous impression that older individuals or those with severe stroke do not make significant or functionally useful gains in rehabilitation. In individuals with more severe involvement, functional improvement occurs more gradually and

the magnitude of improvement is not as large as that seen in subjects with moderate or mild stroke (77). Moreover, the mechanisms underlying functional improvement may differ depending on initial impairment level.

Degree of Neurologic Damage and Multiple Comorbidities

There are numerous covariates associated with motor recovery and responsiveness to therapy such as the pathophysiologic consequences and degree of neurologic damage directly related to the stroke as well as the personal and environmental factors associated with the individual. Cramer (78) discusses the impact that clinical variables such as stroke characteristics (e.g., location, volume, hemorrhagic, or ischemic injury), time after stroke, age, poststroke depression, and other comorbidities have on recovery potential. With advances in imaging techniques such as functional magnetic resonance imaging and diffusion tensor imaging, the relationship between damage to neurologic structures, motor severity, and functional recovery potential are being elucidated (79,80).

In particular, the degree of pyramidal tract damage has been associated with both stroke severity and recovery potential for the upper extremity (81,82). Jayaram and colleagues identified a similar relationship ***for the lower extremity*** and poststroke walking recovery using diffusion tensor imaging to assess the integrity of the corticospinal tract and transcranial magnetic stimulation motor evoked potentials to directly assess functional connectivity from the motor cortex to lower-extremity muscles bilaterally (79). They documented that both increased ipsilateral connectivity and reduced integrity of the tracts on the lesioned side were associated with reduced LEFM scores as well as slower walking speeds. Additionally, case-series evidence for relationships between lower-extremity motor involvement and walking recovery is emerging in adults and children with stroke at birth (62,83). For both upper and lower-extremity function, motor impairment severity measures such as the Fugl-Meyer motor assessment appear to be correlated with the degree of pyramidal tract damage. In other words, lower Fugl-Meyer motor scores indicate more synergistic movement patterns that are associated with a greater degree of pyramidal tract damage and less motor recovery potential. Thus, LEFM score may be a general indicator of both the potential for functional walking recovery and the extent of poststroke brain damage. More importantly, therapeutic strategies for walking recovery that may be most beneficial for individuals with mild to moderate stroke may differ compared to those with more severe stroke (see Chapter 19 for more information on physiological and clinical predictors of recovery after stroke).

Motor Severity

Recovery of walking speed is most strongly linked to the magnitude of initial motor impairment, with less recovery in those individuals with the greatest initial severity (70). The strength of this relationship increases up to the first month after stroke (23,84). Prediction of further recovery after the first two to six months is less clear. The total score from the LEFM has been identified as a moderate predictor of both walking speed and stride length in patients after a stroke (70,85). Walking speed was positively correlated with the Brunnstrom motor stage (measure of selective motor control) in the proximal limb, but not with the motor stages of the ankle or foot (71). The authors concluded that the ability to compensate for poor distal motor control determined the individual's walking speed. More recent literature delineated the limitations of the LEFM for more than just a general indicator of ***current walking speed*** after stroke (53). Complexity of muscle activity synergies during walking was more strongly associated with walking speed than the LEFM, which is based on voluntary isolated movements rather than integrated, multi-joint control of movements and postures involved in walking.

Lower-extremity muscle strength in the paretic limb is strongly correlated with maximum walking speed after stroke (20,56,64,67,68,86). Specific muscle groups that demonstrated the strongest relationship with walking velocity varied greatly between studies depending on the number of muscles investigated, the parameter used to quantify strength (hand dynamometer force, isometric or isokinetic torques), and the method of documenting gait velocity (comfortable or fast speeds, distance walked, with or without assistive devices and orthoses).

Studies that compared multiple muscle groups most frequently identified strength in the hip flexor (27,72,87) and ankle plantar flexor (20,25,68) muscle groups as the strongest predictor of walking speed after stroke, although strength in the knee extensor (72,73) hip extensor (67), and ankle dorsiflexors (64,87–89) muscle groups were also identified as significantly related to gait speed. The dominance of ankle plantar flexion strength in the studies of multiple muscle groups is consistent with the relationship of calf strength and initial severity of the stroke (90). Moreover, the contribution of the hip flexors and ankle plantar flexors to maximizing walking speed has been related to their large bursts of power generation late in the terminal stance and pre-swing phases of the gait cycle (12,17,20,25,27).

Kosak and Reding investigated the effectiveness of gait training using a treadmill with body weight support (TM-BWS) in stroke subjects who required moderate assistance to ambulate prior to training (91). In a posthoc analysis, they found locomotor outcomes varied based on the initial severity of neurologic impairments; training using the TM-BWS was more effective for individuals who required moderate assistance to ambulate initially and presented with combined motor, sensory, and visual impairments. However, it should be noted that this study only investigated stroke patients with severe locomotor impairments and was not a study that compared different locomotor impairment severity levels.

In contrast, Sullivan and colleagues specifically investigated the effect of locomotor severity in chronic stroke (92). Neurologic motor impairment, functional locomotor ability, and locomotor severity were analyzed as potential factors

that might contribute to treatment effectiveness. They demonstrated that initial walking speed was independently correlated to change in overground walking speed as a result of training with TM-BWS. Lower-extremity motor impairment severity as measured by the LEFM score was correlated highly with the magnitude of ***walking speed improvement***.

The mechanisms behind the functional recovery in walking stimulated by the gait training using a TM-BWS after stroke are likely dependent on the individual's initial motor severity (93). The increase in free walking velocity after 6 weeks of training with TM-BWS and strengthening exercises in 15 individuals 6 months to five years after stroke was related more strongly to initial LEFM score (r = 0.65) and isometric ankle plantar flexion torque (r = 0.57) than to initial walking velocity (r = 0.42) (93). This finding indicates that those subjects with more preserved motor function in the paretic limb, in particular distally, have a better capacity for restoration of walking function, and it is also consistent with the finding that relatively fast walking speeds can be achieved after stroke with abnormal kinematic patterns through compensatory strategies (22,94).

Subjects with higher initial LEFM scores (above 25) increased gait speed by improving the terminal stance mechanics of the paretic limb at both the ankle and hip (93). The increase in the plantar flexion power in terminal stance was associated with improved pre-swing hip flexion power, which contributes to increases in both cadence and stride length. In fact, soleus was the only muscle with a significant correlation between increased activation level and increased pre-swing *hip flexion power* (r = 0.54). Increased soleus activation likely augmented hip flexion power by increasing acceleration of the hip into extension in terminal stance (95). Increased hip extension in stance would increase the passive elastic contributions to hip flexor power generation by stretching the soft tissue structures of the anterior hip (96). Most of those individuals with higher LEFM scores also had stronger ankle plantar flexors (more preserved distal function) and responded to the intervention with increased activation intensity of the soleus to accomplish these improved mechanics (increased by 15% of maximum) (93). This represents restitution of the walking function (Figure 24.6).

In contrast, for those subjects with lower initial LEFM scores (and weaker plantar flexion strength), there was no correlation between change in ankle plantar flexion power and improved walking velocity (93,97). Those subjects with low LEFM scores and a few individuals with higher LEFM scores but poor distal function improved paretic limb mechanics by other mechanisms (not related to increased soleus) including improved activity of proximal muscles (gluteus maximus, semimembranosus, and gluteus medius) leading to better knee and hip extension in stance, but no change in ankle plantar flexion power (98). Hip extension power absorption in terminal stance and hip flexion power generation in preswing, however, were related to improved velocity for those with low LEFM scores, indicating that these subjects relied on proximal muscle control of the paretic limb and increased swing phase power of the nonparetic limb.

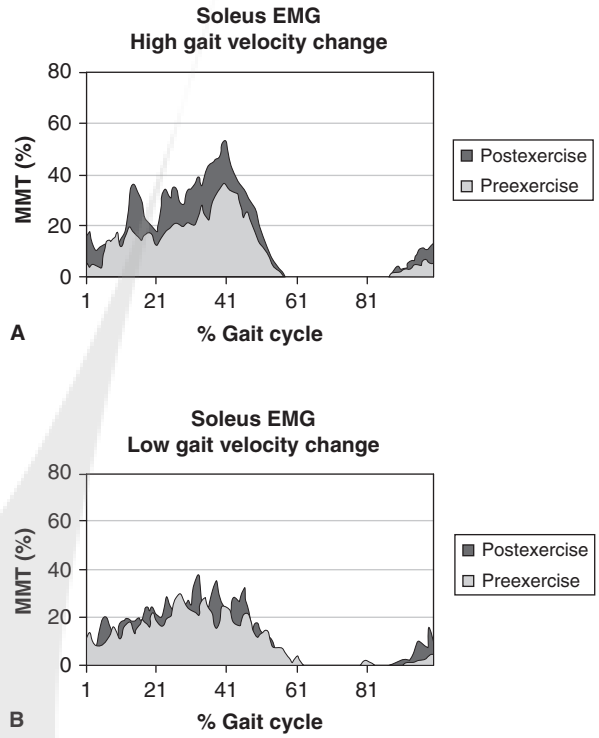

FIGURE 24.6 Change in soleus EMG during walking for subjects who demonstrated high gait velocity (top) and low walk gait velocity (bottom) increases with treadmill training with body-weight support.

This same proximal compensation pattern was documented in subjects without active ankle control from amputation at the ankle joint (Symes level) (99) and for those with reduced ankle power from high-heeled shoes (100).

The proximal muscles demonstrating increased activation in subjects with poor distal control are consistent with predictions of a simulation model developed by Jonkers and colleagues (48), who demonstrated that gluteus maximus, medial hamstrings, and gluteus medius would all contribute to hip extension and heel-off in single-limb stance. Thus, individuals with less severe initial motor involvement from the stroke demonstrated a greater capacity to restore distal control and walking function with intervention, and those with more severe distal motor impairment made more modest improvements by increased proximal and contralateral activity.

The predictive relationship between preserved motor function after stroke and responsiveness to locomotor intervention was confirmed in a study by Bowden and colleagues who found that baseline LEFM scores were significantly higher in participants with a strong response (greater than 0.16 m/s increase in self-selected walking speed) to a 12-week TM-BWS intervention compared to those who had more modest improvements (24.7 ± 4 vs. 19.0 ± 3, $P < .01$) (101). Interestingly, they also found evidence of distal recovery in the responder group with improvements in LEFM, Berg Balance test, and terminal stance propulsion, and evidence of compensatory mechanisms behind the small improvements

in the nonresponders. Bowden's 12-week/36 session study used a higher threshold of walking speed increase for responsiveness than that used with the 6-week/12 session intervention (0.16 vs. 0.08 m/s). Their graph of walking speed change over time indicates continuing improvement over the 12-week intervention without clear evidence of plateau in walking speed improvement in either group indicating a positive dose-response relationship.

Locomotor training interventions with TM-BWS used in the Mulroy (93) and Bowden (101) studies were conducted at faster than customary overground walking speeds. Examining the biomechanical mechanisms used to increase walking speed in the short-term after stroke provides a compelling picture of possible mechanisms underlying the long-term increases in walking speed in the high and low responders with intervention. In a single session study by Jonkers and colleagues, poststroke individuals with faster initial walking speeds went from free to fast walking by increasing both ankle and hip powers, although the increase in ankle power was less than in a speed-matched nondisabled control group (102). The slower walking participants with stroke, however, did not increase joint powers consistently at either the hip or ankle of the PP, but relied on increases in joint powers on the contralateral leg. In the TM-BWS locomotor intervention studies (93,101), those individuals who had the capacity to increase muscle activation particularly in soleus, also increased power generation in the PP engaging in repeated practice at activating muscles at a higher intensity and more rapidly than in their customary free walking which, over time, translated into an increase in free walking speed. Those individuals with lower residual motor function walked at increased speeds primarily by further driving the contralateral leg, which was sufficient for faster walking in the short-term during the intervention sessions, but didn't translate into clinically meaningful increases in free walking speed. A recent study by Routson and colleagues confirmed the critical role of improved soleus activation underlying increased walking speed after TM-BWS intervention particularly for those with less residual poststroke impairment (103). They documented improvements in both timing and intensity of soleus activity during walking after 12 weeks of TM-BWS. For those individuals with faster initial walking speeds and more selective control during walking initially (those who had 4 EMG modules or phasic muscle activity patterns in lower-extremity muscle groups with distinct and independent timing), improved timing of soleus activity was the only significant change in muscle activity after the intervention. These individuals had large increases in walking speed (0.32 m/s), and greater leg extension in preswing, and improved propulsion symmetry. These results closely parallel those of the high response group in our previous study (93).

Standing Balance

Standing balance also has shown strong correlation with walking speed after stroke, particularly for individuals with more severe impairments (56,97,104). Patterson et al. (56) identified that the strongest predictor of both short- (30 feet) and long-distance (6 minute) walking speed in a cross-sectional analysis was the Berg Balance Score for subjects who walked at or below the median speed (56). In contrast, peak VO_2 was the strongest predictor for the faster subjects. Standing balance and lower-extremity strength are strongly related after stroke, and this relationship is particularly strong for those with greater impairments (73).

Improvement in standing balance correlated with increased walking speed after basic rehabilitation and muscle strengthening interventions, particularly for individuals with more severe impairments (73,97). For subjects with less severe initial impairments, however, Pohl et al. documented that improvements in lower-extremity motor function and cardiovascular fitness were most strongly associated with increased walking speed (97). This suggests a hierarchy of functional substrates for walking with the ability to control balance during single-limb stance as a requisite skill for even slow walking and greater muscle strength, selective motor control, and fitness as determinants of faster walking speeds (56,73).

Walking Rehabilitation Interventions

Determining the appropriate and most effective interventions to use for walking recovery is one of the primary roles of the physical therapist during the acute, subacute, and chronic phases after stroke. Evidence is building that innovations in poststroke walking rehabilitation such as resisted lower-extremity strengthening, task specific training, and aerobic training are more effective than conventional neurophysiologic approaches used by physical therapists (69,105–107). Recent innovations in therapeutic approaches to walking rehabilitation derive from understanding the biomechanical and neurologic mechanisms that result in walking impairment after stroke.

As discussed earlier in this chapter, poststroke severity caused by primary motor impairments such as the extent of lower-extremity weakness and selective motor control are significant predictors that contribute to the biomechanics of poststroke gait and responsiveness to rehabilitation interventions. In addition, other secondary impairments such as balance dysfunction and deconditioning also contribute to poststroke walking disability. Current evidence from rehabilitation research suggests that lower-extremity strength training, task specific training such as body-weight supported treadmill training, and aerobic conditioning are interventions that contribute to gait recovery and increased community ambulation for individuals with walking disability after stroke (Figure 24.7).

Strength Training

Resisted strength training for the upper or lower limb after stroke has been questioned by therapists in the past because of the concern that resistance increases muscle spasticity and abnormal movement patterns. However, evidence is building that strength training leads to improvements in both lower-limb muscle strength and gait endurance after stroke (105) without increasing spasticity (108,109). The effectiveness

FIGURE 24.7 Rehabilitation interventions of treadmill training with body-weight support (B), resisted lower-extremity cycling (A), therapeutic progressive resistive exercise example (C), and upper-extremity ergometry (D).

of muscle strengthening to improve walking speed and endurance appears to relate to whether the strength training program is directed at single muscles or groups of muscles that are typically activated during the stance and swing phases of gait. For example, muscle strengthening for a single muscle group after stroke increases muscle strength but results in little or no improvement in walking speed or endurance (110). In contrast, strength training of multiple LE muscle groups is associated with modest functional changes in walking distance or improved balance and/or sit-to-stand ability but not increased walking speed (111–114). This finding is consistent with a recent study that used a resisted LE cycling task specifically designed to strengthen extensor and flexor groups with torque demands biased to emphasize the stance and swing phases of gait. The moderately high-intensity cycling program for 20 to 30 minutes of resisted cycling, 2 days a week for 6 weeks, resulted in significant increases in postintervention LE flexor torque production and walking endurance as measured by the distance walked in six minutes, but did not increase walking speed.

For individuals with moderate to mild walking impairment (i.e., baseline walking speeds approximately 0.30–0.80 m/s), strength programs that incorporate functional weight-bearing activities or dynamic high-intensity resistance training resulted in increases in strength of LE flexors and extensors that produced increases in walking speed, as well. Yang et al. used a program of progressive LE strengthening using functional weight bearing activities for exercise such as step climbing and single-limb heel raises to realize gains in LE strength and walking speed (115). Patten et al. found

that a dynamic resistance training program of eccentric muscle strengthening using isokinetic exercises (15 sessions over 5 weeks) followed by clinic-based gait training (nine sessions over 3 weeks) resulted in increases in both gait speed and LE torque production (116). Increases in speed were not evident for the group that received concentric strength training with gait training. Together these findings suggest that functional task strengthening or strength training programs that emphasize the dynamic muscle control needed to support the kinematics, kinetics, and muscle activation of more normal gait are more effective strength training programs for walking recovery after stroke.

Although it is evident that resisted LE strength training after stroke does not cause harm, there remains a relatively small body of literature that clearly elucidates the overall benefits or limitations of strength training. The recent Canadian Stroke Network (109) systematic review of LE strength training and mobility after stroke concludes that there is strong evidence that strength training improves distance walked after stroke but only moderate evidence that benefits extend to improved performance in other activities of daily living. Furthermore, there is little understanding of the appropriate dosing (i.e., intensity, frequency, duration) necessary to incur significant strength gains in patients with central as well as peripheral mechanisms of weakness. This knowledge gap is further compounded by few to no studies that have examined how principles of exercise for healthy young and older adults translate to individuals with stroke. For example, a recent study that investigated the combined benefits of a rehabilitation program that alternated therapy days of LE strength training with high-intensity treadmill training with body weight support found evidence of overtraining (i.e., impaired strengthening) in the group that received successive days of LE muscle exercise with the group that received a program in which UE and LE exercise were provided on alternate days (117). Clearly, more investigation into maximizing the effects of resisted exercise after stroke is needed.

Task-Specific Training

Task-specific training is the repetitive practice of a task that is specific to the intended outcome. Treadmill training is a therapeutic modality that allows the individual with stroke to actively engage in repetitive stepping. Walking on a treadmill is an example of task-specific gait training that can lead to the achievement of improved walking speed and endurance (111,118–120). TM-BWS is an adaptation of treadmill walking that involves fitting the patient in a harness and suspending him or her over a treadmill with a portion of the patient's body weight reduced so that a physical therapist, with help from another therapist or aide if needed, can assist the patient to step on the moving treadmill belt. Visintin et al. demonstrated that TM-BWS with 40% body weight support provided in early training that was progressively decreased over training sessions resulted in better walking outcomes for individuals in the acute and subacute phases after stroke than treadmill training without body weight support (121).

In a control-comparison RCT of 80 individuals with chronic stroke who had severe to moderate walking impairment (average gait velocity: severe, 0.25 ± 0.12 m/s; moderate, 0.71 ± 0.12 m/s), Sullivan et al. demonstrated a statistically significant, and clinically meaningful, increase in both walking speed and distance that was maintained at a six-month follow-up for *any* of the exercise groups that received TM-BWS compared to the group that received resisted cycling (117). In this study, there were four exercise groups that received exercise four days per week for six weeks. Three of the groups received TM-BWS combined with another exercise such that the program included two days per week of TM-BWS alternated with two days per week of upper-extremity ergometry, progressive resistance LE exercise, or resisted cycling. The fourth group received two days per week of resisted cycling alternated with two days per week of upper-extremity ergometry. Each group was controlled for time in the exercise session (one hour per session) and intensity (moderately high). Moderate- to high-intensity TM-BWS sessions included 20 minutes of cumulative walking time on the treadmill at speeds that ranged from 1.8 to 2.3 mph. In addition to providing specific dose parameters and intervention protocol specifications for the exercise programs, this study demonstrated the overarching benefit of an exercise program that included TM-BWS for making long-term changes (six-month follow-up) in both walking speed and distance in individuals after a chronic stroke.

The locomotor experience applied after stroke (LEAPS) study, a large multi-site randomized clinical trial comparing the effectiveness of TM-BWS in the early (2 months) and late (6 months) poststroke recovery phases with an early phase home exercise program in participants who had been discharged from inpatient rehabilitation, was a landmark study for poststroke rehabilitation of walking (122). All 3 interventions were in addition to "usual care" physical therapy (received by 82% of participants). Several important conclusions can be drawn from the results, and with over 400 participants, the results of the study can be generalized widely. There was no difference between the 3 treatment groups in the primary outcome, transition to a higher functional walking level from baseline to one year after stroke. At six months after stroke, the late TM-BWS group had ***only*** received "usual care" physical therapy and had a mean increase in walking speed from baseline of 0.13 m/s that was approximately 55% of the increase seen in the other 2 groups who had completed the TM-BWS or home exercise program. Addition of TM-BWS after the six months assessment in the late TM-BWS group further increased walking speed so that all groups had similar gait speeds at one year. This study demonstrated that "usual care" physical therapy intervention is not sufficient to optimize potential walking recovery after stroke. The addition of high-intensity intervention to "usual care" even at 6 months after stroke can produce functionally significant improvements in walking. A positive dose–response relationship between treatment week and gait speed increase was seen for all 3 groups. The slope of the improvement trajectory increased for the late training at

the onset of TM-BWS. The more task-specific TM-BWS intervention was not superior to the impairment-based home exercise program in increasing walking speed. The authors felt the critical ingredients in the two experimental interventions that were missing from "usual care" physical therapy were: higher dose (number and frequency of sessions), participant engagement in goal setting, challenging intensity within each session, a progressive increase in intensity over the duration of the program, and task-specific walking training or impairment-based exercise (123). Additionally, the authors felt that conducting the home exercise program in the individual's natural environment may have facilitated retention of the gains (123). In support of that hypothesis, those in the home exercise group did continue to show small gains in walking speed and daily stepping activity from the six-month to the one-year follow-up assessments whereas the early TM-BWS demonstrated slight reductions (122). So although intensive task-specific walking training can optimize walking speed after stroke, it is not the only type of intervention to produce similar results.

Several recent systematic reviews have suggested that the collective findings on treadmill training or TM-BWS effectiveness compared to other gait interventions remain inconclusive (105). However, there is strong evidence that task-specific functional training ***performed at high intensity*** may be a critical factor that modulates gait training effectiveness (106,124,125). With task-specific gait therapies such as treadmill training or TM-BWS, responsiveness to this particular intervention is related to the training parameters used. Recent evidence consistently demonstrates that treadmill training at higher speeds (i.e., higher intensity), with or without body-weight support, is more effective for improving gait speed after stroke than training at slower speeds (92,126,127). These reports of differences in therapeutic effectiveness related to the type and dosing of the exercise program illustrate the importance of exercise prescription. Exercise prescription is a major contributor to therapy outcomes and most likely contributes to the inconclusive findings of systematic reviews that have not included trials in which training intensity is controlled.

Why are higher intensity, task-specific gait interventions more likely to achieve functionally significant changes in walking outcomes after stroke? We propose that walking rehabilitation that combines *specificity* of training intrinsic to walking with the *intensity* of walking at challenging speeds requires that the individual after stroke respond to and develop the gait dynamics and muscle activation patterns associated with more normal gait parameters.

Given the results of the LEAPS trial, intensity and speed may be the most important factors in effective interventions for restoring walking function after stroke. In fact, even a single session of fast functional movements produced increased intensity of muscle activation in both flexor and extensor muscle groups as well as improved temporal coupling of the movements and postural control variables (128). No retention test was included, so it is not clear if the effects persisted over time. More than one session would likely be necessary for long-term change in muscle activation. A 12-week ***combined*** program of high intensity, fast velocity muscle strengthening with TM-BWS produced increased muscle activation during maximal contractions and large increases in walking speed (increase of 0.46 m/s) for participants with mild to moderate impairment in the sub-acute phase after stroke (129). Muscle activation ***during walking*** was not measured in either study, so we cannot be certain that increased muscle activation during maximal effort strength testing generalizes to locomotion. The studies by Mulroy et al. (93) and Routson et al. (103) did measure muscle activation during walking before and after TM-BWS. Based on their results, we can conclude that improved walking speed (in high responders) after this high intensity, task-specific intervention results in increased intensity of soleus activation and a greater number of distinct muscle synergies used in walking.

A study from Hornby's group provides further support for the importance of intervention dosage required to optimize walking recovery after stroke and the lack of intensity in usual care physical therapy (130). Participants were on average 13 months after stroke and had completed an outpatient usual care physical therapy program resulting in a modest increase in walking speed (0.05 ms/s). Number of steps/session in usual care averaged 1886. Participants did not change in daily stepping activity following the usual care program. Participants then underwent four weeks of high intensity TM-BWS with an average of 3900 steps/session. Walking speed increased a further 0.05 m/s and daily stepping activity increased by 850 steps/day. Moreover, they found a moderately strong correlation (r = 0.57) between number of steps in the intervention and increase in daily stepping activity after the intervention. Thus, usual care physical therapy is low in intensity and insufficient to optimize walking recovery in the chronic as well as subacute phases after stroke. Dosage in terms of both intensity within a session and program duration are important determinants of the extent of walking improvement. Neuro-biomechanical mechanisms underlying improved walking after TM-BWS vary depending on initial motor impairment.

In summary, changes in walking recovery and response to appropriately selected and dosed interventions are related to the residual damage to the nervous system after stroke and the response of the nervous system to interventions that provide an appropriate dynamic stimulus to drive recovery. Long-term changes in performance are consistently achieved when the intervention intensity is high and challenging for the individual. Conditions of task practice that are similar to the task and conditions in which long-term changes in performance are expected can facilitate long term improvement in walking function after stroke (131) (see Chapters 19 and 20 for similar discussions).

Aerobic Training

Deconditioning after stroke is a chronic health condition that is evident across the acute, subacute, and chronic phases after stroke (see Chapter 27 for more information). Aerobic training can be safely incorporated into rehabilitation exercise

programs after stroke. Physical activity and exercise after stroke are highly recommended to address deconditioning and to reduce secondary risks for the poststroke survivor (132). In addition, valuable evidence-based sources are now available for the rehabilitation specialist that provide heart rate and blood pressure guidelines to individually monitor the patient during moderately high exercise programs (e.g., see http://www.apta.org/AM/Template.cfm?Section=PFSP_Pocket_Guides&Template=/MembersOnly.cfm&ContentID=42129). Although cardiovascular fitness is essential for good health after stroke, there is building evidence that specific types of aerobic programs are also associated with improved walking outcomes for the stroke survivor.

Pooled data from systematic reviews and well-designed RCTs reveal that walking outcomes such as walking speed and distance, functional tasks such as stair climbing, and increased community mobility and participation are positively impacted by aerobic training for patients with subacute and chronic stroke (105,133,134). Across these studies large-muscle activities such as walking, treadmill, stationary cycle, combined arm-leg ergometry, arm ergometry, and seated steppers were used. Exercise intensity among studies in which walking outcomes were improved ranged from 3 to 19 weeks, 20 to 40 minutes, 3 to 5 days per week at 50% to 80% of heart rate reserve. Pooled data show that aerobic exercise had a small, statistically significant effect on walking speed 0.26 m/s (95% CI: 0.05–0.48, $P = .008$) and a moderate, statistically significant effect on walking distance 0.30 meters (95% CI: 0.06–0.55, $P = .008$).

Aerobic exercise training specifically designed to improve gait and gait-related activities is associated with greater clinically and statistically significant gains in walking outcomes (see systematic review by Van de port (135). Activities such as cycling, water-based exercise, and gait-oriented cardiovascular training resulted in greater postintervention changes in walking speed 0.45 m/s (95% CI: 0.27–0.63) and distance 0.62 meters (95% CI: 0.30–0.95). Across the studies reviewed the most common exercise prescription (i.e., frequency, intensity, duration) averaged three times per week for 60 minutes across 4 weeks (ranges: 8–90 minutes; three to five times per week; 4–19 weeks). Exercise intensity in terms of percentage of heart rate maximum, heart rate reserve, or rate of perceived exertion was not reported.

The wide confidence intervals are most likely associated with the wide variety of exercise methods and prescriptions that ranged across the various trials. Once again, well-designed aerobic exercise rehabilitation clinical trials are needed to better understand the exercise method and aerobic training parameters that result in clinically significant walking recovery in individuals after stroke. However, efficacy of physical activity and aerobic training to improve walking outcomes after stroke is evident.

Research Frontiers

Future directions in walking rehabilitation therapies will most likely include the use of technology to enhance current walking rehabilitation interventions. Currently, technological advances in walking neurorehabilitation that are in either experimental (pre-clinical) or early phase I clinical trials are in the areas of lower-limb assisted robotics, implantable electrodes for neuromuscular function, electrical stimulation, virtual reality enhanced training, and transcranial magnetic brain stimulation.

Lower-limb assisted robotics are in development that will provide machine-assisted stepping because the physical demands during treadmill training are high for the therapist. Examples include both motorized (136) and gravity-balanced (137) exoskeletons that serve as gait-assisted orthotics during walking on a treadmill with a supportive harness and body-weight support. A clinical trial conducted in 2008 that examined walking outcomes in patients with chronic stroke demonstrated that therapist-assisted stepping was more effective than robotic-assisted stepping with a motorized exoskeleton (138). "First-generation" devices, like the Lokomat (Hocoma AG, Switzerland) were developed based on the approach of enforcing gait upon a patient by moving the legs through a prescribed gait pattern diminishing the need for the patients to actively contribute to the required motion. To encourage active participation, more recent robotic devices (including a newer version Lokomat) (139) have been developed with assist-as-needed strategies to control the interaction forces by using impedance or admittance control algorithms (140). They guide the leg by applying a force rather than imposing a trajectory. Impedance control makes the robot's behavior more flexible and adaptive to the patient's capabilities, progress, and current participation. Depending on the impedance levels, small errors are still possible, promoting motor recovery. Catch trials can be utilized to detect and prevent reliance on the robotic support (141). The majority of robotic devices for locomotor training are designed to be fixed to a treadmill (140,142), but devices that can be worn during overground walking act like powered orthoses, such as the ReWalk (Argo Medical Technologies Ltd) are emerging technologies (143). However, more study is needed to determine the optimal training paradigms that integrate the expertise of the therapy clinician with the most effective mechanical assistance.

Advances in technology and reduced device size have allowed neuromuscular electrical stimulation (NMES) to be used functionally as a neuroprosthesis. There is strong evidence that NMES, particularly peroneal nerve stimulation, in conjunction with gait training is an effective walking rehabilitation strategy (105,144) with some evidence of carry-over after long term use (145). Electrical stimulation to ***both*** the ankle plantar flexor and dorsiflexor muscle groups during walking resulted in greater swing-phase knee flexion, greater ankle plantarflexion angle at toe-off, and greater forward propulsion than that produced by stimulation only to the ankle dorsiflexors for persons in the chronic poststroke phase (146). The combination of this stimulation paradigm paired with the fastest sustainable speed TM-BWS further increased the peak anterior GRF (propulsion) providing a more extended leg angle in late stance compared to fast

walking without stimulation and self-selected speed walking with stimulation (147). This research group also identified a dose-response relationship with 36 sessions (12 weeks) of TM-BWS combined with electrical stimulation required to elicit increases in walking speed that exceeded the minimally clinically important threshold (148).

Surface electrode stimulation devices are readily available for clinical use; however, future research endeavors will most likely include the development of implantable electrode devices that will increase the effectiveness of NMES and increase ease of use and comfort for the patient (149). Recent studies demonstrated initial evidence for the feasibility and effectiveness of NMES with implantable electrodes for peroneal stimulation as an adjunct to walking rehabilitation therapy (150–152). Moreover, Daly et al. conducted a randomized clinical trial testing the impact of the addition of 8 channels of electrical stimulation delivered by implantable electrodes to TM-BWS in a 12-week intervention (153). Walking speed and gait coordination outcomes were superior with the addition of the stimulation. The implanted electrodes (as compared to surface stimulation) allowed more specific targeting of individual muscles, particularly in deeper muscles, and permitted higher levels of stimulation without discomfort, because they bypassed the cutaneous pain fibers.

Virtual reality (VR) enhanced interventions provide an enriched training environment and multimodal feedback with the potential to produce superior walking outcomes for persons with poststroke impairment. VR integrated into a 4-week seated ankle motion control program resulted in a 0.16 m/s increase in walking speed with increases in preswing ankle plantar flexion power whereas those who performed the training program without VR and visual and auditory feedback did not improve (154). VR has also been integrated into TM-BWS (155). After three weeks of VR enhanced training walking speed increased by 0.17 m/sec and community walking activity was greater whereas those who received the TM-BWS without VR exhibited minimal improvements. VR enhanced interventions offer several benefits; they provide a variety of different environments, feedback that can be modified according to individual's specific characteristics, and the ability to manipulate and incrementally progress the difficulty of the task as well as obtain an objective assessment of changes in patient's performance. Training in a new environment enhances motivation and engagement (156). VR systems also can be combined with manipulation of physical environments and sensory feedback to create a mixed reality system. Fung and Perez developed a mixed reality advanced locomotor system incorporating VR, a treadmill with surface perturbations, and light touch with a haptic bar that was specially designed to provide somatosensory information through fingertip contact (157). The variety of virtual environments may be able to facilitate transfer of gains produced in walking in the artificial environment of a treadmill to the more complex real-world settings.

Several noninvasive brain stimulation protocols including repetitive transcranial magnetic stimulation (rTMS) can be used to modulate local neural excitability of selected brain areas. These techniques have shown promise in enhancing the effectiveness of locomotor training after stroke. For rTMS, the effect depends mostly on the stimulation frequency. High-frequency rTMS facilitates and low-frequency rTMS suppresses local neural activities (158). Low frequency (1 Hz) rTMS delivered to contralesional hemisphere prior to functional gait training activities every day for 10 consecutive weekdays produced decreased interhemispheric asymmetry of the amplitude of the motor evoked potentials and improved gait speed compared to those who received sham rTMS and gait training (159). Differences in stimulation protocols and gait training interventions have produced mixed results. Transcranial direct current stimulation (TDCS) is another noninvasive brain stimulation protocol that can be either inhibitory or facilitory depending on the stimulation parameters (158). Facilitatory TDCS to the ipsilesional hemisphere had no additional effect on robot-assisted gait training delivered in ten 50-minute treatment sessions, 5 days a week, for two consecutive weeks (160). In contrast, a single session of high-frequency facilitatory rTMS applied over the leg motor areas in ***bilateral*** hemispheres using a double cone coil produced a significant short-term increase in walking function (0.90 to 1.03 m/s) in poststroke hemiparetic patients when compared to sham stimulation (161). The authors used the bihemispheric facilitatory rTMS to enhance uncrossed motor pathways originating from the ipsilateral hemisphere as well as the crossed motor pathways. The stimulation protocol has not been tested with multiple sessions or in conjunction with locomotor training programs. Future studies will need to determine the optimal combination of stimulation protocol, locomotor training program, and patient characteristics for improving poststroke walking function with rTMS. For a review of the complexities involved with using noninvasive brain stimulation to improve walking function after stroke, see Rogers et al. (162)

CONCLUSION

This chapter summarizes the temporal gait characteristics and kinematic and kinetic features associated with poststroke gait dysfunction. Stroke severity affects the dynamic strategies used for walking after stroke. Stroke severity assessed by clinical measures of LE motor impairment (i.e., selective movement control, strength, spasticity) or functional walking ability (i.e., walking speed or distance) is associated with walking outcomes and disability. The capacity to recover movement control as indicated by changes in force production, increased movement selectivity, and appropriate motor unit activation and recruitment during walking appears to be related to the degree of corticospinal tract damage and the methods used during walking rehabilitation.

Walking recovery after stroke is facilitated with rehabilitation strategies that incorporate strengthening of functional muscle groups with power and activation patterns that are more similar to those used in gait. Task-specific interventions such as treadmill walking with or without

support of body weight are examples of effective rehabilitation strategies that incorporate the demands of gait into repetitive stepping and task-specific practice most similar to that of normal gait demands. Furthermore, aerobic training in gait-related activities or LE cycling tasks appears to be an effective intervention to increase cardiovascular fitness associated with reduced activity levels and deconditioning after stroke. Collectively, these types of rehabilitation interventions improve walking outcomes and lead to enhanced participation and quality of life for individuals with stroke.

Recovery and Rehabilitation of Standing Balance After Stroke

Mark W. Rogers, Katherine M. Martinez,
Sandy McCombe Waller, and Vicki L. Gray

Difficulties with balance leading to disability are common occurrences after stroke. This chapter examines the problems of standing balance accompanying stroke and its rehabilitation. The review will synthesize mostly recent information about these themes by:

1. Discussing the scope of the balance problem from the standpoint of interactive motor control factors that may normally contribute to sustaining standing balance
2. Identifying the functional balance limitations and changes in motor control that have been consistently noticed and their relationship with falls
3. Examining the clinical outcome measures used in assessing balance and the intervention approaches directed at improving balance
4. Introducing a protective stepping model of balance control for linking dynamic balance capacity, functional performance, and falls
5. Providing a glimpse of emerging new research frontiers in balance recovery after stroke

SCOPE OF THE BALANCE PROBLEM

Balance: A Multifaceted Control System

In mechanical terms, standing balance involves the maintenance of the relative position and motion of the body center of mass (COM) with respect to the base of support (BOS), usually represented by the feet in contact with the ground (1). Virtually limitless variations of body surface contact with the environment that provides support may reconfigure the BOS conditions that influence balance. Hence, the interplay between the COM position and motion (velocity or momentum) in relation to a stationary (e.g., feet-in-place and/or grasping a fixed rigid object) or moving BOS (e.g., stepping and/or reaching to contact or grasp a secure surface) determines the moment-to-moment conditions of balance stability. The critical importance of the dynamic nature of these relationships is illustrated by observations showing that even healthy adults often naturally respond to balance challenges by rapidly changing their BOS by stepping or grabbing for support even when the COM is positioned well within the BOS boundaries (2). These responses have traditionally been considered to indicate falling in clinical assessments of balance, such as the Romberg test (3). The complexity and multifaceted nature of the interactive factors that normally comprise the standing balance control system are represented in Figure 25.1 and discussed in this section.

Neural Factors

Concerning the neural control mechanisms by which standing balance may normally be achieved, much attention has been given to the role of the spinal cord and brain stem-mediated postural reflexes involving visual, vestibular, and proprioceptive subsystems operating in a reactive mode of control (4–9). Anticipatory postural adjustments involving proactive control processes that may precede and accompany particularly voluntary goal-directed movements have been proposed to involve several higher-level brain centers, including motor cortical areas, basal ganglia, and the cerebellum (10). The interface between reactive and proactive neural control processes for standing balance is not well understood. This dichotomy appears to have somewhat limited current neuromotor approaches to balance rehabilitation after stroke by emphasizing volitional balance tasks with limited focus on reactive responses to balance perturbations (see Intervention Approaches).

Although a commonly held view is that, in mammalian systems, including humans, the balance regulatory system is phylogenetically old and operates relatively autonomously and automatically using polysynaptic reflex pathways involving the spinal cord and brainstem (6,10), emerging perspectives suggest that standing balance may operate like any other form of movement by requiring planning, anticipation, and adaptive internal models (11,12). For example, even during the quasistatic situation of stationary standing balance, sagittal plane sway regulation cannot be achieved by continuous muscle activation adjusted by reactive stretch reflexes at the ankles as generally believed (11). This is because

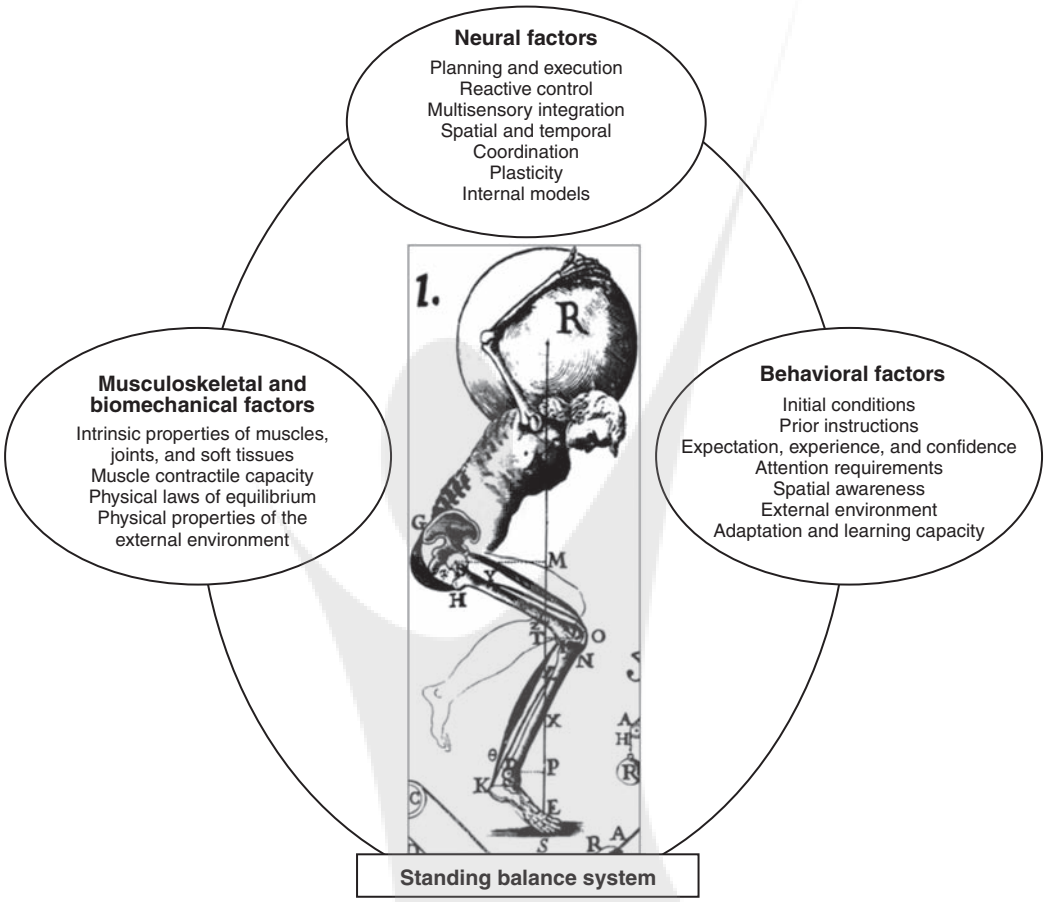

FIGURE 25.1 Conceptual scheme of the multifaceted interactive factors that normally comprise the human standing balance control system.

Source: Adapted from Borelli GA. De Motu Animalium (1680).

the net series elastic component of the calf muscles is less stiff than the body's load stiffness (11,13). Hence, proactive, cyclic calf-muscle activations produce catch-and-throw-like ballistic movements of the body that regulate the COM motion relative to the BOS and produce sway (11). Further details of this form of balance control suggest predictive planning mechanisms implicating the use of internal models relating COM motion and muscle activity linked with skilled, learned behavior (11,12,14,15). Moreover, global, integrated sources of contextually weighted multisensory information, rather than local, joint-specific proprioception information at the ankles are likely utilized to identify the motion of the COM relative to the BOS to maintain balance (16–21). Along these lines, other recent work has focused on cortical and subcortical activity during balance perturbation tasks related to central-set or the readiness to respond, motor preparation, and planning. Postperturbation events have begun to identify links between higher-level neural control processes and balance control (22–33). The influence of attention and other cognitive functions on balance regulation has also become an increasing area of study (see below). The developments illustrated by the foregoing and other studies have important implications for formulating conceptual and theoretical models for understanding and assessing problems with standing balance and for designing the most effective interventions to enhance balance function and prevent related disability after stroke.

Musculoskeletal and Biomechanical Factors

In addition to active muscle contractile capacity and fatigability that can directly impact standing balance stability at the effecter level (34–36), musculoskeletal and biomechanical factors also afford certain advantages and limitations that must be taken into account by neuronal controllers (37). For example, the intrinsic mechanical properties of muscles are designed so they produce greater forces if their rate of strain increases based on the force velocity relationship (38,39). Hence, this effect would rapidly oppose any abrupt stretching effect on muscle caused by disturbances of posture as a first line of defense against instability in advance of reinforcing reactive neuromuscular responses. Similarly, if a contracting muscle is abruptly unloaded, its speed of shortening and force generation decreases (40). Muscle-stabilizing effects on balance will also be influenced by the passive length-tension properties of muscle that are related to the positions of joints at the instant of disturbances to balance (37,41), which may also influence the motor unit recruitment patterns that activate muscles. Moreover, stabilizing joint

torques also depend on changes in the moment arm distances of muscles around a given joint as it is being rotated (42) and on the stiffness of collagenous tissues, like tendons (43).

- At the whole body level, several mechanical factors affecting the COM–BOS relationship at any point in time should be taken into account. Such factors include:
- The height of the COM above the ground
- The load-bearing patterns beneath the feet
- The positional orientation of the feet and any other body surface contacts with the environment that makes up the BOS
- The physical properties of the surfaces used for support (e.g., friction, compliance, and levelness)
- The inertial state of the system (at rest or in motion)
- The mass distribution if external loads are held or applied to the body

Behavioral Factors

The remarkable modifiability and flexibility of essentially all forms of balance-related neuromotor activity to meet the needs of a large variety of functional situations suggest that behaviorally driven factors are another important component of the balance system. Behavioral influences are reflected by:

1. Prior instruction to respond in a particular manner (44)
2. Changes in motor-set reflecting expectations (45)
3. The cognitive demands of attention sharing when performing concurrent tasks (46–50)
4. The experience with a given balance stabilizing situation and confidence (51–54)
5. Changes in initial conditions (55–57)
6. The prevailing environmental conditions (58)

Therefore, a growing body of information has supported the capacity for cognitive processes to influence the control of standing balance. Many of these modulating influences on standing balance have, at least in part, implicated cerebral cortical areas in contributing to shaping neuromotor activity for balance control (59,60).

RECOVERY OF STANDING BALANCE

Clinical Outcome Measures

Problems with balance function accompanying limitations in physical mobility are believed to be common after stroke. Following a total anterior circulation infarct, the median time to recover the ability to stand for 10 seconds is 44 days (61,62). The impact of difficulties with sustaining balance on function has been assessed by studies of balance disability, physical mobility, and performance of activities of daily living (ADLs). The World Health Organization International Classification of Function (ICF) provides a framework for examining both outcome assessments and interventions across a spectrum of functions including Body Structure and Function and Activities and Participation (61). Investigations of balance after stroke should include clinical measures across all three of these domains.

The category of Body Structure and Function includes features of body function that may contribute to balance control and should be part of a comprehensive assessment of persons with balance dysfunction. These measures may include lower extremity joint range of motion, strength and/or muscle recruitment, as well as lower extremity somatosensation. Status of cardiovascular functions may have an impact on the body's ability to adjust to changes in position or maintenance of an upright task and is frequently the underlying factor of the initial stroke. In addition, owing to the multifactorial nature of balance control, assessments of other sensory systems such as somatosensory, visual, and vestibular function that may be impacted by stroke and contribute to overall balance abilities should be included in a comprehensive evaluation (see Chapter 18).

In the Activities domain of balance function, a number of outcome measures have been used in the poststroke assessment of balance. These assessments can be categorized into the aspects of postural control they evaluate: static balance—the ability to hold an upright posture; volitional balance control—the ability to maintain upright postural control while moving; and reactive balance—the ability to respond to an external perturbation. Some of these tools are exclusively measures of balance control whereas others are general mobility assessment tools with balance subsections. Commonly used assessments used to evaluate postural control in a person after stroke include:

Static

One-legged stance test (63)
Clinical test of sensory integration of balance (CTSIB) (64,65)

Volitional Balance

Dynamic Gait Index (DGI) (66,67)
Functional Reach/Multidimensional Reach (68,69)
Timed Get Up and Go (70)
Berg Balance Scale (BBS) (71)
Performance Oriented Mobility Assessment (POMA) (72,73)
Postural Control and Balance for Stroke Test (74)
Balance Evaluation Systems Test (BEST)* (75)
Postural Assessment Scale for Stroke Subjects (76)

*Contains an item of reactive control

Reactive Balance

Equitest (77,78)

Mobility Assessments With Balance

Chedoke McMaster (79)
Brunel Balance Assessment (80)
Rivermead Mobility Index (81,82)
Fugl-Meyer (Balance subscale) (83,84)
Clinical Outcome Variables (85–87)
Community Balance and Mobility Scale (88)

Although each of these tests is a generally valid and reliable assessment of balance function, they vary in their psychometric properties such as their sensitivity to change, their floor or ceiling effects, or their applicability to a wide range of balance abilities (89).

A generally consistent finding in the literature is a positive relationship between balance function and other aspects of functional mobility and ADLs (90–95). It is somewhat difficult to extract a clear picture of the precise relationship between these aspects of recovery because of the variability in outcome measures and subject selection criteria between the studies (96). In one of the more comprehensive studies focused on balance disability in the acute phase of recovery after stroke (2–4 weeks), 75 subjects with a single-incident anterior circulation stroke were evaluated (96). A regression modeling approach was applied to assess the frequency of balance problems, characterize the different severity levels of balance function, and determine the factors associated with balance disability. Balance disability (Brunel Balance Assessment (80)) was present in 83% of the subjects, 40% were able to stand without assistance from another person though they could not step or walk, whereas 33% could step but with limited balance. Subjects in the stepping balance group were less impaired and disabled than those with more limited standing balance, and this reflected differences in the severity of stroke pathology. None of the demographic or stroke pathology factors, including age, gender, premorbid disability, side of stoke, or stroke type, were associated with balance disability. Multiple regression analysis of significant impairment factors indicated that clinical measures of sensation and weakness were independently associated with balance disability and accounted for 47% of the variance. These results were broadly comparable to the few earlier reports of balance disability (97–99) that used correlation designs. The exclusion of assessments of other potentially important balance factors, such as vision, psychomotor speed, musculoskeletal factors, and attention and other cognitive factors, likely accounted for the 53% of variance that was unaccounted for. The contribution of balance self-efficacy or perceived ability to these results and those of other investigations of balance function and disability should also be taken into account (100).

Another representative study (101) of early balance recovery of function in 29 mild and moderately involved individuals after stroke (1 month and 3 months) included functional (Berg Balance Scale [BBS] (71) and Clinical Outcomes Variables Scale [COVS] (85)) and physiological assessments (electromyography and center of pressure recordings). Functional balance and mobility improved over the two-month recovery period in both groups who received inpatient rehabilitation for either one month (moderate group) or four days (mild group). The moderate group showed a threefold greater improvement than the mild group on the COVS and improved performance on the BBS, whereas the mild group approached maximum scores on both outcomes at three months. Improvements in health-related quality of life (Medical Outcomes Study 36-Item Short-Form Health Survey—SF 36) (102) physical component occurred for both groups but remained lower than normative values. These profiles were accompanied by impairments in muscle activation patterns and postural sway that showed some improvements over time but remained significantly impaired relative to healthy controls even in the mild group, which achieved virtually maximum performance scores on functional balance and mobility. Change in physical component COVS scores and change in functional or physiological balance measures were uncorrelated. These results and those of other studies emphasizing balance impairments (see below) suggest that improvements in balance and mobility functions can be uncoupled from changes in many balance-related control factors assumed to be contributing to disability that may limit participation in occupation and leisure interests. These observations direct attention to the need to improve understanding of the relationship between the natural evolution of impaired balance-control factors following stroke, and the adaptive compensatory strategies adopted by individuals to sustain their standing balance.

Balance confidence and falls efficacy may very well be important factors in the third ICF domain of participation that contribute to willingness to engage in life's activities and have also been linked to reduced balance performance and falls (103). The scales used in poststroke research related to balance control and falls include the Falls Efficacy Scale (104), Activities Specific Balance Confidence Scale (ABC) (105,106), the Stroke Impact Scale (67,107) and the WHO—Quality of Life Brief (108).

In summary, a comprehensive clinical assessment of a patient with balance dysfunction after stroke should include assessments across all three domains of function to better understand all the contributing factors to a given individual's balance control that will aid in the development of a specifically targeted intervention to restore balance control, reduce fall risk, and facilitate return to independence in community functioning.

Instrumented Studies of Balance Impairments

Unperturbed Stationary Standing

Instrumented tests of stationary standing balance after stroke have frequently used force platforms to evaluate the patterns of loading forces between the limbs and the center of pressure (COP) excursions beneath the feet, reflecting postural sway. The tests also reflect active contributions from muscle contractions related to ankle joint torque (anterior-posterior [A-P] direction) and hip joint torque (mediolateral [M-L] direction) (109). These measurements generally represent impairment-level outcomes.

A common finding of such reports has been an overall reduced loading and relative overloading of the forefoot beneath the paretic limb side compared with the nonparetic side; increased postural sway (COP excursion area, amplitude, and velocity), especially in the frontal plane; and impaired spatial and temporal characteristics of leg muscle activation patterns (90,91,110–122). COP fluctuations correlated under

both feet indicate movement in the same direction and synchronization of balance control. The between limb synchronization is reduced among individuals with stroke and has been reported to be correlated to motor impairment and prospective fall risk (121).

Building upon earlier reports, de Haart et al. (91) conducted one of the more comprehensive longitudinal studies of standing balance recovery of 37 subjects who received inpatient rehabilitation beginning 10 weeks after first-time stroke (intracerebral infarct or hematoma). COP excursions under each foot were recorded separately when subjects could first stand unsupported for at least 30 seconds and were repeated 2, 4, 8, and 12 weeks later. At the start of training, postural sway (root mean square of the COP velocities) while attempting to stand as still and symmetrically as possible was four to five times greater in both the A-P and M-L directions than age-matched healthy controls. Across time, sway velocity decreased by 33% in the frontal plane and 18% in the sagittal plane. This improvement was mainly reflected in reduced amplitude of sway in both directions and a relatively larger improvement in the frontal plane when tested with eyes closed. Dual-task interference (concurrent arithmetic task) increased overall sagittal sway velocity by a small amount (14%). Static and dynamic parameters of kinetic asymmetry between the sides showed that, at baseline, 13.5% more weight was borne beneath the nonparetic side and was reduced to 10% at 4 weeks with no further change across the 12-week period. The ratio of paretic side COP velocity regulation to nonparetic side regulation was greater than two to one and remained unchanged. The level of paretic side forefoot loading was about 7% to 9% greater than the nonparetic side across standing conditions and did not vary with time of progression. Lack of vision did not affect weight-bearing asymmetry, but introduction of the dual task increased weight-bearing asymmetry by 32% overall compared with standing with the eyes open. This effect did not change with time. Clinical characteristics showed no effects of age, time after stroke, or type and location of stroke. Improvements in walking function occurred during rehabilitation as indicated by the median two-point increase in Functional Ambulation Categories score. Subjects with either lower motor selectivity function at baseline (Brunnstrom Scale Stages I–IV), ankle clonus, or lower ankle joint proprioception had substantially more weight-bearing asymmetry than those with better selectivity (Stages V–VI), no clonus, and normal ankle position sense.

Despite the study limitations, several key points that generally summarize and extend the findings of many studies of stationary standing ability after stroke can be extracted from the above findings:

1. Relatively severe disruption of stationary standing balance control generally exists after stroke in both the A-P and M-L directions of whole body motion. However, it appears that balance ability is disproportionately more affected in the frontal plane compared with the sagittal plane.
2. Over the time of 12 weeks of rehabilitation, M-L balance recovery was considerably more robust than A-P balance recovery, but this might reflect differences in the floor or ceiling effects of measuring performance and/or the specific interventions utilized.
3. Visual deprivation worsened balance performance overall, and this effect accompanied reduced ankle proprioception sense in 65% of subjects, but this dependency decreased for M-L balance during the time of rehabilitation, suggesting possible improved somatosensory integration.
4. The persistence of dynamic and weight-bearing asymmetries between the paretic and nonparetic sides and their worsening when cognitive resources are challenged suggests that automaticity (unconscious) of paretic limb weight-bearing support and use for balance control are common deficits after stroke that may precipitate lateral instability.
5. Similar to the studies of functional balance and disability discussed earlier, the observed recovery of functional mobility and motor selectivity score and residual deficits in controlling standing balance suggest that substantial compensations in sway regulation and functional balance performance are likely contributed by the nonparetic leg, which may be unable to completely compensate for insufficient paretic limb control.
6. There are indications that the standing asymmetry and lateral balance instability after stroke may be linked with visuospatial hemineglect (91,117), though this possibility requires further investigation.

Although considerable emphasis has been given to studying the quasi-static balance task of stationary standing, the ecological validity of such tests may be questionable in view of the more dynamic challenges of everyday balance requirements (123), which normally involve very different biomechanical solutions than those for stationary standing balance (124). Therefore, some caution should be used when attempting to extrapolate information about stationary standing performance after stroke to more dynamic balance situations. Nevertheless, measurements of stationary standing ability after stroke have shown associations with functional measures of balance and gait (90,99,110), suggesting they may provide some useful, though limited, information (123).

External Perturbations of Stance

Externally applied disturbances of standing balance involve mechanical perturbations applied to either the standing support surface or body that alters the COM–BOS relationship, requiring corrective responses from the balance control system to avoid falling. In addition, sensory perturbations of stance entail manipulations in one or more sensory information sources that may be used to sustain balance. Such studies have generally provided useful information about the balance control factors that may become impaired following stroke (muscle recruitment patterns, movement kinetics and

kinematics, and behavioral responses) and thus represent impairment level outcomes.

Mostly cross-sectional studies using external perturbations of stance in older adults with chronic stroke have primarily focused on unchanging BOS or feet-in-place responses. These studies have generally found absent, delayed, altered, or diminished paretic limb postural muscle activation patterns and movements as well as exaggerated compensatory reactions in the nonparetic lower limb that compromise balance (93,110,115,122,123,125–129). These observations support the prevalent reliance on compensatory strategies involving the nonparetic side of the body.

Longitudinal studies examining balance recovery using external perturbation approaches are quite limited. In one study, Kirker et al. (127) used electromyographic (EMG) recordings of hip abductor and adductor muscles and ground reaction force (GRF) measurements to characterize balance-related responses to motorized sideways pushes to the pelvis (2%–3% body weight) in 13 subjects with acute stroke receiving inpatient followed by outpatient rehabilitation. Tests were administered when subjects were first able to stand unsupported (median of 6 weeks after stroke) and serially for up to 38 weeks later. In comparison with normal control responses, four different patterns of hip muscle activation were found in participants with stroke, reflecting a gradation of paretic limb responses from none through progressively more appropriate and larger muscle activations and GRFs and, on the nonparetic side, none through normal or increased responses. Over time, nine subjects showed changes in hip muscle activation and GRFs that progressed toward normal response patterns. EMG latencies of paretic side hip muscles became shorter in seven subjects, but approached normal values in only three subjects. Functional mobility measures (Rivermead Mobility Index (81,82) and 10-m walk test) generally improved in most subjects with time of testing, but those with the most difficulty recruiting paretic-side responses initially used more compensatory involvement of the nonparetic side and had less recovery. However, this reliance on a compensatory balance strategy early on after stroke did not prevent the recovery of more appropriate muscle activation patterns later in recovery (after 21 weeks).

It has previously been mentioned that the lack of information on the active use of protective limb movements, such as stepping or reaching to contact a stable support surface to maintain balance, represents a gap in knowledge about standing balance recovery after stroke (123). This is striking because accumulating evidence has indicated the importance of stepping for dynamic balance recovery during ADLs (130). Moreover, healthy, community-living older adults at risk of falls have an increased reliance on stepping, rather than feet-in-place balance responses (2,54,130–137). Very limited information about perturbation-induced stepping has indicated that evoked steps were initiated primarily with the nonparetic limb following a lean and release postural perturbation in individuals with subacute stroke (121). In addition, increased lower-limb motor recovery scores and initial weight bearing on the nonparetic limb were associated with increased frequency of paretic limb stepping. An acute stroke case study using the same approach to train protective stepping over six sessions plus physical therapy showed short-term improvements in stance loading symmetry and faster speed of stepping (121,138). During inpatient stroke rehabilitation, increased fall rates were associated with increased use of external assistance and frequency of no step trials, lower foot-floor clearance, and delayed time to initiate stepping responses (139). Whereas these studies provide information about the types of changes in induced stepping especially in the acute stages of recovery after stroke, a more comprehensive understanding of the specific impairments in protective stepping performance among chronic stroke survivors that can be targeted for rehabilitation interventions to improve balance and prevent falls is needed.

Influence of Sensory Information on Balance

Studies manipulating sensory information to perturb standing balance with or without accompanying mechanical disturbances have mostly investigated the effects of visual deprivation or distortion. For example, sensory organization testing of 40 chronic poststroke subjects of at least a year's duration indicated greater balance difficulties with eyes closed on a sway-referenced support surface and when visual and vestibular information was incongruent with vestibular information intact (140). This might indicate that individuals with chronic stroke are excessively reliant on visual input (141), but it does not mean a neglect of the vestibular and proprioceptive information, rather a dependence on these two systems for balance control (142). The ability to select the appropriate sensory information for balance is impaired to a greater extent at 1 year than 1 month following a stroke (143). Impairments in the ability to reweight or integrate multisensory sources of information for standing balance, in addition to muscle weakness, also appear to contribute to A-P balance instability and acute falls during sensory organization testing after chronic stroke (129). Additional information is needed to better sort out whether such observations reflect impaired integration or weighting of multisensory information, compensatory substitution strategies, or other possible deficits in sensorimotor interactions for balance control after stroke and remain to be addressed (123).

Given the sensorimotor asymmetries that characteristically occur after stroke, Marsden et al. (144) examined the potential role of alterations in corticobulbar projections to brainstem output pathways involved in vestibular control of balance in 16 subjects with chronic middle cerebral artery stroke (mean = 31 months after stroke), two subjects with isolated corticospinal tract lesions involving the pons and medulla, and healthy control subjects. Vestibular-evoked balance responses consisting of frontal plane segmental displacements and M-L GRFs were determined after unilateral galvanic vestibular stimulation (GVS) whereas subjects stood with their eyes closed and equally loading both legs. Single-pulse transcranial magnetic stimulation (TMS) was

used to determine the motor-evoked potentials (MEPs) in the pre-activated tibialis anterior muscle while seated indicating corticospinal excitability. Compared with the controls, an abnormal interlimb difference in response symmetry was found in the stroke group despite equivalent load bearing between the limbs but in the presence of greater M-L sway. Head and pelvis displacements and the net horizontal GRF caused by GVS were higher after stroke. Individual GRFs were greater beneath the nonparetic limb compared with the paretic side, though the latter was comparable to the individual limb responses of controls. TMS-evoked MEPs indicated similar interlimb asymmetries for stroke subjects as well as delayed and lower paretic side responses compared to the controls. This TMS delay and GVS asymmetry were correlated ($r^2 = 0.60$) with no effect of lesion location (cortical and subcortical) or time after stroke on the GVS asymmetry. These results indicated that middle cerebral artery stroke disrupts the vestibular control of balance possibly by interrupting corticobulbar connections modulating brain stem balance areas. This perspective was supported by the results from the two subjects with discrete pyramidal tract lesions showing that the responses after a pontine stroke (i.e., above the lower pons) were comparable to middle cerebral artery strokes, but those accompanying a medullary stroke (i.e., below the vestibular nuclei) showed symmetrical GVS responses but asymmetrical TMS responses. Hence, these findings provide new insights pertaining to vestibular-mediated asymmetries of stance control that may contribute to the asymmetries of standing balance that have been consistently identified in most investigations of balance recovery after stroke.

Self-Produced Perturbations and Voluntary Recovery of Balance

Voluntary movements of the body segments and of the whole body exert challenges to sustaining standing balance because of their influences on the COM–BOS relationship as well as reactive forces acting on the body that must be counteracted to stabilize the segments and minimize their perturbation effects on balance. In many situations, voluntary movements are preceded and accompanied by anticipatory postural adjustments (APAs) that serve to minimize in advance the self-produced perturbations to balance induced by the goal-directed action or contribute to the evolving movement (10).

Predominantly cross-sectional studies of individuals with chronic stroke have generally found delayed and reduced APAs of the paretic lower limb muscles and increased activation of the nonparetic leg with reduced speed and amplitude of arm or leg movements that may be accompanied by difficulties with controlling balance (90,101,127,145–151). A longitudinal prospective study (90) determined changes in EMG activation patterns of leg muscles (bilateral hamstrings and soleus) during rapid nonparetic limb arm flexion movements performed while standing in 27 subjects with chronic stroke (mean = 32.7 months after stroke) undergoing a 4-week rehabilitation program. Overall, after a month of rehabilitation treatment, arm acceleration was increased, and EMG-onset latencies in bilateral hamstring muscles occurred earlier relative to arm movement onset and were larger in magnitude, indicating improvements in APA responses. The changes in onset timing and probability of muscle recruitment at posttest approximated the muscle activation patterns of healthy subjects observed previously (149). Across the group, these changes were accompanied by clinically meaningful improvements in functional balance and mobility. However, when subjects were stratified into subgroups based on functional balance scores (Berg Balance Scale, Clinical Outcomes Variables Scale, seven-m comfortable gait speed), 12 subjects with low initial balance scores, which improved at posttest, did not have improvements in paretic muscle activation whereas nonparetic-side APAs did improve. Another ten subjects showed an opposite trend whereby APA characteristics improved but functional measures did not. Respectively, these different patterns of recovery were consistent with the development of a compensatory strategy and true physiological recovery.

During natural speed voluntary leaning of the body as far as possible in different directions without moving the feet, hemiparetic subjects have difficulties in all directions and especially toward the paretic side (152). These problems with recovering weight-shifting ability have been examined in-depth longitudinally in 36 subjects who received inpatient rehabilitation beginning 10 weeks after first-time stroke (intracerebral infarct or hematoma). Voluntary frontal plane weight-shifting guided by visual COP feedback was quantified by COP displacements under each foot when subjects could first stand unsupported for at least 30 seconds and after 2, 4, 8, and 12 weeks later. Weight-shifting speed increased by 33% over the first 8 weeks and stabilized at a level that was slower than that of healthy control subjects. The imprecision of weight shifting continued to reduce by 25% over the 12 weeks of recovery and achieved normative values. Subjects retained a constant level of weight-transfer time asymmetry by being 23% slower toward the paretic leg compared with nonparetic-side transfers. Older age of greater than 65 years and the presence of visuospatial neglect were associated with a greater level of weight-shifting speed asymmetry but not with its recovery. Considering the coordinated interlimb hip abductor–adductor muscle control that normally underlies lateral weight transfer and its impairment after stroke (127,150,151,153), the persistence in weight transfer time asymmetry may be indicative of difficulties with weight shifting to either side, as has been emphasized in other studies (147,150,154,155).

Altering the BOS through stepping or by grasping a stable support surface occurs not only in reaction to an external postural perturbation but also can be engaged voluntarily in anticipation of a perceived threat to stability. Studies of voluntary stepping in individuals with chronic stroke have found that decreased weight bearing on the paretic limb prior to stepping was related to less propulsive force for forward momentum during paretic limb gait initiation (145). Reduced paretic limb propulsive force has also been reported to limit gait initiation speed when stepping with

either limb (156). The first step characteristics can be altered to a greater extent for nonparetic limb stepping when the paretic side is in single limb support (157). In reaction time stepping, step speed was observed to be slower in all step characteristics examined under single and dual task conditions for those with chronic stroke compared with controls (158). Moreover, mildly impaired stroke patients have difficulties with initiating and executing visually triggered step adjustments affecting balance control especially involving the medial direction where balance demands were the most challenging (159).

Falls

Stroke is among the leading risk factors for falls in older adults (160). Between 23% to 73% of community-dwelling older adults with chronic stroke fall once or more within four to six months after discharge from hospital (160,161). Community-based prospective studies have found that a history of stroke increases the risk of falling by two to sixfold (160,162,163) and when controlling for falls among older adults the rate is 1.77 times higher in the stroke population (164). Compared with healthy adults, this population has more than seven times the risk of experiencing a fracture (165).

Despite the contributions of multiple risk factors to falls accompanying aging and the complicating effects of stroke (e.g., environmental hazards, orthostatic hypotension, disorientation, and sedation), it is well recognized that those who fall present greater impairments in balance and mobility functions, which have been consistently found to be among the most important risk factors for falls (131,166–168). Cognition also plays an important role with more incidence of falls in those individuals with left hemiparesis (169,170) and a four-time greater risk of a fall in the first six months. In people with acute stroke (up to one month after stroke) and subacute stroke (one to six months after stroke), falls have been associated with balance and mobility impairments (95,161,171,172), visuospatial deficits, hemineglect (173), and cognitive deficits (95,172,174,175). People with chronic stroke (more than six months afterstroke) who have fallen reported that they were usually either walking or dressing when falls occurred, and they have attributed their falls to loss of balance, misstepping, foot drag related to tripping, or a lack of concentration and poor judgment (176). However, among individuals with chronic stroke, the relationship between balance factors and falls is unclear (92).

For people with chronic stroke living in the community, studies of functional balance and mobility have either found a relationship with falls (176–179) or no relationship (92,160,180,181). Part of the discrepancy in these findings appears to be related to whether or not fall prediction outcomes were focused on single fall events and/or multiple fall events (161,177,179–182). The level of stroke chronicity may also be an influential variable related to functional balance and falls (92,180,181). For example, a retrospective study of falls in 99 community-living subjects with chronic stroke (mean time poststroke = 4 years, range = 1 to 24 years) found that clinical measures of balance (Berg Balance Scale), mobility (gait speed), and cognitive status (Mini-Mental Status Exam) did not discriminate between fallers and nonfallers (92). A major conclusion was that routine clinical tests of balance may not test those aspects required to prevent falling and that more sensitive measures of balance that include large components of reactive dynamic balance are needed. At least for the chronic stroke population, this report, together with the other inconsistencies in the literature, raises some caution when using functional tests of balance and mobility to determine fall risk outcomes.

Currently, relationships between changes in motor control factors affecting standing balance after stroke (impairments and compensations) and the risk of falls are largely unknown. One study (183) investigated acutely induced falls into a support harness following standing-platform perturbations of balance in 44 subjects with single-episode chronic stroke (mean time poststroke onset, about 3.5 years) involving variable lesion sites who were not currently receiving rehabilitation. EMG activity from leg muscles, GRFs, and kinematic recordings were used to characterize postural balance responses with subjects classified as either fallers (required harness support to prevent falling in one or more trials) or nonfallers (no support needed). One-fourth of the subjects fell during the forward displacement trials, leading to a backward balance disturbance with 7% of subjects falling during posterior displacement trials. Comparison of balance responses for the anterior perturbations indicated slower paretic muscle activation timing for the fallers in the tibialis anterior, rectus femoris, and biceps femoris muscles, with longer intramuscular onset timing intervals bilaterally. At perturbation onset, the nonparetic side ankle was more dorsiflexed, the paretic hip more flexed, and the trunk position more anterior for the nonfallers compared with the fallers. At the completion of perturbation, the trunk position was more posterior, and the backward velocity was greater for the faller group compared with the nonfaller group. The muscle activation timing differences and differences in kinematics between the groups were consistent with the possibility that they directly contributed to the large number of fall episodes among the faller group. However, the muscle onset timing delays of approximately 20 to 35 ms and intramuscular delays of less than 20 ms were relatively small, making their potential to directly cause loss of balance somewhat uncertain. However, these changes might compound the overall balance stability deficit. Furthermore, the initial postural conditions adopted by the nonfallers likely provided them with a compensatory mechanical advantage that somewhat offset the backward falling tendency produced by subsequent movement of the platform.

Behavioral Factors

Behavioral factors influencing balance and mobility performance may also be an important determinant contributing to falls after stroke. Fall-related self-efficacy refers to the confidence an individual has in performing routine daily

activities without falling or losing balance (184). An increasing number of studies in this area have reported significant relationships between fall-related self-efficacy (measured by the Falls Efficacy Scale or Activities-specific Balance Confidence Scale) and balance and mobility (185–187) and falls (181,186). It is striking that though balance and mobility performance may not be a determinant of falls in some studies (92,181,186), fall-related self-efficacy is independently associated with balance, mobility, and falls in these reports. A recent longitudinal study following 98 participants with hemiparesis for one year after inpatient rehabilitation revealed balance confidence is lower than controls initially and remains lower than controls after one year (185). The improvement in balance confidence was influenced by the number of falls. Therefore, increased attention should be given to assessing and treating behavioral factors underlying fall-related self-efficacy associated with falls and fractures after stroke.

Site of Brain Lesion

To date, there have been relatively few studies that have examined the relationship between the specific location of the brain lesion causing stroke and the recovery of standing balance. The majority of information has addressed balance outcomes relative to the side of hemispheric stroke. In general, these reports have indicated that acute and more chronic problems with balance recovery are more marked for right hemispheric lesions compared with left-sided insults (189–194). Other studies, however, have not been able to confirm this general finding (99,140,195). Right hemispheric lesion effects on balance have been linked with hemispatial neglect manifested by lack of awareness or acknowledgement of objects or people on the side of the body opposite of the lesion (196). Right hemisphere neural networks are thought to be important for both spatial attention and postural awareness of verticality (196). The perception of visual verticality is often disrupted after stroke and might be an underlying component of balance impairment. For example, visual verticality was tested for 30 individuals with hemiplegia after a single hemispheric stroke within 45 days of stroke, and then at 3 and 6 months after stroke (197). Sixty percent of the participants had an initial inaccurate perception of verticality, and 39% of these recovered during the first three months after stroke. The evolution of visual verticality depended on the side of the lesion where recovery was better in left hemisphere-lesioned patients suggesting that poorer recovery after right-side stroke might be caused by the predominant role of the right hemisphere in spatial cognition contributing to the poorer recovery of balance.

Brain imaging studies (198) in healthy human subjects have implicated a network of cortical neurons activated by vestibular activity (inferior parietal lobe, temporal–parietal junction, posterior insula, and frontal eye fields) mainly in the right hemisphere of right hand-dominant individuals with neglect. This vestibular cortical network may also be involved with spatial orientation of the body relative to gravity (198). It may also play a more general role in representing the physical laws of motion by producing an internal model of gravity that estimates gravitational effects on the body and external objects (199). One such problem involves "the pusher syndrome," in which patients push toward the paretic side, especially while standing, and this may lead to falling (189). Vestibular cortical areas are frequently damaged after right middle cerebral artery stroke, resulting in neglect (140,191,200). Stroke lesions involving parietotemporal and parieto-insular vestibular cortical areas result in major difficulties with balance control (140,191,200). Thus, problems with multisensory integration of balance related information and/or reduced spatial awareness of vertical orientation may be major contributors to deficits in standing balance following stroke (see Chapter 18).

INTERVENTION APPROACHES

Interventions on balance control after stroke include various modalities and intensity of treatment. Some interventions emphasize a task-orientated approach to balance retraining, and others focus on the impairment level of the problem. This section addresses the results of recent intervention studies on standing balance after stroke and is categorized into five areas also found summarized in Table 25.1:

1. Training the neuromuscular system
2. Training using visual feedback
3. Somatosensory re-training
4. Impact of attention: implicit versus explicit training and cognitive strategies
5. External devices

Training the Neuromuscular System

Exercise programs that train the neuromuscular system take on many forms ranging from group, individual, functional training, or impairment-based approaches. Many of the recent research studies incorporated group or station exercises to improve balance in participants following a stroke. Whereas each study focused on a different structure of activities for the intervention, all incorporated functional tasks, such as step-ups, sit-to-stand, lunges, reaching, weight shifts, and walking activities. Others included various brisk-walking activities, obstacle courses, side stepping, marching or functional leg strengthening, and stretching. Some of the stations included tasks that specifically challenge standing balance by narrowing the BOS (foot placement), changing the sensory input (eyes closed, foam surface) or even perturbations by the instructor (93,201–210). Each program was supervised by a trained instructor who provided individually tailored modifications to the prescribed tasks so as to progressively challenge the individual capability of each participant. Varied sensorimotor challenges modified the difficulty level, complexity, and dosage utilized. These challenges allowed each participant the opportunity to develop effective strategies to deal with the many changing environmental conditions that may arise during daily balance tasks. Improvement in strength, static and dynamic balance, and occasionally

Abbreviations: 6MWT, 6-minute walk test; ABC, activities-specific balance confidence scale; AFO, ankle foot orthosis; AP, anterior/posterior; BBS, Berg balance scale; BI, Barthel index; CoP, center of pressure; CV, cardiovascular; DHP, Duke health profile; DGI, dynamic gait index; EFAP, Emory functional ambulation profile; Ex, exercise; FES, falls efficacy scale; FM, Fugl Meyer assessment (LE, lower extremity; B, balance); FOF, fear of falling; FRT, functional reach; GDS, geriatric depression scale; GUG, get up and go (variation of TUG); LOS, limits of stability; MAS, motor assessment scale; MI, motricity index; ML, medial/lateral; NHP, Nottingham health profile; NRCT, nonrandom controlled trial; PASS, postural assessment for stroke; POMA, performance oriented mobility assessment; RAS, rhythmic auditory stimulation; RCT, randomized controlled trial; RMI, Rivermead mobility index; ROM, range of motion; SIS, stroke impact scale; SLS, single leg stance; SOT, sensory organization test; SPPB, short physical performance battery; Tinetti, Tinetti gait and balance; TUG, time up and go.

balance self-efficacy were reported in the studies. Only two studies included an assessment of reactive balance control. After agility training Marigold et al. (93) found that although both groups improved in the clinical outcome measures, the agility group had faster postural reflex onset in the paretic leg compared to controls and had less falls with platform perturbations after interventions. Reactive balance control improved as measured by the ability to step when released from a lean for an individual in the subacute phase after a stroke (121).

Two studies investigated the use of intense practice for improving balance with subjects at least 10 months after stroke (208,211). The training consisted of functional tasks, similar to those listed in the previous exercise studies. Training occurred for three to 6 hours per day for 10 days delivered in one-on-one sessions. Both studies showed improvement in balance with some retention up to three months after training. Although these studies did not use control groups, they support the feasibility of intense practice and the need to offer additional practice to maximize usefulness of treatment interventions.

Numerous studies have investigated the effectiveness of Tai Chi exercise on balance in various populations of older adults (212–216). The majority of the studies have reported improvements in balance and some studies reported changes in proprioception with Tai Chi in older adults (216,217). To date, only two studies have examined the effects of Tai Chi on stroke survivors (204,218). Each of these studies used a different form of Tai Chi for the 12-week duration. One of the studies found that the Tai Chi group did not improve their balance or walking compared to the control group; however, they did show improvements in quality of life (204). In the second study, the stroke group showed significant improvements over control group's limits of stability and reaction time but neither group showed improvement in mobility as measured by the Timed Up and Go. Similarly, Yoga has been used as an intervention to improve balance and showed improvements in balance and a decrease in fear of falling (219). Based on these limited studies, Tai Chi and Yoga appear to be beneficial but not significantly different than other exercise interventions.

Much has been written about treadmill training for gait in many different populations including stroke. Four studies have reported improvement in clinical measures of static and dynamic balance with treadmill training. The interventions varied in intensity and application (body weight, robotic trainer, progressive speed, early vs. late) but reported no difference in balance outcomes between groups or showed improvements with no control group (220–223), except with virtual reality treadmill training. Compared to traditional treadmill training, the virtual reality treadmill incorporating turns had improved stance symmetry and sway excursion during sit to stand. This is in contrast to two studies on walking interventions that showed improvement in balance self-efficacy as measured by the ABC and no change in the balance measure (224,225).

Other studies have investigated the effects of aerobic exercise (226,227), leg cycling (228,229), sit to stand (230), auditory stimulation walking program (231,232) or progressive structured exercise on poststroke survivors (93,201–203,205,206,225,233–238). Only three of these studies examined falls as an outcome measure and two had a decrease in falls (93,208) and one did not change the number of falls (233). Each of these studies included subjects of different stroke duration and different training duration and frequency but all reported improvement in some aspect of balance depending on the clinical balance measure used. The similarities in these interventions are that they require the individual to use their neuromuscular system to move and control their body in challenging tasks. The intensity, duration, and exact activity to produce the most improvement in balance has yet to be identified, but the system must be challenged to change.

Training Using Visual Feedback

Visual feedback training has typically utilized center of pressure trajectory information as feedback to the patient. Commercially available machines, custom computer programs, pressure mats, and electro-goniometers have been used for balance training after stroke to provide the online feedback about movement (239–246). All these studies showed improvement in center of pressure excursion, stability, or limits of stability, and one reported a nonsignificant reduction in falls (240). Most showed improvement in the clinical outcome measure they selected and one study reported an increase in the ABC (242). Use of a single group or unequal treatment intensities and lack of control conditions make it difficult to conclude the direct effect of the visual feedback on the reported changes.

Virtual reality and interactive video gaming have become more prevalent with advances in interactive media technology. A wide variety of applied technology methods have been developed and utilized from limited immersion with simple visual display using 2-D graphics with or without audio feedback to high-end total immersive virtual environments that utilize 3-D stereoscopic multisensory, multiple user experience (247). The potential benefit for these systems may be the ability to easily manipulate the task, safety, more fun, real-time feedback, and varied practice schedules. Virtual reality and interactive video games for balance training after stroke have utilized commercial devices and custom computer programs that offer limited immersion experience (248–252). These studies showed that participants tolerated the experience well and improved in the balance assessment measured. Small sample sizes and unequal treatment intensities limit understanding about the relative effectiveness of such training compared to real world practice.

Utilization of interactive gaming in the clinic has expanded. Application of appropriate games and understanding of the feedback provided will assist the clinician in effective utilization of this new technology into patient care. One study (253) in 2011 provided an analysis of games included in a commercially available gaming system. This analysis included tables of game description, impairments

targeted, and type of feedback provided in each game. Assessment of interactive programs is needed to appropriately match patient needs to selected training approaches.

Somatosensory Retraining

Diminished or altered sensation is a frequent impairment after stroke, and it has been related to reduced standing balance and mobility (98,129,182,254,255). Several studies have shown promising results using sensory retraining of the upper limb (256–259); however, there are relatively few studies that have investigated sensory training for standing balance. One study used functional electrical stimulation of the tibialis anterior muscle of the paretic leg during balance and mobility training and reported an increased toe clearance, but there was a decrease in the self-efficacy surrounding falls prevention measured by the ABC (260). More systematic sensory retraining of pressure detection, hardness, and texture identification under the foot has been reported in three studies (261–263). These studies of sensory retraining in the lower extremity reported encouraging results on changes in sensory measures but little impact on balance. Two of the studies showed improvement of sensory and balance measures over time in subjects with postacute stroke (261,262). However, only one of the studies found a difference in balance measures between the sensory training and control group (263). The positive findings from this study may be attributed to the increased standing time the sensory training group received.

Alteration of visual input is easily accomplished in the clinic by having the patient close their eyes or occluding his or her vision, and improvements in balance were shown in two studies (140,264). One study compared two balance training programs with and without visual cues (140). Compared to the vision-free group, fewer falls were observed in the vision-deprived group with improvement in static standing balance (140). The authors concluded that visual deprivation forces patients to increase their use of somatosensory and vestibular information and a reliance on visual information may be a natural compensatory strategy for dealing with impaired balance early on in the rehabilitation process.

Another simple way to manipulate sensory inputs in balance training is by using soft and firm surfaces. Bayouk et al. (265) used the same exercise program with two groups of chronic stroke survivors. One group performed the exercise with their eyes open; the second group performed the balance tasks with their eyes open and closed and on soft and firm surfaces. The group who performed the exercises with their eyes closed did better in the balance tasks and the 10-meter walk (265). Tilt boards, dimly lighted environments, and uneven or variously textured surfaces are other ways to manipulate sensory inputs in the clinic and challenge the patient to utilize or alternate their use of various sensory systems.

Whole body vibration (WBV) has recently emerged as an intervention that has positive effects on neuromuscular and sensorimotor systems by presumably activating muscles and stimulating sensory receptors (266–269). However, recent studies demonstrate equivocal results regarding the effectiveness of this approach. An investigation of the added benefit of WBV to leg exercises found that, although the treatment was well tolerated, there were no differences in outcomes with the WBV versus exercise alone (270). When WBV alone as an intervention was compared to exercise training to improve balance, gains were seen in balance outcomes that were no greater than exercise training (271,272).

Impact of Attention on Balance Training: Implicit Versus Explicit Training and Cognitive Strategies

Standing balance control requires the integration of multiple systems, the ability to adapt to changes in the task and environment, and some degree of attention (47,50,273). Cognitive deficits after a stroke can occur in the domains of language, orientation, attention, memory, information processing, executive function, and learning. Studies have shown that performance of a dual-task impacts balance in persons after stroke (47,274–276), suggesting that, after stroke, people utilize increased attention to maintain balance.

Current rehabilitation therapies typically involve using many complex and explicit instructions from the clinician on how to perform tasks and evaluation procedures. Recent work involving upper extremity tasks, suggests that this type of information is less helpful and may hinder implicit motor skill learning after stroke (277–279). In a recent study by McCombe Waller et al. (280), implicit training of balance function was investigated in a single cohort of participants after stroke receiving arm training in standing with no explicit cues related to postural control. Gains were found in functional and quantitative measures of balance control. The authors suggested that the improvements in postural control may result from the use of more "automatic" or unconscious processes for balance control given that the attentional focus was on performing the upper extremity task. It has been suggested that training with an attentional focus on postural control may, in fact, be disruptive to the unconscious control processes that subserve these often automatic postural actions (281). Orrell et al. (282) investigated implicit motor learning on a dynamic balance task with and without concurrent cognitive load. They found that all groups (healthy controls and persons after stroke) improved in the balance task, regardless of the task instructions. However, balance performance in the explicit learning poststroke group was impaired during secondary cognitive loading and not impaired in either the implicit learning poststroke group or the control groups. This suggested that providing explicit information may be detrimental to learning and execution of a dynamic balance motor task in some people after stroke. In summary, implicit training of postural control is an alternate intervention option for training balance function in the poststroke population in contrast to more traditional balance interventions that focus on isolated stability and weight shift training with explicit feedback.

Motor imagery has been used as an intervention whereby individuals evoke an imagination of a motor action to improve a particular task. Two studies that have examined motor imagery in conjunction with an existing therapy both showed improvements in postural control and balance (283,284).

External Devices

Assistive devices and lower extremity orthoses are frequently prescribed for individuals after stroke to help with ambulation. These devices have also been shown to increase postural stability (285,286). Canes decrease postural sway with some studies reporting that the quad is more effective in reducing sway (285). However, straight canes and quad canes do not appear to improve symmetrical weight bearing (285). The use of an ankle foot orthosis (AFO), on the other hand, does appear to increase symmetrical weight bearing, decrease postural sway initially, and improve balance, but this effect does not appear to be maintained over the long-term (287–289). One study utilizing a small lift under the stronger lower extremity reported an immediate improvement in symmetry of standing and postural control of individuals with hemiparesis (290).

In addition to external devices worn by patients as assistive devices, external devices have been developed that are used only in training. Recent advances in robotics have led to the development of untethered robotic devices for use in task-oriented training to improve balance control after a stroke (291–293). In one study, three patients used the robotic devices as part of training 1.5 hours at a time, two to four times a week for four weeks. Testing without the device after training showed gains in all three patients in gait parameters, Timed Up and Go, and the 5x's sit-to-stand outcomes (294). Similarly, a case study using a robotic knee orthosis involved three patients training for 18 sessions over a 6-week time period as part of task-oriented mobility training. All subjects demonstrated gains in both the Berg balance scale and the six-minute walk (292). In summary, canes, ankle foot orthosis, and lifts appear to be beneficial for improving standing balance in some situations by providing external support of body load and by increasing the BOS area; however, this may interfere with protective responses of the lower or upper limb (130). Newer robotic external devices worn during task-oriented mobility training show promise for improving balance control without the device after training.

Summary

The studies of standing balance rehabilitation after stroke presented in this section utilized a variety of intervention approaches. The common theme has been one of task-oriented practice under various environmental, sensory, motor, and cognitive challenges. Dosages varied between the studies from intensely concentrated one-on-one rehabilitation sessions to group activities held twice per week. Guidelines for effective standing balance training following stroke remain unclear. However, one might consider two simple straightforward modifications to augment current balance training programs. First, incorporate more training activities with vision occluded as a method to challenge an individual to increase their awareness and use of other sensory modalities. Second, minimize the amount of explicit information that is given during a treatment session to allow the person time to process through the implicit procedural learning system the balance strategies that work best for them.

PROTECTIVE STEPPING: A MODEL FOR LINKING DYNAMIC BALANCE CONTROL, FUNCTIONAL OUTCOMES, AND RISK OF FALLS

As discussed earlier in this chapter, falls and associated injuries related to problems with standing balance are common and are considered some of the most debilitating secondary complications accompanying stroke. The relationship between changes in balance control factors, functional balance, and mobility, and falls in chronic stroke is poorly understood. For example, a retrospective study (92) found that clinical measures of balance, gait mobility, and cognitive status were not associated with falls. A major conclusion was that routine clinical tests may not assess the aspects of balance required to prevent falls and that more sensitive measures of balance that include large components of reactive dynamic balance are needed (92). To a large extent, such current deficiencies in knowledge that limit the development of the most effective rehabilitation interventions to improve standing balance and prevent falls and related disabilities after stroke are likely caused by the lack of comprehensive approaches linking physiological measures of dynamic balance, functional performance, and falls.

The scarcity of information about the active use of limb movements, such as stepping or reaching to contact a stable support surface as a standing balance recovery mechanism after stroke appears to be importantly related to the foregoing observations.

From a biomechanical standpoint, stepping modifies the BOS in relation to the position and motion of the COM to maintain balance. Protective stepping may be initiated in anticipation of an impending loss of balance or fall or in reaction to sensorimotor events following external perturbations to balance. Contrary to traditional views, reactive stepping may be initiated well before the COM reaches the limits of the BOS (2). In addition, protective stepping shares many of the requirements of ongoing gait and therefore is an attractive framework for identifying physiological changes underlying impaired balance and mobility and falls among people with chronic stroke.

Measures of Protective Stepping Predict Future Falls in Healthy Older Adults

From our ongoing studies of generally healthy, community-living older adults at risk for falls, we have identified two

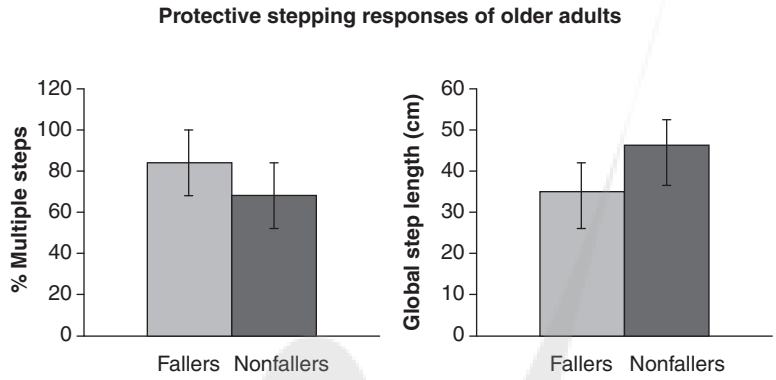

FIGURE 25.2 Group means 1 SD for prospectively identified healthy older fallers (n = 19) and nonfallers (n = 32) showing group differences between (left) first-step global length combining the A-P and M-L directions (two-sample t-test: $P = .003$) and (right) between the percent of the total balance perturbation trials with multiple recovery steps in response to lateral waistpulls K-W: ($P = .018$).

Abbreviations: A-P, antero-posterior; M-L, medio-lateral.

key performance markers of protective stepping that are predictive of prospectively identified falls, including the percentage of trials with multiple recovery steps and first-step global length combining the A-P and M-L directions (135). These measures reflect the effectiveness of stepping to arrest the motion of the COM at foot landing (137). We have previously demonstrated that the distance between the COM and the margin of the BOS, coupled with the COM velocity, is importantly related to effective balance recovery through stepping (2,295). These safety margins are smaller for older fallers than nonfallers (2,295). Hence, step placement relative to body position and motion is a fundamental means by which balance is maintained. Because stepping is often impaired in chronic stroke, we propose that multiple stepping behavior and impaired step length regulation (as well as other factors) will be importantly related to clinical assessments of impairments, functional performance, and falls.

Data from our previous studies of protective stepping using waist-pull perturbations of standing balance in 51 generally healthy, community-living older individuals (mean age 73.3 years) included subjects' prospective fall history for a period of 1 year after testing (135). Logistic regression analyses determined potential predictors of falls. Fall status was included as the dependent variable after dichotomization. Independent variables included percent total trials with multiple steps (rather than a single-recovery step) and first-step global length following multidirectional waist-pull perturbations that always induced stepping. Because controlling sideways balance during multidirectional stepping may be particularly problematic for older people (54,296–298) and is largely dependent upon hip joint abduction–adduction torques (296,298), we also evaluated clinical measures of isokinetic hip abduction (AB) torque (60 degrees through a range of motion of 0–30 degrees).

Overall, 74% (14 out of 19) of the fallers and 31% (10 out of 32) of the nonfallers used multiple steps in 100% of the trials (chi square: $P = .003$) in response to lateral perturbations. Figure 25.2 shows the percent total trials with multiple recovery steps used by the fallers and nonfallers (K-W: $P = .018$). The fallers also had a shorter (two-sample t-test: $P = .003$) first-step global length (34.0 cm 13.9 sd) than the nonfallers (46.1 cm 12.3 sd). Differences in hip strength further discriminated between the groups, whereby fallers produced lower peak hip AB torque than nonfallers (t-test: $P = .008$).

The percent trials with multiple steps were first entered into the single-variable regression model. Then, global-step length was added using a forward stepwise method. The percentage of trials with multiple steps was the strongest predictive value for falls (odds ratio = 6.160, $P = .005$). Fallers who used multiple steps in 100% of the trials were 6.2 times more likely to fall than individuals who did not always use multiple steps. Single variable analysis also showed that, for every decrease of 10 standardized units in step length, the odds of falling increased 2.0 times (odds ratio = 2.028, $P = .006$) and, for every decrease of 0.1 standardized units of peak isokinetic hip AB torque, the odds of falling increased 1.8 times.

The percent trials with multiple steps were combined with global-step length in the two variable models. This combination was not better in predicting fall status than the single-variable models. However, the percent multiple step-hip AB strength model was significantly ($P = .016$) improved over the percent multiple step model alone. Subjects who used multiple steps to recover their lateral balance 100% of the time and had lower peak isokinetic hip AB torque generation were 5.9 times more likely to fall.

We also determined the cutoff scores that provided the highest combination of sensitivity and specificity for predicting one or more falls. For example, in the protective stepping assessment, a cutoff score of 100% multiple steps resulted in 70.5% of the subjects being correctly identified as fallers or nonfallers, a sensitivity of 74%, and a specificity of 69%.

Protective Stepping Performance in Adults With Chronic Stroke Resembles Performance for Healthy, Older Fallers

The kinetic and kinematic characteristics of stepping following waist-pull perturbations of standing balance were evaluated in 10 independently ambulatory subjects with single-episode chronic stroke (mean age = 59.6 years). Three waist-pull trials at a single magnitude level (9 cm, 18 cm/s, 360 cm/s/s) were randomly applied in each of three directions:

- Straight forward (0 degrees)
- Diagonally forward at 30 degrees to the right (–30 degrees)
- To the left (+30 degrees)

Subjects were placed in a safety harness and instructed to react naturally to prevent falling. Overall, regardless of the direction of perturbation, subjects' first step was taken with their nonparetic leg in 66% of the trials. This indicated that they either selected to use and/or were limited to using their paretic leg more often for single-limb support rather than for relocating the BOS during the initial balance recovery step. It was anticipated that forward diagonal perturbations would involve stepping with the passively unloaded leg on the opposite side. This was mostly seen when the nonparetic leg (77% of trials) compared with the paretic leg (52% of trials) was unloaded. However, the use of the paretic leg was greater when that leg was passively unloaded compared to the straight forward perturbations (52% vs. 33%). This indicated that the perturbation direction may be a useful way to encourage forward stepping with the paretic leg.

The data shown in Figure 25.3 further indicates that, regardless of perturbation direction, subjects used multiple recovery steps in a high percentage of the total trials (pulls forward and toward paretic side = 70%, pulls straight forward = 83%, pulls forward and toward nonparetic side = 97%) that generally equaled and exceeded that of older fallers (83%) and occurred with a smaller magnitude of perturbation. Notably, steps taken in response to forward-diagonal waist-pulls toward the nonparetic side were almost always multiple recovery steps. This likely occurs because pulls to the nonparetic side cause passive loading of the nonparetic limb (and paretic limb unloading) that further complicates nonparetic limb stepping. In this case, subjects crossed over the midline of the body with a medially directed paretic limb step, which severely challenged their control of step landing.

In addition to the high incidence of multiple stepping responses, the initial global-step length (combined A-P and M-L directions; Figure 25.3) was shorter for paretic limb steps than for the step length identified for older fallers (Figure 25.2). These data from stroke subjects 13 years younger than the mean age of the older fallers suggest that they are at high risk of falling caused by impaired stepping performance.

To more fully determine the relationship between dynamic balance control and the functional impact of impairments in protective stepping and risk of falling, clinical assessments of balance and mobility and prospective fall data are needed. Falls are tracked through monthly postcards mailed in at the end of each month for one year after testing. For each reported fall, a follow-up telephone call is made to ask about precipitating factors, and, if any injuries were sustained, the medical care sought. The use of monthly mail-in reporting and follow-up is among the most rigorous approaches (299).

Implications and Importance

Application of this or other models to people with stroke will help to fill important deficiencies in knowledge, linking physiological measures of dynamic balance, functional performance, and falls. More elaborate applications of the framework would

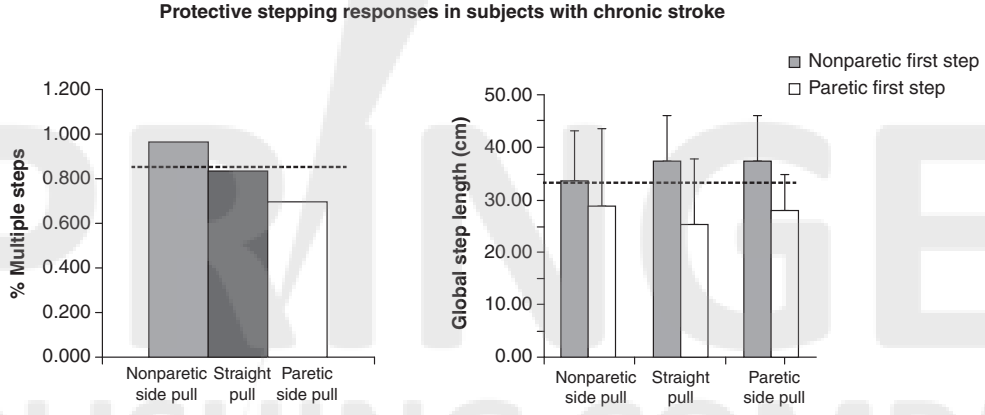

FIGURE 25.3 Means 1 SD for subjects with chronic stroke (n = 10) showing (left) the percent of the total trials with multiple recovery steps for each waist-pull direction and (right) the first-step global length (combined A-P and M-L displacement) for paretic and nonparetic limb steps for each direction of waist-pull perturbation. The broken horizontal lines indicate the levels of healthy elderly faller performance.

Abbreviations: A-P, antero-posterior; M-L, medio-lateral.

include assessing other potentially important factors such as changes in sensory systems, patterns of paresis, individuation of multijoint control, spasticity and joint mobility, response timing and multisegmental coordination, adaptive capacity, attention, and hemispatial neglect. Moreover, comprehensive approaches that attempt to link impairment level outcomes with functional and disability level outcomes, along with ecologically valid tests of dynamic balance recovery, will provide empirically grounded and evidence-based foundations for designing the most effective rehabilitation approaches to improving balance control, functional balance and mobility, and preventing falls.

RESEARCH FRONTIERS

This section provides a glimpse of selected research frontiers that have bearing on understanding the recovery of standing balance after stroke and on the development of the most effective rehabilitation interventions to enhance balance recovery and reduce related disabilities.

Cortical Control of Balance

A growing number of studies have begun to identify the involvement of cerebral cortical areas in the control of standing balance, a role that has been traditionally associated with spinal cord and brainstem systems. Using neural probes such as electroencephalography, positron emission tomography, or transcranial magnetic stimulation, studies of healthy individuals have identified contributions of cortical-mediated activity during standing (27), preceding or following external perturbation of stance (22–24,26,59,300), and accompanying anticipatory postural adjustments during voluntary tasks (25,29,30,33). Although understanding the role of cortical areas in regulating standing balance is still quite limited, this area of investigation is of obvious potential significance to balance recovery after cerebral stroke. Thus, balance-related cortical involvement likely influences several important aspects of standing regulation that may be impaired after stroke, including:

1. Response preparation, planning, and selection
2. Adaptive control mechanisms
3. Attention and other cognitive resources

A recent cross-sectional study, using event-related functional near-infrared spectroscopy examined the cortical involvement in balance recovery after hemiplegic stroke by determining longitudinal regional cortical activation (301). Cortical activation during external postural perturbations was studied in 20 postacute patients with subcortical stroke undergoing inpatient rehabilitation. Perturbation-related activation of the supplementary motor area (SMA) of the affected and unaffected hemispheres was significantly increased after intensive rehabilitation. The enhanced activity in the SMA of the unaffected hemisphere was associated with improved balance function as measured by the Berg balance scale. These findings suggested that the SMA plays an important role in postural balance control, and may be important for balance recovery after hemiplegic stroke. Additional information about the contributing roles of altered cortical mechanisms after stroke and their potential to be modified in the course of functional recovery by rehabilitation interventions such as those being applied to the upper limb (302–306) would be useful for developing the most effective balance intervention programs.

Changes in Skeletal Muscle

It is striking that there have been very few studies of fundamental physical and physiological properties of skeletal muscle after stroke, particularly as they relate to function and the recovery of balance and mobility. However, recent evidence from muscle biopsy (307) has indicated substantial structural and metabolic changes in muscle after stroke, including gross atrophy and shift to fast myosin heavy chain in paretic leg muscle that is associated with gait deficit severity. Evidence also suggests that inflammatory pathway activation and oxidative injury could lead to wasting, altered function, and impaired insulin action in skeletal muscle (307) (see Chapter 11 for further discussion).

Other work (308) using computed tomography to examine changes in muscle composition in 60 subjects with chronic stroke demonstrated 20% lower muscle cross-sectional area and 25% higher intramuscular fat area in the paretic thigh compared to the nonparetic thigh. In older adults without stroke, this low-density lean tissue (fat infiltration) is associated with lower physical fitness levels (309,310) and is implicated in muscle weakness (reduced contractile capacity) and reduced balance function (44,55,140,274,309–313). Few studies have examined the relationship between muscle structural changes and deficits in the paretic muscles. Muscle atrophy is evidence after stroke, and there is a correlation between quadriceps muscle atrophy and knee extensor torque deficits in the paretic limb (314). Importantly, exercise training can modify or reverse skeletal muscle abnormalities in people with chronic stroke (315). Ryan et al. (316) demonstrated the benefits of resistance training on skeletal muscle in participants 6 months after the stroke in a 12-week resistance training program. In the paretic limb, mid-thigh cross-sectional muscle area increased by 13%, maximum leg press strength increased 33%, and paretic knee extension increased by 56%, with a significant reduction in mid-thigh intramuscular fat.

Other changes in the paretic skeletal muscle properties that may contribute to balance deficits are decreased pennation angle (317,318), decreased muscle fiber length (317,318), and changes in tendon length (319,320). However, there are no studies examining the relationship between balance deficits and muscle property changes. Therefore, it would be important to determine the extent to which changes in skeletal muscle after stroke are contributing to balance problems. Further insights into this area could potentially shift or expand the focus of balance and mobility rehabilitation interventions by emphasizing the mitigating roles of muscle properties and mechanisms.

Balance Recovery: Physiological and Compensatory

Difficulty with identifying and understanding balance recovery following stroke is further complicated by the presence of what are commonly thought to be compensatory mechanisms or behaviors that often develop together with improvements in motor control factors that normally contribute to sustaining balance, thought to represent true physiological recovery. In practical terms, it is likely that the two recovery states and their overlap represent a continuum of available solutions that the balance system uses to sustain the COM position and motion within the actual or projected stability limits defined by the BOS conditions.

An intriguing parallel situation to the recovery of balance exists for the recovery of upper limb function in chronic stroke, whereby an individual's potential for functional recovery of limb use can be predicted from neurophysiological (TMS) and imaging (fMRI) measures of neural capacity (321). A major finding of this work was that, in subjects without TMS motor-evoked potentials (MEPs) and a hemispheric cortical asymmetry level that exceeded a critical cutoff value, no functional gains in arm motor recovery were possible with practice training. In contrast, those individuals for whom MEPs could be elicited and who had lower cortical asymmetry were capable of arm motor improvements with training. Thus, corticospinal tract integrity predicted the clinical potential for functional arm recovery in people at about three years after the time of stroke onset. One suggestion was that this approach can be used to help formulate goals for rehabilitation and identify patients for particular types of rehabilitation programs. The applicability of the findings with respect to true recovery and compensatory recovery processes is that those individuals identified to have residual neural capacity could be selected for programs emphasizing motor control factors whereas those with limited capacity might emphasize alternative compensatory solutions. If, as it appears, cortical areas are extensively involved in the control of standing balance (59,60), then a similar, though possibly modified, algorithm could be developed to assess the balance recovery process. Furthermore, from a recovery standpoint, evidence from animal models suggests that a time-limited window of neuroplasticity occurs after stroke where the greatest gains in recovery are likely to occur (322,323). Thus, the challenge for improving motor recovery and balance control following stroke is to determine how to optimally involve and modify residual and intact neuronal networks to enhance recovery from impairment and to develop compensatory strategies to improve function. To expand beyond the neural basis of recovery, it would also be informative to identify similar biological and physiological markers of skeletal muscle capacity and cognitive capacity after stroke to more fully capture the multifaceted nature of standing balance control problems. Overall, this line of investigation is an attractive and important research frontier for advancing the understanding and optimization of the functional recovery and rehabilitation of balance and mobility after stroke.

SUMMARY

The rapid expansion of recent scientific and clinical knowledge has driven the field of rehabilitation to an unprecedented level of growth and understanding. At the forefront of these efforts has been the increasing development of interdisciplinary approaches blending clinical, experimental, and technological expertise. Inherently, the complex and multifaceted nature of the human standing balance system and the challenges to balance rehabilitation will continue to require such integrated approaches to identifying the different factors contributing to balance problems and the means by which they can be effectively treated. In this chapter, we have synthesized current information derived from many of these different approaches. In doing so, we have attempted to identify those areas in need of additional information, areas where information is lacking, and some promising newer areas of inquiry.

ACKNOWLEDGMENTS

The research presented in the section "Protective Stepping: A Model for Linking Dynamic Balance Control, Functional Outcomes, and Risk of Falls," was supported by grants from the National Institutes of Health/National Institute on Aging (grant R01AG16780) to Mark W. Rogers and by the Foundation for Physical Therapy to Carolee J. Winstein.

V

POSTSTROKE COMPLICATIONS AND THEIR TREATMENT

26

Secondary Prevention of Ischemic Stroke

Joshua Z. Willey and Karen L. Furie

Survivors of a first-ever stroke or transient ischemic attack (TIA) are at high risk for recurrent stroke as well as myocardial infarction (MI) and mortality. Only a small proportion of patients with ischemic or hemorrhagic stroke will be eligible for acute therapy, and thus the greatest impact can be made through prevention. Recurrent stroke, whether symptomatic or silent, increases the morbidity and mortality associated with cerebrovascular disease. Assessment of stroke risk factors and etiology allows for tailored approaches to stroke prevention. It is critical to assess the cardiovascular risk profile and initiate aggressive management of vascular risk factors in all patients (1). Adequate treatment and risk reduction depends on a rapid and accurate classification of the cause of ischemic symptoms, regardless of whether they are transient or permanent (Table 26.1) (2–4).

THERAPEUTIC APPROACH

Large Artery Atherosclerosis

Extracranial Internal Carotid Disease

The benefit of carotid endarterectomy (CEA) was established by three prospective randomized trials: the North American Symptomatic Carotid Endarterectomy Trial (NASCET) (5), the European Carotid Surgery Trial (ECST) (6), and the Veterans Affairs Cooperative Study Program (7). These studies compared endarterectomy plus medical therapy with medical therapy alone. Among symptomatic patients with TIA or minor strokes and high-grade carotid stenosis (greater than 70%), there is overall a significant absolute (from 26.2% to 9% at 2 years) and relative risk (RR) reduction of recurrent stroke with a favorable number needed to treat (NNT = 17). Imaging of the carotid artery can be performed with a variety of modalities, including ultrasound, CT angiography, and MR angiography (Figure 26.1).

For patients with symptomatic carotid stenosis between 50% and 69% (moderate category), the results from NASCET demonstrated a lesser magnitude of benefit with CEA as compared to medical therapy (8). Patients over 75 years old, male, suffering from a recent stroke (rather than TIA), and with hemispheric symptoms are the ones deriving the greatest benefit from CEA. Intracranial stenosis, absence of leukoaraiosis, early surgery, and the presence of collaterals were also associated with better outcome (6,8). There was no significant benefit with surgery if the stenosis was less than 50%. More contemporary data have suggested that the benefit is greatest with early performance of surgery in an otherwise stable patient in view of the approximate 1% per day risk of stroke in the first 2 weeks (9). Emphasizing the importance of identifying symptomatic internal carotid artery stenosis, rapid-access TIA clinics can significantly reduce the risk of subsequent stroke, primarily by improving access to rapid carotid imaging and subsequent intervention (10–12). Stroke or TIA patients awaiting endarterectomy benefit from other maximal medical therapies to aggressively manage risk factors, notably antithrombotic medications and statins (1). After carotid revascularization, patients will continue to benefit from aggressive management of all other traditional cardiovascular disease risk factors.

However, in patients with complete carotid occlusion, CEA is not technically possible. Older (13) and recently completed trials (14) of extracranial–intracranial (ECIC) bypass surgery showed no benefit of surgery, even when perfusion failure was identified by advanced imaging techniques not readily available in most centers

The use of carotid artery stenting (CAS) has been investigated in multiple registry-based studies, as well clinical trials, because of the perceived lower perioperative morbidity, particularly as related to MI. The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial randomized 334 patients to endarterectomy or stenting with the use of an embolic protection device (15). Most of the benefit was detected in the lower risk of MI for the stent compared with the higher surgical risk of endarterectomy. Two randomized, multicenter trials (EVA3S and SPACE) compared complication rates and long-term complications between CAS and CEA in patients with a symptomatic carotid stenosis of at least 60%. EVA3S aimed to show superiority; the study was stopped prematurely after the inclusion of 527 patients because of excessive stroke risk in the CAS cohort, despite the obligatory use of cerebral protection devices. The 30-day incidence of any stroke or death was 3.9% after endarterectomy and 9.6% after stenting; the RR of any stroke or death after stenting as compared with endarterectomy was 2.5 (95% CI, 1.2 to 5.1) (16). In contrast, SPACE aimed to show noninferiority between the two

Unknown/Cryptogenic (30%)

Source: From Refs. (2,4).

interventions and included 1,183 patients in the analysis. The rate of death or ipsilateral ischemic stroke from randomization to 30 days after the procedure was 6.8% with CAS and 6.3% with CEA (absolute difference 0.51%, 90% CI –1.89% to 2.91%) (17). The Carotid Revascularization Endarterectomy vs. Stenting Trial (CREST) enrolled both symptomatic and asymptomatic patients and demonstrated that CEA and CAS are equivalent at preventing the combined end point of stroke, MI, and death (18). In that trial CAS was associated with a higher risk of periprocedural stroke, while CEA was associated with a higher risk of MI. In subgroup analysis, patients over the age of 70 seemed to derive a greater benefit from CEA. The International Carotid Stenting Study (ICSS) was performed in Europe and enrolled patients with only symptomatic ICA stenosis. Similar to CREST, investigators showed similar increased rates of neurological complications in the CAS arm compared to CEA, with the overall results favoring CEA (19).

At present, CAS is recommended in selected patients in whom the stenosis is difficult to access surgically and patients with high surgical risk, radiation-induced stenosis, or restenosis after CEA. For patients with extracranial vertebrobasilar disease, medical treatment should be the first choice (antithrombotics, statins, and management of other risk factors). In exceptional circumstances, when patients continue to have symptoms despite maximal medical therapy, endovascular treatment of extracranial vertebral artery origin disease (20) may be considered.

Intracranial Atherosclerosis

High-grade symptomatic intracranial atherosclerosis (ICA) is associated with a high risk of recurrent ischemic stroke. In the Warfarin and Aspirin for Symptomatic Intracranial

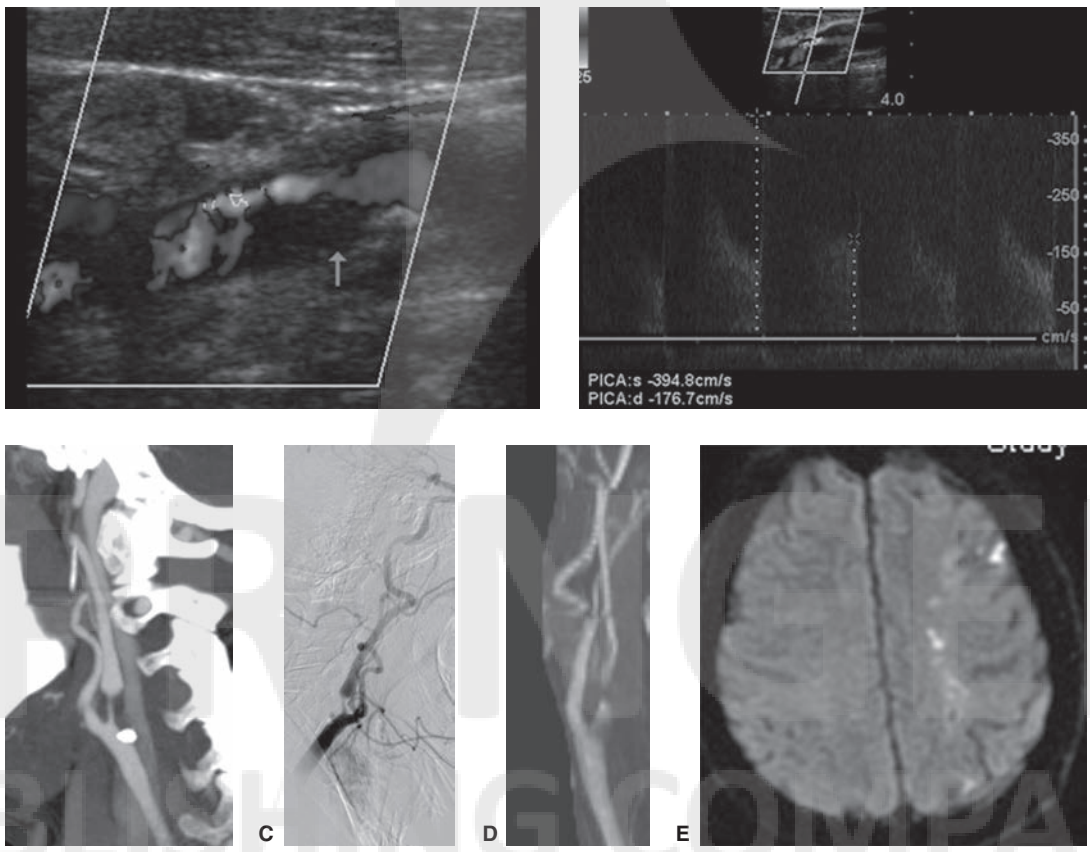

FIGURE 26.1 Imaging of symptomatic internal carotid artery atherosclerosis. (A) Carotid duplex showing plaque and associated elevated velocities (390 cm/s systolic and 177 cm/s diastolic). (B) CT angiography. (C) Digital subtraction angiography. (D) MR angiography. (E) MR image showing left hemispheric infarction.

Disease (WASID) trial, investigators compared high-dose aspirin (1300 mg daily) to adjusted-dose warfarin; the trial was stopped early because of an excess of mortality in the warfarin arm (21). Subgroup analyses in WASID identified those at high risk for recurrent stroke, including patients with stenosis greater than 70% and among patients with blood pressure (BP) that is not controlled to below 140/80 mmHg.

These high-risk subgroups were included in the Stenting and Aggressive Medical Management for Preventing Recurrent Stroke in Intracranial Stenosis (SAMMPRIS) trial in which patients were randomized to stenting and best medical therapy versus best medical therapy. The medical arm of the trial was novel in including a comprehensive program to reduce the low-density lipoprotein-cholesterol (LDL-C) to less than 70 mg/dL with high-dose statins, tight glycemic control, counseling on exercise and tobacco cessation by a nurse over the phone, target BP less than 140/80 mmHg (lower for diabetics), and treatment with dual antiplatelet agents, aspirin, and clopidogrel for 90 days (22). The SAMMPRIS trial was stopped early due to an excess number of new strokes in the stenting arm (23). Many of the new strokes occured in the posterior circulation and in the territory of perforating arteries, while the medical arm had a lower than expected stroke risk compared to historical baseline from WASID; on long-term follow-up, the risk of stroke remained higher in the stenting arm (24). Therefore, *at this time there is no clear role for routine intracranial artery stenting in the treatment of symptomatic arterial stenosis.*

Cardiogenic Cerebral Embolism

Patients with cardiac conditions such as atrial fibrillation (AF), valvular heart disease, acute MI, cardiomyopathy, patent foramen ovale (PFO) with atrial septal aneurysm, left ventricular dysfunction, and other structural diseases have an increased risk of presenting a first-time ever and recurrent stroke and/or TIA. These cardiac conditions are highly prevalent in the population at risk for stroke, though not all are associated with the same degree of recurrent stroke and not all require anticoagulation. These patients often have multiple vascular risk factors in addition to the cardiac source of embolism. In some cases, this potential dissociation can make the selection of an antithrombotic agent or a decision regarding an intervention complicated. Table 26.2 outlines antithrombotic treatment recommendations for cardioembolic stroke from the American Heart Association secondary prevention guidelines (1).

Atrial Fibrillation

More than 75,000 cases of stroke per year are attributed to AF. Multiple clinical trials have demonstrated the superior therapeutic effect of warfarin compared with placebo in the prevention of thromboembolic events among patients with nonvalvular AF (25). The efficacy of warfarin has an overall RR reduction of 68% (95% CI, 50 to 79). Warfarin has also been shown to be relatively safe and the optimal INR (international normalized ratio) range for anticoagulation appears to be 2.0 to 3.0 (26,27).

There is no evidence that combining anticoagulation with an antiplatelet agent further reduces the risk of stroke compared with anticoagulant therapy alone, though it does significantly increase the risk of bleeding (28). Novel anticoagulants have now entered the market and can be divided into direct thrombin inhibitors (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban). These three agents were shown to be statistically noninferior compared to warfarin and were associated with fewer complication rates (29–31). A major limitation of these agents, however, has been the inability to reverse their anticoagulant effect and the limited data on patients with renal dysfunction; dabigatran has also been associated with a possible increased risk of MI (32), and cannot be crushed to be administered through enteral means. The combination of aspirin and clopidogrel may be considered for warfarin-ineligible patients, with marginal reductions in absolute risk reduction in stroke compared to aspirin and associated higher hemorrhagic complication rates (33,34).

Exclusion of the left atrial appendage where many of the thrombi form in AF, with either an endovascular or external device, was an attractive alternative to treatment for patients ineligible for warfarin. Though the first trial proved the equivalency of warfarin to the Watchman device (35), a subsequent trial is ongoing and the device has not been FDA approved. An external device is available on a case-by-case basis as a humanitarian device exemption (HDE).

In general, the guidelines for prevention of stroke in patients with ischemic stroke or TIA recommend initiation of oral anticoagulation within two weeks of an ischemic stroke or TIA. In patients with large infarcts, hemorrhagic transformation of an ischemic stroke, or uncontrolled hypertension, additional delays may be appropriate.

Valvular Heart Disease

Rheumatic Mitral Valve Disease. Recurrent embolism occurs in 30% to 65% of patients with rheumatic mitral valve disease who have a history of a previous embolic event. Multiple observational studies have reported that long-term anticoagulant therapy reduces the risk of systemic embolism in patients with rheumatic mitral valve disease (1).

Mitral Valve Prolapse. Mitral valve prolapse (MVP) likely reflects a normal variant rather than a single disease process. Despite years of research, the symptomatology and significance of MVP remain controversial (36). No randomized trials have addressed the efficacy of selected antithrombotic therapies for this specific subgroup of stroke or TIA patients.

Patent Forament Ovale

PFO is a congenital cardiac atrial defect that may provide a conduit for peripheral venous clots to be shunted to the cerebral arterial circulation. The prevalence of PFO is approximately 25% (37). Patients with PFO-associated strokes tend to be younger and are less likely to have traditional

TABLE 26.2 Recommendations for Patient With Cardioembolic Stroke Types

RISK FACTOR	RECOMMENDATION	CLASS/LEVEL OF EVIDENCE
Atrial fibrillation (AF)	Anticoagulation with adjusted-dose warfarin (INR range 2.0–3.0) is recommended for patients with ischemic stroke or TIA with persistent or paroxysmal AF.	Class I, Level A
Valvular heart disease	Long-term warfarin therapy is rational with adjusted dose (INR 2.0–3.0) whether or not AF is present.	Class IIa, Level C
Rheumatic mitral valve disease	Antiplatelet agents should not be added to warfarin, to avoid additional bleeding risk.	Class III, Level C
	For patients who have a recurrent embolism while receiving warfarin, adding aspirin (81 mg/day) is suggested.	Class IIa, Level C
Mitral valve prolapse (MVP)	Long-term antiplatelet therapy is reasonable.	Class IIa, Level C
Mitral annular calcification (MAC)	Antiplatelet therapy may be considered for patients with MAC not documented to be calcific.	Class IIb, Level C
	For patients with mitral regurgitation resulting from MAC without AF, antiplatelet therapy or warfarin may be considered.	Class IIb, Level C
Aortic valve disease	Antiplatelet therapy may be considered for patients who do not have AF.	Class IIa, Level C
Prosthetic heart valves	Oral anticoagulants are recommended for patients with modern mechanical valves (INR 2.5–3.5).	Class I, Level B
	For patients with mechanical valves who have an ischemic stroke or systemic embolism despite adequate therapy with anticoagulants, adding 75–100 mg/day of aspirin (INR 2.5–3.5) is rational.	Class IIa, Level B
	Anticoagulation with warfarin (INR 2.0–3.0) may be considered in patients who have bioprosthetic valves.	Class IIb, Level C
Acute MI and left ventricular thrombus	For patients with ischemic stroke caused by an acute MI in whom LV mural thrombus is identified by cardiac imaging, oral anticoagulation is reasonable (INR 2.0–3.0) for at least 3 months and up to 1 year.	Class IIa, Level B
	Aspirin should be used concurrently for the patient with ischemic coronary artery disease during oral anticoagulant therapy in doses up to 162 mg/day.	Class IIa, Level A
Cardiomyopathies	In this group of patients, either warfarin (INR 2.0–3.0) or antiplatelet therapy may be considered for prevention of recurrent strokes.	Class IIb, Level C
Patent foramen ovale (PFO)	Antiplatelet therapy is reasonable to prevent a recurrent stroke.	Class IIa, Level B
	Warfarin should be used in patients with other indications for oral anticoagulation.	Class IIa, Level C
	PFO closure may be considered for patients with recurrent cryptogenic stroke despite medical therapy.	Class IIb, Level C

risk factors such as hypertension, hypercholesterolemia, or smoking (38,39). PFO can be detected by transthoracic echocardiography using agitated saline injection, though transcranial Doppler with agitated saline injection may be superior (40). The diagnosis of a hypercoagulable state or deep venous thrombosis in the lower extremities in conjunction with the presence of PFO raises the suspicion of a causal role in stroke (41). There has not been a definitive study to establish best medical therapy in the absence of venous thrombus in the young. However, the PICSS study showed no benefit from warfarin in a group of older, conventional stroke patients enrolled in the WARSS trial (42). The question of optimal management remains unresolved. The CLOSURE I trial, and other recently completed trials, have not demonstrated the benefit of percutaneous closure on stroke prevention (43–45); in these trials the overall risk of recurrent stroke is small, particularly among those for whom the PFO is most likely to be causal. Indices have been proposed to identify those in whom PFO is most likely to be causally related to stroke; in most instances these are young patients without stroke risk factors (46). These same patients are at low risk of recurrent stroke.

Noncardioembolic Stroke or TIA

Recently published trials have contributed to the large body of evidence supporting the benefit of antiplatelet agents for stroke prevention in patients with history of noncardioembolic ischemic stroke or TIA. In a meta-analysis of 21 randomized trials comparing antiplatelet therapy with placebo in 18,270 patients with prior stroke or TIA, antiplatelet therapy was associated with a 28% RR reduction in nonfatal strokes and a 16% reduction in fatal strokes (47). In cryptogenic stroke there is often a high suspicion for undetected AF, particularly among patients with infarcts in the cortical surface or cerebellum. Recent data with prolonged rhythm monitoring for up to 30 days with a surface monitor, or for longer periods with an implantable monitor, have demonstrated detection rates for AF that are approximately 30% across multiple studies (48). At many institutions patients with cryptogenic stroke will be discharged with one of these monitors if they are eligible for warfarin and were detected with AF, although the clinical significance of such rare and difficult-to-detect AF remains to be tested.

Antiplatelet Agents

Aspirin

Two randomized controlled trials have demonstrated that aspirin in doses ranging from 162 to 300 mg/day administered within 48 hours of ischemic stroke reduced the rate of recurrent stroke within 2 weeks (49). In the long term, multiple clinical trials have shown the benefits of aspirin compared to placebo at reducing the risk of stroke.

Clopidogrel

The CAPRIE trial randomized patients with stroke, MI, or peripheral arterial disease to clopidogrel versus aspirin. Overall there was a 0.8% absolute risk reduction in stroke, MI, or vascular death in favor of clopidogrel, with much of the benefit among the peripheral arterial disease outcomes (50). The CAPRIE trial, however, was not powered to detect treatment differences within patient subgroups

Overall, the safety of clopidogrel is comparable to that of aspirin, and it has clear advantages over ticlopidine, which is rarely used because of the risk of neutropenia. A few cases of thrombotic thrombocytopenic purpura have been described with clopidogrel.

Addition of Clopidogrel to Aspirin for Prevention of Vascular Events

The double-blind, randomized study Clopidogrel and Aspirin versus Aspirin Alone for the Prevention of Atherothrombotic Events (CHARISMA) randomized 15,603 subjects with cardiovascular disease or multiple risk factors to either 75 mg of clopidogrel plus a low dose of aspirin (75–162 mg) or a placebo plus aspirin (51). Thirty-five percent of subjects (n = 4320) qualified because of a history of cerebrovascular disease within 5 years of enrollment and there was no significant difference in risk of nonfatal ischemic stroke (1.9% vs. 2.4%, $P = .10$) or intracerebral hemorrhage (ICH).

In the Management of Atherothrombosis with Clopidogrel in High Risk Patients with TIA or Stroke (MATCH) trial (52), the combination of dual antiplatelet agents was not associated with an overall decrease in the risk of ischemic stroke compared to clopidogrel alone, particularly when considering the risk of hemorrhage. Patients with a prior stroke or TIA plus additional risk factors (n = 7599) were allocated to 75 mg of clopidogrel or combination therapy with 75 mg of clopidogrel plus 75 mg of aspirin per day up to 6 months from their initial stroke. There was no significant benefit of combination therapy compared with clopidogrel alone in reducing vascular events, death-related vascular events, or rehospitalization secondary to ischemic events. The risk of major hemorrhage was significantly increased in the combination group compared with clopidogrel alone, with a 1.3% absolute increase in life-threatening bleeding. The combination of aspirin and clopidogrel was further tested in the secondary prevention of small subcortical strokes trial, where there was an overall increase risk of mortality in the aspirin and clopidogrel arm compared to aspirin alone (53). In the long term, there is no proven indication for the combination of aspirin and clopidogrel over a single agent for noncardioembolic stroke.

The combination of aspirin and clopidogrel over shorter periods has gained significant attention in the acute setting for minor stroke and TIA. In the recently completed Clopidogrel in High-Risk Patients with Acute Nondisabling Cerebrovascular Events (CHANCE) trial (54,55), aspirin and clopidogrel for 21 days followed by clopidogrel monotherapy versus aspirin alone, reduced the risk of ischemic stroke at 90 days without an increase in hemorrhage. Further confirmatory trials are ongoing and must be completed and reviewed before this can be adopted as the standard of care.

Aspirin and Dipyridamole

Several trials have evaluated the efficacy of aspirin in combination with dipyridamole. The European Stroke Prevention Study (ESPS-2) randomized 6602 patients with prior stroke or TIA into 3 groups: (a) 50 mg/day of aspirin plus 400 mg/day of extended-release dipyridamole, (b) aspirin alone, (c) extended-release dipyridamole alone, and (d) a placebo. The risk of stroke was significantly reduced by 18% on aspirin alone, 16% with dipyridamole alone, and 37% with a combination of aspirin plus dipyridamole. The combination was superior to aspirin alone in reducing recurrence of stroke (23%) and 25% superior to dipyridamole alone (56). The effect of the combination was further confirmed in a later clinical trial (57), while the combination seems to have similar efficacy to clopidogrel alone (58). The most common side effect of dipyridamole was headache, which can represent an adherence issue during treatment. Bleeding was not significantly increased by dipyridamole.

Aspirin, a combination of aspirin and extended-release dipyridamole, and clopidogrel all remain accepted options

for initial therapy for patients with noncardioembolic ischemic stroke and TIA; therefore, the selection of an antiplatelet agent should be individualized on the basis of patient risk factors, tolerance, and other clinical characteristics.

Hypercoagulable States

Inherited coagulation disorders such as antithrombin III, protein C or proteins S deficiency, prothrombin gene G20210A mutation, or Factor V Leiden (FVL) may contribute to strokes in pediatric or young populations. These abnormalities rarely contribute to stroke in adults and can be overinterpreted if only measured during acute stroke, when levels can be temporarily affected by the active thrombotic event (59).

Hypercoagulability may be a symptom of an underlying malignancy, and diagnostic studies should be performed to exclude this as a possible underlying cause.

The strongest link between a thrombophilic disorder and stroke is the association between antiphospholipid (APL) antibodies and stroke in young adults (less than 50 years of age) (60). The Antiphospholipid Antibodies in Stroke Substudy (WARSS/APASS) was the first study to compare randomly assigned warfarin (INR 1.4 to 2.8) with aspirin (325 mg) for the prevention of a second stroke in patients with APL antibodies. Patients with both lupus anticoagulant and anticardiolipin antibodies had a higher event rate (31.7%) than patients negative for both antibodies (24%), but this was not statistically significant (61). Antiplatelet agents appear reasonable as first-line therapy. For patients with stroke or TIA who meet the criteria for APL antibody syndrome, oral anticoagulation with a target INR of 2 to 3 is recommended.

Sickle Cell Disease

Sickle cell anemia is an autosomal recessive genetic disease that causes production of a defective form of hemoglobin, hemoglobin S (HbS). The central nervous system manifestations of vaso-occlusive crises include cerebral infarction (children), hemorrhage (adults), seizures, TIA , cranial nerve palsies, meningitis, sensory deficits, and acute coma. Ischemic strokes are common in children, and they tend to be recurrent. These patients are often maintained on transfusion programs to suppress HbS. A retrospective multicenter review of sickle cell disease (SCD) patients with stroke showed that a reduction of HbS to less than 30% was associated with a reduction in the rate of recurrence at 3 years from more than 50% to 10%. Exchange transfusions in children who have already had a stroke are often performed, though the data are more limited than for the primary prevention scenario (62).

Cerebral Venous Sinus Thrombosis

Cerebral venous sinus thrombosis (CVST) results from occlusion of a venous sinus and/or cortical vein and is usually caused by a partial thrombus or an extrinsic compression. CVST can be caused by a multitude of factors, including hypercoagulable state, extrinsic compression of the venous system, infection, dehydration, pregnancy, and oral contraceptives. CVST has highly variable clinical manifestations (alteration of consciousness, seizures, focal neurologic deficits, and headache), making its diagnosis a challenge. Magnetic resonance (MR) venography or computed tomography (CT) venography is used to confirm the diagnosis.

Observational data and recent guidelines suggest that both unfractionated heparin (UFH) and low molecular weight heparin (LMWH) are safe and effective in acute cerebral venous thrombosis followed by oral anticoagulation for three to six months (63). Anticoagulation is recommended, even in patients with hemorrhagic venous infarcts. The novel anticoagulants have not been well studied in cerebral venous occlusive disease.

Arterial Dissections

Dissection, a tear in the subintimal layer of a large artery, is most common in the internal carotid artery as it enters the petrous bone and the vertebral arteries as they course through the foramen transversarium. Intracranial dissections are less common. Dissections lead to ischemic strokes through artery-to-artery embolism or by causing significant stenosis and occlusion of the proximal vessel (64). Dissections can also cause a pseudo-aneurysm, creating a source for thrombus formation. Intracranial dissections can cause subarachnoid hemorrhage when the dissection becomes subadventitial. Although the treatment is unproven, patients are often treated with intravenous heparin followed by oral warfarin for three to six months. There has not been a trial comparing this approach to antiplatelet therapy (65). The duration of therapy is based on the period of anticipated high risk and the natural history of the vessel repair. No studies have examined the safety and efficacy of therapy using different durations of anticoagulation. For patients with recurrent ischemic events, long-term anticoagulation may be considered.

CONVENTIONAL MODIFIABLE STROKE RISK FACTORS

Hypertension

Hypertension is one of the most common global diseases. Because of the associated morbidity and mortality and the cost to society, hypertension is an important public health challenge. Hypertension is the single most important risk factor for stroke and also causes "silent" infarcts, which contribute to cognitive dysfunction (66,67). There is a continuous association between both systolic and diastolic BPs and the risk of ischemic stroke (68).

Seven published randomized controlled trials with a combined sample size of 15,527 participants with ischemic stroke, TIA, or ICH focused on the relationship between BP reduction and the secondary prevention of stroke and other vascular events (69). The patients were followed up for two to five years. Treatment with antihypertensive drugs was associated with significant reductions in all recurrent strokes,

nonfatal recurrent stroke, MI, and all vascular events. The overall reductions in stroke and all vascular events were related to the degree of BP lowering achieved, but whether a particular class of antihypertensive drug offers a particular advantage for use in patients after ischemic stroke remains uncertain.

Blood pressure management is recommended for both prevention of recurrent stroke and prevention of other vascular events in persons who have had an ischemic stroke or TIA. Benefit has been seen with an average reduction of approximately 10/5 mmHg. The optimal drug regimen remains uncertain; however, the available data support the use of diuretics and the combination of diuretics and an angiotensin converting enzyme (ACE) inhibitor (1). In patients with history of MI, a beta-blocker and ACE inhibitor are recommended. In patients with mild hypertension with increased cardiovascular risk, an ACE inhibitor or a calcium channel blocker were not found to be superior to low-dose thiazide diuretic therapy. However, in clinical trials ACE inhibitors provided better outcomes than placebo. The SPS3 trial recently completed its BP arm and demonstrated a trend toward lower stroke with tighter BP control (<130 mmHg) compared to up to 150 mmHg among lacunar strokes (70).

Diabetes

Diabetes mellitus is a chronic disease that requires conscientious longitudinal medical attention. Diabetes mellitus and age were the only significant independent predictors of recurrent stroke in a population-based study of stroke (71), and it is a strong determinant for the presence of multiple lacunar infarcts in two different stroke cohorts (72).

Most of the available data on stroke prevention in patients with diabetes are on the primary rather than secondary prevention of stroke. Intensive treatments to control hyperglycemia, hypertension, dyslipidemia, and microalbuminuria have demonstrated reductions in the risk of cardiovascular events (73).

Thiazide diuretics, beta-blockers, ACE inhibitors, and angiotensin II receptor blockers (ARBs) are beneficial in reducing cardiovascular events and stroke incidence in patients with diabetes (74). ACEIs and ARBs are preferred because they have been shown to reduce albuminuria and favorably affect the progression of diabetic nephropathy. More meticulous control of lipids is also recommended among diabetics, with an LDL-C of goal as low as 70 mg/dL (75).

Glycemic control has been shown to reduce the occurrence of microvascular complications (nephropathy, retinopathy, and peripheral neuropathy) in several clinical trials and is recommended in multiple guidelines of both primary and secondary prevention of stroke and cardiovascular disease (75). Analysis of data from randomized trials suggests a continual reduction in vascular events with the progressive control of glucose to normal levels. Diet, exercise, oral hypoglycemic drugs, and insulin are recommended to reach glycemic control.

Dyslipidemia

The impact of lipid abnormalities on ischemic stroke has been somewhat controversial, although mounting evidence supports aggressive management for secondary prevention. The guidelines of the American Heart Association and the NCEP Adult Treatment Panel III (ATP III) define *hypercholesterolemia* as a blood cholesterol concentration of greater than or equal to 240 mg/dL. Desirable cholesterol concentrations are less than 200 mg/dL.

The 2011 American Heart Association/American Stroke Guidelines for prevention of recurrent stroke make the following recommendations for lipid management in ischemic stroke and TIA patients (1):

1. Follow the national Cholesterol Educational Program III (NCEPIII) guidelines for patients with stroke or TIA who have elevated cholesterol (Table 26.3)
2. Administer statins and aim for a cholesterol-lowering goal of LDL-C lower than 100 mg/dL for those with CHD (coronary heart disease) or symptomatic atherosclerotic disease, or LDL-C lower than 70 mg/dL for very high risk persons with multiple risk factors

TABLE 26.3 LDL Cholesterol Goals and Cut Points for Therapeutic Lifestyle Changes (TLCs) and Drug Therapy in Different Risk Categories

RISK CATEGORY	LDL GOAL	LDL LEVEL AT WHICH TO INDICATE LIFESTYLE CHANGES	LDL LEVEL AT WHICH TO CONSIDER DRUG THERAPY
CHD or CHD risk equivalents	<100 mg/dL	>100 mg/dL	>130 mg/dL (100–129 mg/dL drug optional)
2+ risk factors	<130 mg/dL	>130 mg/dL	10-year risk 10%–20% >130 mg/dL 10-year risk <10% >160 mg/dL
0–1 risk factors	<160 mg/dL	>160 mg/dL	>190 mg/dL (160–189 mg/dL drug optional)

3. Consider administration of statins for ischemic stroke or TIA patients with atherosclerotic stroke but no preexisting indications for statin therapy.

The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial was a randomized, double-blind study designed to determine if 80 mg/day of atorvastatin or placebo would reduce the risk of fatal or nonfatal stroke in patients with no known CHD who had a stroke or TIA 30 days earlier and within the previous 6 months (76). The trial randomized 2365 subjects to atorvastatin and 2366 to placebo. There were no significant differences between the two treatment groups in the incidence of serious adverse events. However, there were 55 hemorrhagic strokes in the atorvastatin treatment group and 33 in the placebo group. Myalgia (5.5% vs. 6.0%), myopathy (0.3% vs. 0.3%), and rhabdomyolysis (0.1% vs. 0.1%) did not differ in the atorvastatin or placebo treatment groups (76).

The SPARCL results provide evidence that 80 mg/day of atorvastatin administered to patients with stroke or TIA and without known CHD reduces the risk of stroke and cardiovascular events, despite a small increase in the risk of hemorrhagic stroke.

Smoking

Smoking increases the risk of ischemic stroke in a dose-dependent fashion. In the Women's Health Initiative study (WHI) of 39,783 patients, smoking fewer than 15 cigarettes a day had a RR of 1.93 for total hemorrhagic stroke. This risk increased to a risk ratio of 3.29 for women who smoked more than 15 cigarettes per day. The risk of ICH and subarachnoid hemorrhage were also increased in this population (RR 2.67, 4.02, respectively). On average, smoking doubles the risk of stroke (77).

Patients should be approached during their acute hospitalization regarding the importance of a smoking cessation program. The use of nicotinic patch, alone or in combination with bupropion, may be considered. The potential risk for a reduction in seizure threshold associated with bupropion use may be a concern in patients with large cortical strokes.

Alcohol Intake

The role of alcohol is controversial. Studies are difficult to conduct because of multiple socioeconomic variables. Meta-analysis of multiple studies indicates that heavy alcohol consumption (>60 grams per day) increases the individual's risk for all stroke subtypes, especially intracerebral and subarachnoid hemorrhages, and is also correlated with increase in the incidence of hypertension (78). Therefore, alcohol cessation is an important intervention for heavy drinkers.

MODIFIABLE RISK FACTORS EXCLUSIVE TO WOMEN

Oral contraceptive pills (OCPs) are a very common method of birth control globally, but the risk of stroke with OCPs—especially in conjunction with factors such as smoking, hypertension, genetic predisposition to thromboembolism, and migraine—has a major impact in secondary stroke prevention. Preparations with a high estrogen content (150 mcg) have been associated with both arterial and venous thromboembolism, and the third-generation OCP, containing gestodene or desogestrel and the same low dose of estrogen, has been associated with an increase in the risk of venous thromboembolic disease (79). In heavy smokers over the age of 35 and in women with previous thromboembolic events, OCPs are contraindicated.

Migraine with aura is an independent risk factor for stroke, particularly for young patients (80). There is also evidence that the risk of stroke is high during the peripartum and postpartum periods, with an increased risk up to 12 weeks from delivery (81). There is no definite guideline for the use of antiplatelet/antithrombotic therapy in stroke prevention for women with a history of pregnancy-related stroke.

SUMMARY

Stroke and TIA have great impact on the global public health, affecting millions of people of varied ethnicity, age, gender, and socioeconomic status and causing serious disabilities that affect the quality of life of these people. Therefore, stroke prevention is an important field of secondary prevention considering both conventional and population-specific risk factors. Modifiable risk factors such as hypertension, diabetes, smoking, physical inactivity, obesity, and dyslipidemia should be aggressively managed to prevent recurrent stroke and first MI. Diagnostic evaluation for an etiology should be thorough, with a particular emphasis on symptomatic internal carotid artery disease and AF due to the high risk of recurrence.

Prevention of Deconditioning After Stroke

Frederick M. Ivey and Richard F. Macko

Stroke is associated with profound cardiovascular deconditioning (1). Peak fitness levels for individuals with history of stroke are approximately half that found in age-matched sedentary controls, indicating significant functional aerobic impairment (2–4). Low fitness levels compromise the capacity of stroke patients to meet the elevated energy demands of hemiparetic gait (5–7), and this diminished physiological fitness reserve capacity limits basic activities-of-daily-living (ADL) capacity, contributing to activity intolerance and subjective fatigue (8,9). Poor fitness also increases atherothrombotic risk after stroke by impacting elements of the cardio-metabolic syndrome (10,11) and promoting insulin resistance (12,13).

Whether poststroke fitness reductions are primarily because of premorbid conditions, direct effects of the stroke itself, or poststroke physical inactivity remains unclear. All are likely contributors, but understanding the relative contribution of each will require further research into biological and etiological mechanisms (1). Whatever the case, the need to address stroke-related decrements in fitness is gradually emerging as a clinical care priority in mainstream practice. For example, the Commission for Accreditation of Rehabilitation Facilities (CARF) International has newly revised best-care standards for stroke, applicable to all health care facilities (www.carf.org). These include plans for prevention of physical inactivity and physical deconditioning as a cornerstone for improving cardio-metabolic health and preventing recurrent stroke events. The information presented in this chapter should serve to advance the rationale for promoting the CARF model throughout the international health care system. This clinical care model must continue to develop, working toward full and broad implementation in such a way as to efficiently combat the devastating health consequences of aerobic deconditioning after stroke.

Hemiparetic body composition abnormalities affect multiple physiological systems, contributing to poor fitness (14) and the high prevalence of insulin resistance (12,13) in this population. Secondary biological abnormalities include unilateral gross muscular atrophy (15,16), increased intramuscular area fat (15,16), and a shift toward a fast-twitch muscle fiber type (17–19). These unilateral tissue changes are pronounced, with implications for both disability and worsening cardio-metabolic risk. Additionally, accelerated hemiparetic osteoporosis coupled with heightened fall risk predisposes to serious fractures (20). All stroke-related body composition and metabolic abnormalities are worsened by physical inactivity and advancing age. The first section of this chapter defines the profile of diminished physiological fitness reserve and details some of the underlying body composition and tissue-level abnormalities. We discuss the clinical relevance of these findings in terms of functional impairment and risk factor profiles.

Stroke survivors retain capacity for physiological adaptation to an exercise training stimulus. A variety of different exercise training modalities have been used to safely improve cardiovascular fitness after stroke (3,21–25). Increasing evidence from randomized studies further shows that structured exercise programs, particularly those employing task-repetitive locomotor training, can improve sensorimotor function even years after stroke (23,26–29). Hence, several exercise regimens are successful at both increasing fitness and improving gait patterning to reduce the energy costs of hemiparetic gait. This may ultimately improve mobility function and basic ADL capacity after stroke. The second section of this chapter reviews the physiological and functional effects of exercise after stroke. Although further research is needed to optimize exercise design, new evidence regarding dose intensity and health benefits of exercise after stroke is presented. Importantly, stroke participants can tolerate and benefit from higher-intensity exercise models, including treadmill (TM) training for maximal aerobic benefit (25), and aggressive strength training models, which have the capacity to dramatically affect leg skeletal muscle both on the paretic and the nonparetic sides (30).

The third section rounds out the chapter by providing general guidelines for implementing exercise programs after stroke. Goals should be oriented toward a multiple-physiological systems approach intended to improve fitness, sensorimotor function, and cardiovascular-metabolic health and to prevent or reduce deleterious body composition abnormalities that accompany disuse while aging with the chronic disability of stroke. The high prevalence of residual neurological deficits, as well as medical and cardiovascular comorbid conditions, presents unique safety and

feasibility issues related to implementation of exercise programs after stroke. Thus, recommendations are provided for initial medical evaluation to optimize safety and overcome the barriers to exercise participation. We reference some evidence-based protocols and exercise progression formulas that have proven successful in research settings and touch upon some future research directions that are likely to influence the practice of exercise to best promote health and wellness after stroke.

CARDIOVASCULAR HEALTH AND FITNESS AFTER STROKE

Cardiovascular health and fitness are integrally linked to exercise behaviors. To gain perspectives on the health impact of physical deconditioning following stroke, exercise behaviors must be considered across the phases of recovery. Conventional subacute stroke rehabilitation primarily focuses on optimizing basic ADL skills and functional independence, and preventing complications that can hinder recovery during the crucial early subacute stroke period (31). It is not clear that conventional rehabilitation systematically provides an adequate exercise stimulus to reverse the profound physical deconditioning and associated hemiparetic muscular atrophy that worsen neurological disability and cardiovascular health profiles in this sedentary population. In one study, cardiac monitoring of conventional physical therapy during the subacute stroke recovery period revealed that less than 3 minutes per session reached an aerobic intensity of 40% of measured heart rate reserve (HRR) (32). This level represents the lowest target for exercise in usual cardiac rehabilitation care. A large metropolitan catchall area in the United States reported that after a stroke, the typical patient attends a mean of 9 ± 5 outpatient physical therapy visits. The same study went on to say that therapy usually ended entirely between 30 and 180 days after stroke (3). These findings suggest that conventional physical therapy during the subacute recovery phase provides an inadequate exercise stimulus to address the domains of physical and metabolic deconditioning.

Measuring Fitness Levels After Stroke

Several studies have measured cardiovascular fitness levels using open circuit spirometry after stroke (Table 27.1). Although exercise testing strategies have been diverse, the general finding has been dramatically lower peak VO_2 levels in stroke survivors, contrasting with age-matched elderly controls who are physically inactive but otherwise healthy. Individuals in their 60s are expected to have peak oxygen levels ranging between 25 and 30 mL/kg/min depending on a number of factors (33). Thus, the mean peak oxygen consumption level in stroke patients averages

TABLE 27.1 Studies on Peak Aerobic Fitness After Stroke

STUDY	SUBJECTS	TESTING DEVICE	MEAN VO_2 PEAK (ML/KG/MIN)
Potempa et al. (22)	42 chronic stroke, 43–72 years	Cycle ergometer	15.9
Fujitani et al. (35)	2–49 months poststroke (n = 30), 53.6 years	Cycle ergometer	17.7

Abbreviations: BWS, body weight support; GXT, graded exercise test.

approximately half that of age-matched individuals. This is partially a function of the extremely high energy cost of hemiparetic gait contributing to diminished physiological fitness reserve (34).

Functional Consequences of Reduced Fitness After Stroke

The extremely low levels of peak oxygen-consuming capacity found in stroke survivors can compromise functional mobility and are below the level required for some basic activities of daily living. The human body at rest consumes roughly 3.5 mL/kg/min of oxygen or 1 metabolic equivalent (MET) (45). The MET calculations associated with various forms of activity (46,47) reveal that light instrumental activities of daily living (IADLs) generally require approximately 3 METS of oxygen consumption, whereas more strenuous ADLs require approximately 5 METS or 17.5 mL/kg/min. Notably, published MET values for different activities do not take into account neurological disability, which may be associated with even higher energy requirements for gross motor activities as a result of biomechanical inefficiency (7).

The impact of low fitness on function after stroke is best illustrated when peak fitness values are considered in the context of the range of energy expenditure necessary to perform daily activities (Figure 27.1) (2). Whereas peak values for age-matched healthy individuals far exceed the approximated ADL range, the exhaustion value falls somewhere in the middle of the zone for most stroke patients (Figure 27.1) (2). Thus, many stroke patients must work to complete exhaustion to achieve the middle of the established ADL range, making mid- to upper-level ADLs either impossible or unsustainable for extended time periods.

Of course, low fitness levels have consequences beyond functional impairment. In a seminal study involving more than 60,000 participants, Hooker et al. (48) demonstrated that cardiorespiratory fitness was an independent predictor of first-time stroke. Whether these findings extend to recurrent stroke awaits further research, but, until proven otherwise, it is prudent to assume that low fitness is a prominent factor in recurrent risk as well. Further, low fitness levels have been found to correlate with impaired metabolism (38) and reduced cerebral blood flow (49) in chronically disabled stroke survivors, indicating the central relevance of conditioning status to general health in this population.

Mechanisms Underlying Poststroke Deconditioning

Although consensus has emerged that stroke leads to extreme deconditioning, the underlying biological mechanisms have not been systematically investigated. The disability of stroke is widely attributed to brain injury alone, and the diminished fitness attributed to reduced "central" neural drive. However, there are a number of changes in skeletal muscle and surrounding tissues that propagate disability and contribute to low fitness levels, including gross muscular atrophy, muscle fiber type shift, tissue inflammation, and altered vasomotor function, as discussed in the following sections.

Role of Muscle Atrophy

In stroke patients, reduced muscle mass plays a role in the ability to use oxygen. The level and quality of metabolically active tissue partially accounts for the amount of oxygen a person can utilize. Ryan et al. (14) confirm a strong relationship between thigh muscle mass by dual energy x-ray absorbtiometry (DEXA) and peak VO_2. In this study, VO_2 was related to the lean muscle mass of both thighs, with lean mass predicting more than 40% of the variance in peak aerobic fitness (14).

Stroke patients have reduced lean tissue mass that is related to the degree of neurological disability. Bilateral mid-thigh CT scans are used to illustrate the severe atrophy caused by chronic hemiparesis (Figure 27.2; 15). There is extreme gross muscular atrophy in paretic leg mid-thigh CT scans, showing 20% lower muscle area compared to the nonparetic thigh. The findings of exaggerated muscle erosion on the paretic side have been confirmed by a study utilizing serial CT measurements from the knee to the hip, enabling the calculation of muscle volume bilaterally (16). Intramuscular area fat is 25% greater in the paretic thigh compared to the nonparetic thigh (15,16), and is linked to elements of the metabolic syndrome and their associated complications (50). Therefore, the significance of stroke-related body composition abnormalities extends beyond poor fitness and function in this disabled population.

Unilateral Muscle Fiber Type Changes

Cellular changes in skeletal muscle may also contribute to poor fitness and worsening cardiovascular disease (CVD) risk after stroke. Prior studies of hemiparetic muscle reveal variable findings related to altered fiber type proportions,

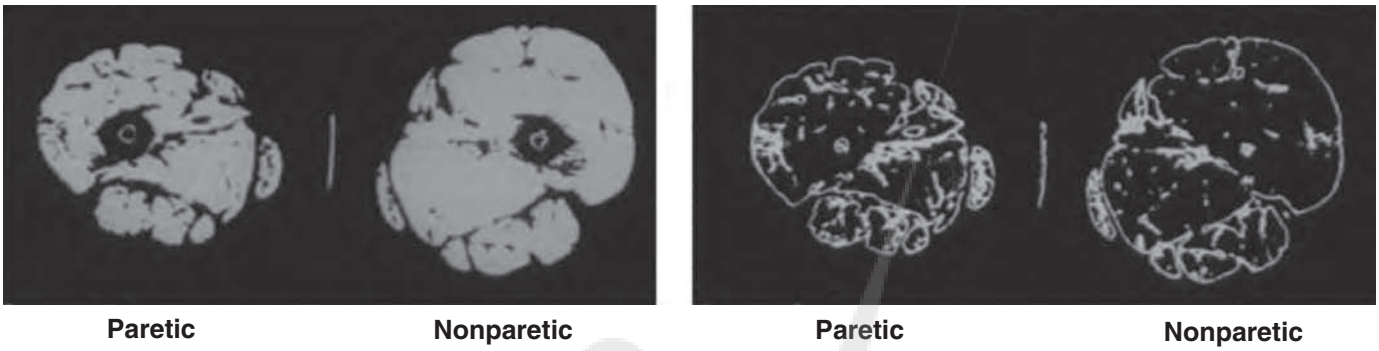

FIGURE 27.2 Bilateral CT scan illustrating muscle atrophy and elevated intramuscular area fat on the paretic side.

Source: Reproduced with permission from *Topics in Stroke Rehabilitation*.

loss of type I muscle fibers, fiber atrophy, and reduced oxidative capacity (18,19,51–54). A slow-to-fast fiber type conversion has been reported (17,18,53). Skeletal muscles are composed of fibers that express different myosin heavy chain (MHC) isoforms. Slow (type I) MHC isoform fibers have higher oxidative function, are more fatigue resistant, and are more sensitive to insulin-mediated glucose uptake. Fast (type II) MHC fibers are recruited for more powerful movements; they fatigue rapidly and are less sensitive to the action of insulin (55). Routine ATPase staining of paretic leg muscle biopsies shows elevated proportions of fast type II fibers in the paretic leg of stroke survivors (Figure 27.3) (2).

Similar findings are reported in the hemiparetic upper extremity (53). Further, densitometric analysis of MHC gel electrophoresis analyzing bilateral vastus lateralis biopsies shows significantly elevated proportion of fast MHC isoforms in the paretic versus nonparetic leg (17). These findings contrast with the relatively equal proportions of slow and fast MHC fibers found in vastus lateralis of individuals without stroke (53). Interestingly, a shift to fast MHC composition in the paretic muscle is also seen in animals and humans after spinal cord injury (56). This suggests that neurological alterations may be partially responsible for the shift of muscle phenotype. A switch to fast MHC can occur with muscle unloading or disuse. The relative inactivity after stroke could also facilitate these changes. The shift to fast MHC is in contrast to the changes seen in normal aging, where fast MHC fibers are preferentially lost through denervation and slow MHC fiber density increases (57). Hence, this shift after stroke is an abnormal muscle molecular phenotype that would be expected to result in a more fatigable, insulin-resistant muscle.

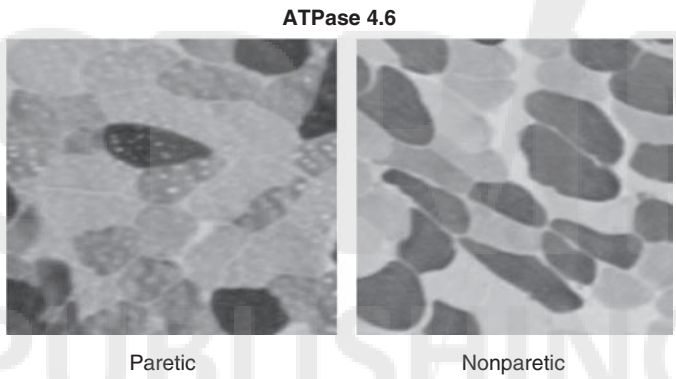

FIGURE 27.3 Fiber-type shift on paretic side.

Inflammatory Pathway Activation in Hemiparetic Muscle

The molecular mechanisms underlying muscular atrophy and insulin resistance after stroke are not fully understood. Bilateral biopsies from the vastus lateralis muscle of chronic stroke patients reveal a nearly three-fold increased tumor necrosis factor-alpha mRNA expression in the hemiparetic leg muscle, compared to age-matched nonstroke controls (58). In addition, there is a significant 1.6-fold increased TNF-alpha mRNA expression in the nonparetic leg muscle of stroke patients compared to controls (58), evidence of a bilateral or systemic process conferring more widespread inflammatory effects. Immunohistochemical studies further show that TNF-alpha localizes to interfascicular space as well as the muscle fascicle, suggesting that increased inflammatory cytokine production may arise from both muscle and surrounding adipocytes (2). The clinical significance is that TNF-alpha blocks insulin signaling and mediates muscle atrophy (59–62). Thus, inflammatory mechanisms may contribute to both muscular atrophy and insulin resistance after stroke, thereby both lowering fitness and elevating recurrent stroke risk.

Myostatin Elevation in Hemiparetic Muscle

Myostatin is a key negative regulator of muscle mass in humans and animals (63,64), having direct and indirect influences on several other molecular regulators of atrophy and hypertrophy. In a recent study, vastus lateralis biopsies of the paretic and nonparetic muscle were used for

measurement of myostatin gene expression by Real-time (RT)-PCR (30). Myostatin mRNA expression levels were 40% higher in the paretic than nonparetic muscle ($P = .001$) at baseline and decreased by 49% in the paretic muscle ($P < .005$) and 27% in the nonparetic muscle ($P = .06$) after a 3-month resistive exercise training program. This is significant given myostatin's established role as an inhibitor of skeletal muscle growth. The reduction in myostatin was greater in the paretic than nonparetic muscle ($P < .001$) by repeated analysis of variance (ANOVA) measures (30). Thus, the increased myostatin mRNA in the paretic thigh and reduction with resistance training imply an important regulatory role for myostatin after stroke.

Hemiparetic Osteoporosis

Hemiparetic osteoporosis is a clinically important body composition abnormality that is linked to duration of immobility, muscular atrophy, and poor cardiovascular fitness after stroke (65–67). Osteoporosis is more severe in the upper than lower extremity, but fracture risk is greater for the hip (65). Hip fracture risk is reportedly 7-fold elevated in the first year after stroke, and 15% projected across 5 years (20), and is increased 7-fold for each 2 standard deviation decrease in femoral neck bone mineral density (68). Paretic leg femoral neck bone density declines up to 14% within a year after stroke (69)—a period in which up to 73% experience a fall (70). Hence, exercise strategies to improve both balance and bone health may serve as important adjuncts to best medical care. Despite the established role of exercise as an adjunct to best medical care for treatment of osteoporosis (71), few studies have systematically examined the potential for exercise to improve balance and bone health after stroke. Three studies with positive outcomes on falls (72–74) used repetitive functional tasks, which most likely improved motor coordination, movement speed, and strength (72). In 2008, Eng et al. (65) published a review paper indicating that randomized trials support the use of exercise training to reduce fracture risk after stroke, but that further studies are required to draw definitive conclusions. Most recently, Pang and Lau (75) showed that tibial bone geometry improved more in TM exercise trainers than controls after stroke.

Impairments in Blood Flow

Findings of unilaterally impaired paretic leg blood flow in chronic stroke identify yet another clinical feature related to reduced cardiovascular fitness and enhanced CVD risk. When resting and postischemic reactive hyperemic blood flow was compared between the affected and unaffected legs of stroke patients, results showed 32% and 35% reductions, respectively (76). These results were replicated in a more recent trial from our laboratory (77). Of equal or greater importance were the findings that middle cerebral artery blood flow is reduced on the ipsilesional side of the brain (49). Importantly, both peripheral and cerebral blood flow dynamics can improve with regular progressive fitness training after stroke (49,77), and arterial function has been shown to improve subsequent to strengthening exercises in community-dwelling stroke survivors (78).

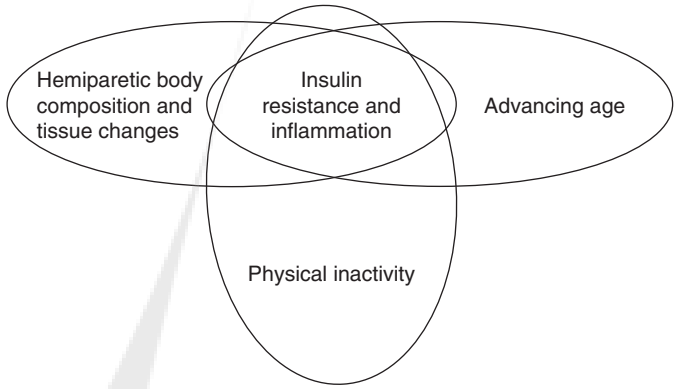

FIGURE 27.4 Interacting features in the stroke population that combine to produce elements of the metabolic syndrome.

Clinical and Metabolic Consequences of Paretic-Side Tissue-Level Changes

The skeletal muscle, bone, and vasomotor regulatory abnormalities on the paretic side may contribute to worsening cardiovascular risk by propagating physical inactivity, insulin resistance, and the metabolic syndrome. Kernan et al. (12,79) originally identified a high prevalence of insulin resistance during the subacute stroke recovery period. Subsequent findings in chronic stroke reveal an extremely high prevalence of abnormal glucose metabolism (13). In a chronic stroke study involving more than 200 volunteers, 35% screened had documented diabetes by medical history. Additionally, fasting and postload hyperglycemia were highly prevalent in those who are not identified as diabetic by medical history. The findings suggest that the rate of abnormal glucose metabolism may be as high as 80% in chronic stroke (13). This is clinically relevant given that impaired and diabetic glucose tolerance prospectively predict two- to three-fold increased risk for recurrent cerebrovascular events (80). Figure 27.4 depicts some contributors to poststroke metabolic syndrome and their interaction with one another.

We now know that the metabolic status of stroke survivors can be beneficially impacted by TM exercise training, as evidenced by highly significant reductions in insulin area under the curve during oral glucose tolerance testing as well as improved diabetes status in 58% of participants (38). A recent paper in stroke also shows that resistive training can improve insulin sensitivity by 31% in as little as 3 months (81).

PHYSIOLOGICAL AND FUNCTIONAL EFFECTS OF EXERCISE AFTER STROKE

This section provides an overview of evidence that several exercise modalities can improve health, fitness, and functional outcome categories after stroke. Our focus is on exercise programs involving the lower extremities or

whole body, consistent with the mission of improving mobility function, fitness, and metabolic health, and countering the secondary body composition abnormalities that occur as a consequence of stroke and physical inactivity. In practical terms, this approach primarily engenders elements of aerobic training by incorporating larger muscle groups that are more effective to provide a cardiovascular exercise stimulus to improve metabolic health, consistent with consensus statements for exercise recommendations in high CVD risk populations (10). Where such information is available, the specific exercise intensity and progression formula are described, as these may affect the nature and temporal profile of exercise-mediated adaptations. We include recent advances in the application of resistance training in stroke survivors, which provide evidence of strength gains and paretic leg performance capacity without deleterious increases in spasticity. Preliminary steps have also been taken in the direction of alternative therapies such as tai chi (82,83) and yoga (84,85) that may hold promise in the rehabilitation of those with stroke. There is a growing emphasis on community-feasible and home-based exercise models, which may afford opportunities to better disseminate health and function, promoting training programs to larger numbers of stroke survivors. Finally, efforts to capture the recent trends in stroke exercise rehabilitation related to intervening earlier, more aggressively, and more creatively (e.g., with family support) are also ongoing.

Exercise Training for Cardiovascular Fitness After Stroke

Several exercise modalities have been shown to increase cardiovascular fitness in stroke survivors. A synthesis of these studies suggests that approaches to exercise training may necessarily vary as a function of neurological deficit severity, baseline fitness levels, and the time phase of recovery after stroke (Table 27.2) (26). Moreover, differing elements of training prescriptions and their progression (e.g., aerobic intensity, training velocity, repetition) may further determine the nature of exercise-mediated outcomes. Table 27.2 summarizes some of the more widely cited exercise intervention studies measuring impacts on peak aerobic capacity. Note that the work of Globas et al. (25) (Table 27.2) showed that higher than previously observed relative increases in peak aerobic capacity may be possible by placing a greater emphasis on TM training intensity progression. Other evidence is also now available to demonstrate that stroke survivors benefit from higher-intensity exercise training protocols (86).

Notably, a gain in peak fitness of as little as 1 MET (3.5 mL/kg/min) prospectively predicts 17% to 29% lower nonfatal and 28% to 51% fatal cardiac events in men (92), and, as stated previously, fitness level predicts first-time stroke risk (48). Therefore, the gains reported in the studies listed in Table 27.2 are clinically important. Beyond goals of improving function after stroke, tertiary stroke prevention and CVD risk factor modification should be a major objective of exercise in this population (10). In high CVD risk nonstroke populations, exercise has been shown to improve a number of physiological factors linked to stroke and cardiac event risk, including insulin sensitivity (93), hemostatic and inflammatory markers (94,95), and indices of vascular endothelial dependent vasomotor reactivity in coronary and peripheral circulations (96). Other health benefits include improved lipid profiles (97) and improved autonomic tone, which is linked to lower cardiac mortality (98). Exercise is established as an adjunct to best medical care in management of obesity, dyslipidemia, diabetes, and hypertension, strongly supporting a role for exercise to address cardiovascular comorbidities in stroke survivors. Exercise improves insulin and glucose areas under the curve during oral glucose tolerance test after stroke (38), with postload insulin response having previously been identified as a predictor of stroke risk (99).

Effects of Exercise on Sensorimotor Function After Stroke

Approximately 75% of stroke survivors are left with residual deficits that persistently impair function. In particular, sensorimotor deficits impairing gait and balance limit functional independence and promote a sedentary lifestyle with subsequent physical deconditioning. Until recently, the window for motor recovery with conventional rehabilitation was widely considered to be only three to six months, with little functional improvement thereafter (100,101). Seminal studies in rehabilitation of the paretic upper extremity now inform us that task-repetitive training can improve arm motor function in chronic stroke, and that the functional gains are associated with brain plasticity (102). A similar paradigm shift is taking place in our understandings of brain plasticity and lower-extremity motor control.

Increasing clinical and experimental data provide evidence that exercise has the potential to improve selected motor performance outcomes, even years after stroke, and that the functional improvements are associated with mechanisms of neuroplasticity (89,103,104). Table 27.3 presents some examples of exercise intervention studies producing significant improvements in basic ADL-related functional parameters in subacute and chronic stroke patients (26).

Exercise Intervention Strategies After Stroke Using Multiple Modalities

Although a comprehensive review of the exercise literature in stroke is beyond the scope of this chapter, details related to some of the more widely cited studies are provided in the following paragraphs. Efforts were made to select several representative studies that employ diverse training modalities, including cycle ergometry, recumbent stepper training, water-based exercise, home- and community-based therapies, resistance (strength) training, and TM training, as well

TABLE 27.2 Exercise Intervention Studies and Their Impact on Peak Aerobic Fitness

STUDY	DESIGN/POPULATION	INTERVENTION	+ VO_2 PEAK
Potempa et al. (22)	Randomized/chronic stroke	10 weeks cycle training 3×/week versus passive range of motion	Treatment: +13%[a] Control: +1 %

as multi-modal therapy and other alternative interventions. Clearly, much work remains to be done in elucidating the optimal exercise formula for producing maximal gains in fitness and function to delay disability and cardiovascular morbidity/mortality after stroke.

Cycle Ergometry and Recumbent Stepper Training

A seminal study conducted by Potempa et al. (22) compared 10 weeks of adapted bicycle ergometer exercise with a control intervention consisting of passive range of motion exercise in chronic stroke patients. Results showed a significant between-group difference in VO_2 peak change over time, with the bicycle ergometer group (n = 19) achieving 13% gains compared to no change for controls (n = 23). Though Fugl-Meyer sensorimotor scores were positively correlated with gains in peak VO_2, neither of the treatment groups showed significant differences in functional outcome scores. This study showed that aerobic exercise using cycle ergometry is feasible and improves fitness in chronic hemiparetic stroke, but provided no clear evidence that cycle exercise could improve neuromuscular function or functional mobility. Since then, a few studies have been conducted examining the effects of cycle ergometry after stroke (4,90), but none have produced conclusive findings that this form of intervention improves functional outcome. However, the use of a recumbent stepper device (Nu Step) has shown promise for improving poststroke function, with gains observed in the Berg Balance Scale (118).

Water-Based Exercise

Chu et al. conducted a water-based exercise study lasting 12 weeks (21). Those in the experimental group exercised for one hour, three days per week, in a swimming pool. The patients were progressed to 30 minutes of water aerobics at 80% HRR, with the remainder of time consisting of stretching and warm-up/cool-down. Although this study had a very small sample size (7 treatment and 5 controls), the intervention produced large relative gains in peak aerobic capacity (23%), perhaps arguing for strong consideration of this form of intervention for stroke survivors. A higher level of baseline fitness and function may have influenced results and confounded interpretation relative to other experiments in the field of poststroke exercise rehabilitation. Aquatic therapy has also been shown to improve balance, forward and backward weight-bearing abilities of the affected limbs, and knee flex or strength (112). However, a recent Cochrane review concluded that the few randomized studies done to date in this area provide inconclusive evidence regarding whether aquatic therapy reduces stroke disability (119), and that better and larger studies are required.

Home- and Community-Based Therapies

Duncan et al. (106) were the first of the randomized studies to utilize a home-based intervention model. The program consisted of 36 sessions of 90-minute duration over 12 to 14 weeks. Subjects in the usual care group had services as prescribed by their physicians. All sessions for the exercise group were supervised by a physical or occupational therapist at home. Components of the program were range of motion and flexibility, strengthening, balance, upper-extremity functional use, and endurance training (riding a stationary bike for 30 minutes). Both the intervention and usual care groups improved in strength, balance, upper- and lower-extremity motor control, upper-extremity function, and gait velocity. Gains for the intervention group exceeded those in the usual care group in balance, endurance, peak aerobic capacity, and mobility. The study was important in demonstrating the practical utility of home-based interventions compared to the more frequently applied hospital-based intervention programs for improving fitness and function after stroke. However, it should be noted that there was still a high level of supervision despite the study being home-based. More recently, Duncan and colleagues showed that a home-based intervention supervised by physical therapists compares favorably to more intensive hospital-based body-weight-supported TM rehabilitation in terms of adaptations in walking speed, 6-minute walk distance, and 24-hour activity across the subacute phase of stroke recovery (116). Additionally, trials have been conducted to determine the effectiveness of community-based ambulation training after stroke (29,120–123), with some success shown in improving basic functional outcome measures. However, Langhammer et al. observed advantages for TM training compared to walking outdoors with respect to walking speed, stride symmetry, and 6-minute walk distance (121). Whatever the modality, returning to independent community ambulation is a challenging rehabilitation goal (123).

Resistance (Strength) Training

Several systematic reviews of outcomes related to progressive strength training after stroke show great promise for this form of rehabilitation intervention (124–127). Of the original eight studies conducted during or before 2007, three (128–130) were randomized controlled trials (RCTs), with the remainder being single-case time-series analyses (131) or single-group pre–post trials (132,133). Since then, seven important strength training studies (four randomized) have been added to the mix (30,117,134–138), thereby broadening our understanding of the extent to which this intervention can affect a diverse array of outcome categories in this population. Wide variation was found in the frequency and duration of the training programs as well as type of equipment used. Studies had participants training anywhere from 2 to 5 sessions per week with a total intervention period ranging from 4 to 12 weeks. Several of the studies used isokinetic dynamometers for training (Cybex or Kin-Com) (131,132), with the remainder using weight machines, hand weights, and a purpose-built static dynamometer. Training was originally primarily targeted to larger muscle groups of the lower limb, with the exception of one study exercising wrist extensors and upper-limb flexors (131). Harris and Eng recently published a meta-analysis demonstrating that strength training can also improve upper-limb function without increasing tone or pain for individuals with stroke (127). All of the studies that measured strength reported significant increases with large effect sizes. Two of the single-group pre–post studies (132,133) and one RCT (128) measured effects of the training on spasticity by Hoffman reflex, stretch reflex, Achilles tendon jerk, the pendulum test during knee flexion, electromyography (EMG) in the quadriceps and hamstring groups, and the modified Ashworth scale. None of the studies reported increases in spasticity after a resistance training exercise program. All measured the effects of training on at least one functional outcome. Generally, walking speeds were significantly increased with this form of training, with effect sizes ranging from 0.5 to 1.5. The RCT with the largest walking speed effect size (128) focused training on the hip, knee, and ankle of each patient's paretic limb. Collectively, this small group of clinical trials provides preliminary evidence that progressive resistance strength training can be effectively used to improve strength and function without a concomitant increase in spasticity after stroke. Interestingly, a few studies now show that beyond strength and ambulatory function adaptations, this intervention type may be effective for mental health (134,137), perceived participation (138), and paretic-side skeletal muscle hypertrophy (30). With regard to the latter point, evidence now shows that progressive lower-extremity strength training, provided it is intense enough, can cause large increases (+15%) in both paretic and nonparetic thigh muscle volume measured by serial CT scanning from the knee to the hip. Further, this muscle volume increase

coincides with reductions in skeletal muscle myostatin, a primary inhibitor of muscle growth (30).

Treadmill-Based Training Approaches

Based on pioneering studies of hind limb stepping recovery in despinalized cats, variants of treadmill (TM)-based training have emerged to promote locomotor learning after stroke (139,140). A biomechanical basis for this approach is supported by findings that TM walking improves reflexive gait patterning in hemiparetic patients (141,142). The facilitation of gait patterning with TM is well characterized for both body weight support (BWS) (141) and self-supported full-weight-bearing TM exercise conditions (142). TM produces a 50% improvement in interlimb stance to swing symmetry ratios, 30% improvement in impulse symmetry, and improved timing of quadriceps activation compared to overground walking in hemiparetic stroke patients (143). TM-based training also provides the task repetition that animal and human studies suggest is requisite to mediate motor learning and neuroplasticity (144). Randomized studies show that the benefits of TM training translate into improved overground walking, and can be extended to more severely impaired subjects using BWS strategies (145). TM-based training can also be combined with progressive aerobic exercise to improve both fitness and ambulatory function (23), as discussed in the following sections. There is currently a greater appreciation for the importance of more aggressively advancing TM training intensity (146–151) and duration (152,153) in the context of affecting health outcomes after disabling stroke. Aerobic fitness gains can be almost double the average normally seen with close attention to TM intensity progression details (25).

Partial Body Weight Support Treadmill Training

Partial BWS TM training has received much investigation, particularly as a means to provide a physiological gait training stimulus to more impaired subjects across earlier phases of stroke recovery (141). This approach utilizes a suspensory harness to progress patients from 30% to 40% BWS to full-weight-bearing TM walking, typically with 1 to 2 therapists facilitating stepping and truncal stability across 4 to 6 weeks. Early studies by Hesse et al. provide evidence that BWS TM training may restore gait in severely affected nonambulatory patients (141,145). Subsequent randomized studies confirm that BWS TM training is better tolerated and more effective than full-weight-bearing TM to improve gait and balance function in more severely hemiplegic patients, specifically that subset with lower gait velocities (<0.2 m/s) and poorer balance (Berg scores < 15 points) (154,155) and in advancing age. The latter finding may be explained by the significantly lower oxygen demands of BWS TM training—a finding that brings into question whether BWS using current protocols provides adequate aerobic intensity for metabolic health benefits (156).

Despite some positive results, a Cochrane review found no significant effects from BWS TM training except greater walking speed in those already ambulatory (157). Whether BWS TM or other TM-based training strategies are more effective than conventional therapy in durably improving function or fitness after stroke remains unclear (158). However, few studies have systematically investigated the training parameters or conditions to BWS TM training outcomes. One promising avenue is that BWS TM training at higher velocities may be more efficacious to improve walking velocity during the subacute stroke period (159). These findings have spurred important clinical trials investigating the relative benefits of BWS TM training across the subacute versus chronic stroke phases (114,160–165). However, the results published by Duncan et al. cast doubt on the relative utility of this intervention model during stroke recovery (116).

Full Body Weight Support Treadmill Training

Although partial BWS TM training may be an effective means for initiating training, particularly for those with greater gait impairment (154), this form of training has not traditionally utilized aerobic progression formulas (156). Thus, based on studies of exercise rehabilitation in the frail elderly, we have studied the profile of fitness and mobility function gains across six months of progressive full BWS TM aerobic exercise training in stroke survivors with chronic hemiparesis (23). This is a much longer therapeutic duration than is typical for most stroke rehabilitation programs. Our results show that the time profile of cardiovascular fitness gains with regular TM exercise training are progressive and nearly equal across the initial three months and the third to sixth months of training (Figure 27.5) (23). There is no evidence of

Source: From Ref. (23). Macko RF, Ivey FM, Forrester LW, et al. Treadmill exercise rehabilitation improves ambulatory function and cardiovascular fitness in patients with chronic stroke: a randomized, controlled trial. *Stroke*. 2005;36(10):2206–2211.

plateau, suggesting that training even beyond six months may produce further benefits in peak fitness levels. In addition, full BWS TM exercise also improves 6-minute walk performance and self-reported indices of functional mobility across 6 months, with greater gains in 6-minute walk occurring within the initial 3 months of training (Figure 27.6) (23).

Notably, prospective studies show a plateau in mobility recovery within 3 months after stroke in 95% of hemiparetic patients receiving conventional rehabilitation care (101). Our findings in a randomized study show that TM training improves both fitness and mobility function long after conventional rehabilitation care has ended and that the duration of exercise therapy to optimize these outcomes is at least six months. Again, greater than previously observed improvements with TM training may be possible by aggressively tailoring progression formulas such that participants are challenged to the greatest extent within any given disability level (25,148). Results from studies of TM training after stroke support incorporating long-term exercise after stroke, consistent with public health recommendations for sustained regular exercise to improve fitness and cardiovascular health for all Americans (10).

Multi-Modal and Alternative Approaches to Stroke Exercise Rehabilitation

A trial involving primarily African American stroke survivors utilized a multi-modal intervention (36). A delayed-entry controlled design was used to provide training to all 35 participants. Outcome testing included measures of peak VO_2, strength, flexibility, and body composition. The 3×/week training protocol consisted of the following components: cardiovascular endurance (30 minutes), muscle strength and endurance (20 minutes), and flexibility (10 minutes). Results showed significant time increases by group interactions for the following measures during cycle ergometer fitness testing: VO_2 peak, time to exhaustion, and maximal workload. This was among the first randomized exercise studies in stroke to show significant between-group effects for muscular strength and endurance as well as improvements in body composition (body weight, BMI, total skinfolds). Other multi-modal exercise therapies have also been successful after stroke (72–74), particularly in the context of falls prevention.

Several additional alternative approaches to stroke rehabilitation have been tested within the past five years, including split-belt TM training (166), TM locomotor training with leg weights (167), elliptical machine training (168), dual-task exercise training (28), balance training (169), Lokomat robotic training (170,171) and virtual reality-based training (172). Although data are somewhat preliminary at this time, some have shown promise for restoring health and function in this population. One of the more interesting discoveries to come to light in recent years is the capacity for multiple exercise modalities to improve cognitive function and mental health after stroke (173–177). Animal studies preliminarily indicate that this may partially be a function of exercise-induced increases in brain-derived neurotrophic factor (BDNF) levels (178).

Community- and Home-Based Intervention Strategies

Numerous behavioral and psychosocial issues associated with chronic disability and aging influence exercise adherence and can serve as barriers to participation following stroke (179,180). Limited access and labor intensity of individualized conventional stroke therapies further constrain resources for poststroke exercise programs. Although both home- and rehabilitation center-based programs have been studied, the safest and most effective settings and behavioral strategies to best disseminate exercise programs to stroke survivors are unknown. Group exercise programs feasible for conduct in the community setting have recently been investigated to increase access (113), while providing a socially reinforced model for structured physical activity across the chronic stroke period.

A seminal Canadian study by Pang et al. (88,111) was the first to examine effects of community-based exercise programs on bone health and mobility outcomes in older individuals with chronic stroke. Individuals with remote stroke (>1 yr) who could walk 10 meters independently (with or without walking aids) were randomized to 19 weeks of three 1-hour sessions per week of an Arm Exercise Group or a program that included brisk walking, sit-to-stand exercises, stepping onto low platforms walking obstacle course, and partial squats and toe rises to improve strength. The latter program significantly increased VO_2 peak by 9%, extended 6-minute walk distance by 20%, and improved paretic leg strength, but not Berg Balance Scores. However, most subjects had milder balance deficits, whereas that subset with moderate deficits did not successfully progress their exercise intensity.

Notably, this intervention prevented the declines in femoral neck bone mineral density that occurred in the Arm Group and increased distal tibial trabecular bone mineral content on the paretic side. This shows that community-based exercise programs can improve fitness, walking capacity, leg strength, and bone health for older individuals with milder chronic deficits (88,111).

Based on models of task-oriented exercise and social learning to facilitate exercise behaviors in the frail elderly, an adaptive physical activity (APA) program with gymnasium and home components was designed to improve mobility and ADL function for chronic stroke patients (113). Group exercises targeting improved gait and balance were utilized to enhance social support, with a parallel home regimen to build self-efficacy for habitual physical activities. Two months of the APA program improved Berg Balance, 6-minute walk distance, and Barthel index scores in 20 older subjects with chronic hemiparetic deficits (113). Tuscany Regional Health Authorities have established APA programs at 11 community sites in a 30 × 30 km region of Italy where health services outcomes are tracked. These findings provide proof of concept that community-based exercise programs improve mobility and basic ADL function and can be implemented in geographically defined regions to improve outcomes for older chronic stroke patients.

Progress continues to be made in the area of home and community rehabilitation after disabling stroke (115,181,182). Of particular note are recent attempts to incorporate family members into the rehabilitation programs (115,182). Evidence now shows that family involvement may be critical to optimizing patient recovery (115). Also, the study by Duncan et al. strongly suggests that home physical therapy (PT) care may be equal to or surpass more complex interventions delivered in hospital settings (116).

STRATEGIES FOR DESIGNING EXERCISE PROGRAMS IN STROKE SURVIVORS

Goals of Exercise Training

Structured exercise programs should be considered for all stroke survivors. As detailed in the prior section, a number of randomized studies now demonstrate that various exercise modalities can significantly improve cardiovascular fitness after stroke. Although fundamental questions remain regarding how to optimize the exercise prescriptions, the magnitude of VO_2 peak gains that are attainable with exercise after stroke is considered clinically significant in terms of both functional capacity and cardiovascular health promotion (92). Risk factor modification is a second major objective of long-term exercise after stroke. Cardiovascular fitness and metabolic health are integrally linked and modifiable by exercise training, which may translate into reduced recurrent stroke risk and cardiovascular events in this population (10). Individuals aging with the chronic disability of stroke are further subject to body composition abnormalities that are propagated by sedentary lifestyle, worsening rehabilitation outcomes, and cardiovascular risk. The interrelated goals for improving fitness and preventing the body composition complications of physical inactivity constitute a multiple physiological systems model defining the targets of exercise therapy after stroke (Figure 27.7).

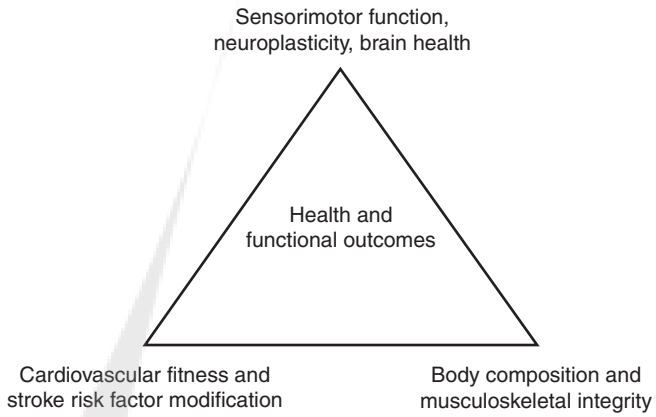

FIGURE 27.7 Multiple physiological systems that define the targets of exercise after stroke.

Intrinsic to this model is an emerging recognition that exercise can improve function by leveraging principles of motor learning even years after stroke. Emerging clinical and experimental data show that task-repetitive training can mediate functionally relevant motor learning in both the paretic upper and lower extremity (141,142). Conversely, lack of practice or "disuse" can propagate disability at a musculoskeletal and central nervous system level. Habitual daily physical activity patterns are a determinant of outcomes that warrant attention as an adjunct to any structured exercise program in the long-term care of stroke survivors. Hence, an objective of exercise therapy is improving the sensorimotor function that translates into improved daily activity profiles and quality of life across the continuum of stroke care. Motor learning strategies can be combined with aerobic training in a clinically appropriate way to improve the multiple physiological systems that determine functional and health outcomes, as shown in Figure 27.7.

The planning of exercise programs for stroke patients should be initiated early on with specific education to participants and family regarding the clinical relevance of exercise to functional recovery, cardiovascular health, and stroke risk factor modification. Most stroke survivors and many health care providers outside the field of rehabilitation care are unaware that both lower- and upper-extremity motor function can be improved by structured motor learning-based exercises even years after the initial stroke event (23,183). That physical inactivity is an independent risk factor for stroke and "disuse" leads to deconditioning, which worsens disability and stroke risk, are understated health concerns that should be reinforced across the phases of rehabilitation care. Patients should be informed that consensus statements strongly recommend exercise as an adjunct to

medical treatment for optimal management of hypertension, dyslipidemia, obesity, insulin resistance, and diabetes, all of which are elements of the cardio-metabolic syndrome and highly prevalent after stroke.

Medical Evaluation and Safety Issues Related to Exercise

As a result of the high incidence of medical and cardiovascular comorbid conditions that can influence exercise participation, evaluation for an exercise program should begin with a medical history and physical and cardiopulmonary examination. Medical exclusions for exercise after stroke are consistent with ACSM criteria for high CVD risk subject (33). In brief, exclusion criteria that have been systematically employed for exercise research include symptomatic heart failure, unstable angina, peripheral arterial occlusive disease, chronic pain syndromes, dementia or severe aphasia (operationally defined as incapacity to follow two-point commands) (27), and other medical conditions that preclude participation in low-intensity aerobic exercise, consistent with the 2012 ACSM guidelines. Using these eligibility criteria along with entry exercise tests, our safety data tracking across more than 10,000 TM aerobic training sessions and more than 400 peak exercise tests in chronic hemiparetic patients reveals no study-related serious adverse events. Analyses from a randomized study reveal only occasional minor musculoskeletal complaints reported by these deconditioned patients across six months of progressive TM aerobic training at an expected rate not different from controls performing supervised stretching exercises and low-intensity walking (23).

However, cumulative experience in safety of exercise after stroke is limited to research studies with very small sample sizes. These are inadequate to identify the full scope of medical or neurological factors that could complicate different exercise training approaches in the diverse stroke population. In one study, Rimmer et al. reported transient stroke symptoms, a seizure, and a hypotensive response during exercise testing (36), whereas other analyses of full-weight-bearing TM exercise revealed no serious training-related adverse events (23). However, hemiplegic arm and major hemisensory deficits predicted higher noninjurious fall risk, prompting our use of safety harnesses for subjects with specific deficit profiles. A further consideration is that strenuous exertion, such as that accompanying peak exercise testing, can precipitate arrhythmias and lower blood pressure in predisposed individuals with cardiac disease (33). Hence, exercise testing should be approached with caution in subjects with hemodynamic carotid stenosis or recent large territorial brain infarction. Although no exercise safety data yet exist, these conditions are known to markedly impair cerebral autoregulation, reducing capacity to compensate for drops in systemic blood pressure (10). Until more information is available, best clinical judgment and appropriate cardiopulmonary assessment should be used to guide the timing and design of exercise testing and training poststroke.

Exercise in Subacute Stroke Period

Structuring exercise programs after stroke presents unique safety and feasibility questions. Clinical research has not yet resolved basic questions regarding when to start structured exercise, nor shown which training modality(ies) or dose intensity are optimal across the phases of stroke recovery. Implementing exercise during the subacute stroke period is further complicated by the greater deficit profiles (101,141,154), high prevalence of cardiac comorbid conditions (184,185), and medical problems such as autonomic deconditioning and pain syndromes that are common and known to affect rehabilitation care (27). These factors limit patients' activity tolerance, forcing clinicians to weigh the feasibility of adding further exercise to already demanding early intensive rehabilitation. However, delay can be costly. Inactivity produces rapid declines in fitness and muscle mass that could worsen the functional aerobic impairment already present in the early stroke period (32).

Conventional rehabilitation does not likely provide adequate exercise intensity to reverse deconditioning after stroke (31,32,186). However, practice patterns differ considerably, as can the physical efforts and cardiopulmonary response to exertion during rehabilitation in different stroke patients (185). One practical approach is to assess the exercise intensity of usual physical therapy, focusing on upright and transitional movements that produce greatest exertion (31). Heart rate monitoring and ratings of perceived exertion (RPE) scales can be used for this purpose. If the aerobic component of usual rehabilitation care is considered deficient, therapists can consider adding low-intensity exercise, based on the cardiopulmonary safety profile, tolerability, and rehabilitation needs for each patient. Although the long-term benefits of starting specific exercise modalities early after stroke is not yet established, BWS TM training is better tolerated by individuals with greater gait deficits (154), and can provide an aerobic stimulus if properly administered (105). Hence, BWS TM training or other modalities to facilitate exercise in more disabled subjects warrant consideration early on.

Exercise Programs and Barriers to Participation in Chronic Stroke

For exercise programs to be successful across the chronic phase of stroke, a thorough pre-exercise entry evaluation, including assessment of barriers to exercise, is important (10). Numerous factors can interrupt the continuity of health-promoting exercise programs when transitioning from subacute to the chronic phase of stroke. Whereas most stroke survivors desire and would participate in regular exercise if available, a number of common psychosocial and behavioral factors can become formidable barriers. Stroke patients have a poor self-efficacy for exercise, which predicts reduced free-living physical activity and exercise behaviors in chronic stroke patients (10,179). An important and often ignored component of poor self-efficacy for

exercise and ADL function after stroke is fatigue (9,187). Nearly half of stroke survivors report fatigue as a factor that interferes with daily function, and reduces confidence to participate in regular exercise (9). Hence, evaluation using validated instruments, such as the Fatigue Severity Scale (9), can be used to identify this common barrier in the pre-exercise evaluation. Similarly, depression after stroke is common and could impede exercise participation (188). Because some studies show that exercise can improve mood after stroke, pre-exercise evaluation of depression and tracking using validated scales is advised. Another factor related to poor self-efficacy for exercise after stroke is inadequate outcome expectations. Most stroke patients are unaware that exercise can be undertaken to improve fitness, health, and function even years after a disabling stroke. Further, physician recommendations influence exercise patterns in aging and disability populations and are historically underutilized to promote exercise in the chronic stroke phase. Collectively, these findings are consistent with social learning theories to promote exercise behaviors in aging and chronic disease and highlight the importance of education and behavioral strategies to overcome barriers.

Important additional barriers are lack of resources, social isolation, and limited family support to sustain successful exercise programs in the chronic phase of stroke. Assessment of family and psychosocial support in the context of resources for maintaining exercise programs is advised (106). In practical terms, most stroke patients have limited access to exercise facilities or community programs that can provide the social support and oversight to successfully implement evidence-based exercise programs. Moreover, the efficacy and viability of long-term home exercise programs after stroke is unknown. These issues underscore the importance of rehabilitation health professionals partnering with primary medical care providers to jointly increase access to community and home services promoting exercise, health, and wellness after stroke.

Recent advances in home- and community-based exercise programs supporting this model are promising (88,106,109,113).

Selecting Exercise Training Formulas

By the time most individuals have reached the chronic phase of stroke, gait deficits are less pronounced, and subsequently, exercise-training capabilities are different. Most have achieved some degree of ambulatory function and may not require BWS or more dependent modalities for training. The gains in function often enable patients to participate in more rigorous and longitudinal exercise programs that have the potential to maintain and improve fitness and function while aging with the disability of stroke. Exercise modalities appropriate to deficit severity can optimally be implemented according to specific aerobic progression formulas based on cardiopulmonary exercise testing that can enhance safety and cardiovascular-metabolic health effects, as outlined in the following sections.

Exercise Testing Poststroke

Epidemiological studies show that 75% of stroke patients have CVD (184,185). Although uncommon, exertion-related myocardial events are possible in individuals with pre-existing cardiac disease and sedentary lifestyle (33). Further, many stroke patients have marked activity intolerance, particularly older individuals and those with greater gait deficits, which predict lower fitness levels after stroke. Exercise testing has revealed previously undiagnosed or asymptomatic coronary artery disease in 20% to 40% of stroke survivors (34) and provides information regarding the cardiopulmonary response to exertion that can be used to optimize safety and customize design of the aerobic exercise prescription. Therefore, submaximal effort or symptom-limited maximal effort exercise testing is recommended when clinically feasible to evaluate the cardiopulmonary safety and toleration of stroke patients of strenuous physical exertion before starting exercise training. Treadmill testing and training recommendations are summarized in Tables 27.4 and 27.5.

The selection of exercise testing modality may be influenced by many clinical factors, such as deficit profile, rehabilitation goals, or planned congruence with anticipated training modality. Because exercise testing can provide a reliable and valid means for quantifying fitness gains with training for both TM and bicycle testing modalities in hemiparetic stroke patients (22,189), congruence in testing and training modalities is recommended. There are no studies in stroke patients to discriminate between choices of submaximal versus symptom-limited peak effort exercise protocols. The term "peak effort," rather than maximal exercise test, is employed here because most stroke patients do not achieve full criteria for VO_2 max by open circuit spirometry testing (189). Peak exercise testing provides the most useful information for aerobic exercise in high-risk populations. Peak exercise heart rates are most accurate and have proven useful in the design of heart rate (HR) training progression in accordance with the Karvonen Formula. For high cardiac risk patients, training should be conducted at least 10 beats

TABLE 27.4 Treadmill Exercise Tests

TEST	PURPOSE
Zero-incline TM tolerance test	Acclimatize to TM; select speed for stress test
Screening TM exercise stress test	Identify cardiopulmonary response to strenuous exertion. Screen for underlying cardiac abnormalities
VO_2 peak exercise test	Measure peak oxygen-consuming capacity with open circuit spirometry as an outcome variable on a separate day from the screening TM exercise stress test

TABLE 27.5 Suggested Exercise Testing Protocol for Stroke Survivors

1. Start at 0.1 mph and increase to velocity determined from zero-incline TM test.
2. Fastest comfortable walking velocity maintained at no incline for initial 2 minutes, then:
   - Milder gait deficits: advance to 4% incline for next 2 minutes, then increase incline 2% every minute thereafter (velocity constant) to peak volitional exertion.
   - Moderate-to-severe deficits: advance to 2% incline for next 2 minutes, then increase incline by 2% every 2 minutes thereafter, with velocity held constant.

per minute below the exercise intensity that produces systolic blood pressures higher than 250 mmHg or diastolic blood pressure higher than 115 mmHg, ST segment depression of more than 1 mm, or other significant ECG or clinical cardiopulmonary intolerance (33). These criteria may best be revealed using peak exercise protocols.

Little is published regarding use of submaximal exercise to design aerobic prescriptions after stroke or exercise planning for stroke patients who cannot undergo exercise tests. Peak exercise testing may not be feasible or desired for some patients, particularly those less than 1 month poststroke, a period within which cerebral autoregulation is likely to be most impaired. In a seminal American Heart Association (AHA) consensus statement, submaximal exercise testing was recommended using predetermined endpoints of 70% of age-predicted maximum HR, consistent with practice in postmyocardial infarction patients (10). A period of ECG telemetry monitoring is recommended for those stroke patients deemed at high cardiac risk and who cannot undergo any exercise testing (33). Although no studies have yet established the efficacy in stroke, low-intensity exercise at increased training duration and/or frequency has been recommended for cardiac patients without an entry exercise test. Such guidelines extrapolated from cardiac patients may be useful until further data are available for stroke patients considered at high cardiac risk.

General Guidelines for Exercise Training and Progression

Treadmill Aerobic Training

The target training parameters used in chronic stroke patients from our laboratory (27) consist of three 40- to 45-minute sessions per week of TM walking at 60% to 70% of HRR, where target heart rate is calculated with the Karvonen Formula:

Heart rate reserve (HRR)
= Maximum heart rate – Resting heart rate

Target heart rate = (HRR × training %) + Resting heart rate

Creating a zone of 60% to 70% simply requires performing the calculation twice to come up with an upper and lower limit for the desired range. Training intensities of up to 80% HRR are now shown to be efficacious and safe in this population (25). Training is initiated conservatively at 40% of HRR for durations of 10 to 15 minutes and advanced as tolerated. Discontinuous training epochs consisting of three to five minutes TM walking with similar duration interval rests are used in those highly deconditioned or more severely disabled patients incapable of continuous training. Total training duration is then advanced as tolerated toward the target. Handrail support is used, and 5-minute TM warm-up and cool-down periods at approximately 30% of HRR are phased into each workout as participants develop the necessary endurance for longer bouts of training. Regression analyses of clinical factors related to training safety reveal that arm hemiplegia (inability to grasp TM handrail for support) and presence of major sensory deficit are associated with increased risk of falls during TM training. Although such events are uncommon and of low impact, we use suspensory safety harnesses (Biodex Medical, Shirley, NY) in a nonweight-bearing fashion to eliminate the risk of fall injury in our patients. Heart rate is monitored continuously by two-lead ECG (Polar Electro, Woodbury, NY), and blood pressure recordings are taken before, at the midpoint, and at the conclusion of each exercise session to ensure safety and to document the intensity of the training session.

Progression of training workload is determined biweekly by monitoring each patient's gait, HR response, and patient-reported level of fatigue at the end of a training session. If no gait instability, exaggerated HR response (HRR > 80%), or extreme fatigue is noted (Borg Perceived Exertion used as adjunct to rate tolerability), an increase in training speed by 0.1 mph increments is prioritized to reach the target training intensity. Increase in TM grade (1% increments) is utilized secondarily to achieve target aerobic intensity for those individuals who do not tolerate further TM velocity progression to meet this goal. Training duration is typically advanced approximately 5 minutes every 2 weeks, as tolerated, to arrive at a total 45 minutes of training by the third month of training. For those completing intermittent bouts of exercise, only duration is altered in order to progress to one continuous bout of 15 minutes.

Bicycle Aerobic Training

Potempa et al. achieved aerobic fitness gains after stroke using a bicycle ergometer training protocol (22). In this case, subjects exercised on an adapted cycle ergometer for 30 minutes 3 times per week. The intervention period lasted a total of 10 weeks. In the first 4 weeks, the training load was increased from 30% to 50% of maximal effort to the highest level attainable by the subject. The highest training load was then maintained for the final six weeks of training. Although this protocol resulted in fitness gains, sensorimotor function was not improved using this adapted bicycle ergometry protocol.

Resistive/Strength Training

A diverse array of equipment and RT exercise progression protocols have been used successfully in stroke (30,117,134–138). From the standpoint of building muscle mass, muscle strength, and muscle endurance, our group has emphasized a high-repetition, relatively high-intensity lower-extremity training format (30,81). This is accomplished through a series of exercises performed on three separate Keiser K-300 lower extremity air-powered machines utilizing pneumatic resistance (leg extension machine, leg curl machine, leg press machine). Because of the large discrepancy in strength and function between the paretic and nonparetic legs after stroke, limbs are always exercised separately on each Keiser machine. This ensures the maximum degree of stimulus on each side. Participants perform 2 sets of 20 repetitions on each leg on each machine (3 × 4 sets = 12 sets total, 12 × 20 repetitions = 240 repetitions). Each unilateral set of 20 is conducted with the goal of achieving at least one instance of muscle failure (sometimes more), such that the participant must lower the pneumatic resistance to achieve 20 repetitions. Generally, the initial weight is set at a level that will cause muscle failure somewhere between the 10th and 15th repetitions. The weight is then lowered gradually, enabling the participant to achieve additional repetitions up to the 20th. If necessary, the weight is lowered a second, third, or fourth time to achieve 20 repetitions. Often, during the initial stages of training, arriving at the ideal weight is a matter of trial and error, meaning that several training sessions are required for participants to fully comprehend what is being asked of them and to consistently train at the level of difficulty and intensity described here. Once the participant is performing 16 to 20 repetitions at a given weight, it is left to the discretion of the trainer on when and how much to advance the weight for the next set/session. Ideally, the trainer progresses the weight to a level that again causes the first incidence of muscle failure between the 10th and 15th repetition. Having more than the usual number of repetitions per set also imparts the added benefit of producing a cardiovascular effect with more prolonged elevations in heart rate and breathing. As with TM aerobic exercise implementation, consistent and careful monitoring of vital signs is essential for safety.

SUMMARY AND FUTURE RESEARCH

Reduced cardiovascular fitness is commonly observed after stroke, with physiological and functional consequences. More work is needed to fully elucidate the precise causes and consequences of this decline, but preliminary evidence points to several noteworthy biological correlates. Specifically, changes to paretic side extremities, including muscle atrophy, muscle fat accumulation, fiber type alteration, hemodynamic impairment, reduced capillary density, and increases in inflammatory markers, may both contribute to and be compounded by reductions in cardiovascular fitness. Moreover, there are systemic disturbances in metabolism and respiration that are exacerbated with sedentary living and the accompanying fitness decline. Hence, preventing and reversing the deconditioning trend after stroke is of paramount importance. Despite encouraging developments over the past few years, more is needed to ensure that cardiovascular/metabolic deconditioning becomes a focal point for poststroke care in mainstream clinical practice.

Fortunately, exercise training models have demonstrated high efficacy for addressing many deconditioning-associated issues in stroke. Degrees of training response to any given exercise stimulus, provided it is implemented carefully with optimal and safe progression in mind, is often comparable to that observed in healthier, nonstroke aging populations. A variety of exercise protocols show promise as a potent stimulus for improving fitness and associated physiological and functional outcomes in stroke-disabled individuals. Although the body of evidence for exercise-induced adaptation in stroke is still somewhat limited, substantive progress has been made in showing the extent to which exercise can be used to improve VO_2 peak, sensorimotor function, systemic metabolism, peripheral hemodynamics, cerebral hemodynamics, muscle tissue quantity, muscle biology, tissue inflammation reduction, pulmonary function, and cognition. Larger randomized research studies aimed at effective exercise prescription and informing best practice in stroke rehabilitation are essential to the advancement of stroke recovery.

There remains a significant practice gap, with many basic questions regarding the practice and effects of exercise after stroke left unanswered. The optimal training modalities and dose intensity of exercise, and how these may relate to deficit profiles or time since stroke, are unclear. Although selected CVD risk markers have improved, there are no long-term data to determine whether exercise reduces recurrent stroke, cardiovascular events, or progression of insulin resistance to diabetes. Future research could consider the promising findings from bench and clinical studies in nonstroke populations that exercise improves cognitive function, depression, and alters neural growth factors that could improve brain health in aging and mediate brain plasticity linked to motor learning. In practical terms, many of the recommended safety and training approaches for stroke patients are borrowed from the cardiac literature. These should be empirically tested in stroke patients—a population that in many ways is clinically and biologically unique. Further studies in community translation and systematic strategies to overcome barriers to longitudinal participation are needed to better realize the benefits of exercise after stroke.

Medical Complications After Stroke

Lalit Kalra

Patients with stroke are at risk of developing a wide range of medical complications that have the potential of causing death or delaying successful rehabilitation. Several studies have shown that medical complications may be the primary cause of hospital-related death in more than 50% of stroke patients and may contribute to death in an even larger proportion (1). The timing of deaths in stroke is bimodal: the first peak occurs in the first week, predominantly as a direct consequence of brain damage; and the second peak occurs several weeks later, mainly as a result of potentially preventable medical complications such as infection, venous thromboembolism, or cardiac disease (1–5). Medical complications not only increase mortality during inpatient care, but have also been shown to have a significant effect on long-term mortality. A study of nearly 600 patients has shown that the presence of one or more medical complications during hospitalization was associated with a hazard ratio for mortality ranging from 2.67 in the initial cohort to 8.93 in patients who had survived for three or more years, after adjusting for age, gender, initial stroke severity, stroke subtype, comorbidity, and disability at the time of discharge from hospital (6).

Medical complications have also been associated with increased disability and poor functional outcome in stroke patients. The scope of intensive therapy is limited in patients suffering complications during rehabilitation, which may result in longer hospital stays, increased resource use, and institutionalization (4,7). Mortality-adjusted data analysis from the RANTTAS trial, which excluded patients who died at three months after stroke, showed that serious medical events during hospitalization were associated with a four-fold increase in residual severe disability, independent of stroke severity and other variables (5). The length of hospital stay for rehabilitation is directly proportional to the number of medical complications suffered by patients, and 7% to 17% of stroke patients undergoing rehabilitation need to be transferred back to acute care settings, which further increases the overall cost of stroke management (4,8). It is, therefore, both inaccurate and misleading to view inpatient stroke rehabilitation as a medically quiescent process that does not require ongoing medical input.

FREQUENCY AND TYPE OF MEDICAL COMPLICATIONS

Medical complications are known to be common in patients with stroke, but estimates of their prevalence in rehabilitation settings differ significantly, ranging from 27% to 96% in various studies, with a median of 75% (9). Complications appear to be more frequent in patients with severe strokes (94%) compared to patients with mild or moderate deficits (16%) (7). Prevalence of complications is higher (75%–85%) in studies that include acute patients and in studies that have used rigorous and prospective methods for data collection (9). The type of medical complications also varies with patient characteristics and management settings. The commonest medical complications seen in rehabilitation settings are infections (particularly of the chest or bladder), falls, deep vein thrombosis (DVT) and thromboembolism, pain, loss of skin integrity and/or pressure sores, and other mobility-related problems, such as musculoskeletal pain or limb edema. During rehabilitation, patients with stroke are also more susceptible to exacerbations of pre-existing cardiac, vascular, and metabolic diseases, which are frequently present in this population. A list of frequently encountered medical complications is given in Table 28.1, which is by no means exhaustive.

The wide variation in estimating the frequency and types of medical complications that people with stroke experience during their rehabilitation (Table 28.2) reflects the methodological problems and inherent biases encountered in undertaking such studies (9). Earlier studies have either incorporated a retrospective case ascertainment design (2–4,10) or prospective analysis of patients selected for intervention studies (5,7), with different criteria for patient selection, definition of complications, timing of assessments, and duration of follow-up. The retrospective identification of complications from case notes is further influenced by the diagnostic criteria used, interobserver bias, and the standard of notekeeping. Most studies have recorded only symptomatic complications that occurred during the inpatient stay, which will be influenced by reporting bias and duration of observation (11). Very few studies have investigated the

TABLE 28.1 Medical Complications Reported in Stroke Patients

Infections	Aspiration pneumonia, chest infections, urinary tract infection, sepsis, cellulitis, *Clostridium difficile* enteritis
Mobility-related problems	Falls, fractures, musculoskeletal pain, edematous limbs, DVT in calf, thigh or axilla, PE, loss of skin integrity, breaking skin, pressure ulcers, urinary retention or incontinence, constipation, diarrhea
Comorbidity	Angina, myocardial infarction, congestive cardiac failure, atrial or ventricular arrythmias, cardiac arrest, hypertension, hypotension, poor diabetic control, hypoglycemia, ischemic colitis, exacerbation of chronic lung disease, peripheral vascular disease
Others	Noncardiac pulmonary edema, gastrointestinal bleeding, dehydration and electrolyte imbalance, renal impairment, anemia, malnutrition

prevalence of complications in a defined representative sample of stroke patients from a fixed time point early in the course of their disease, using prespecified objective criteria for identifying complications, prospective data-collection methods, and regular follow-up.

THE DETERMINANTS OF MEDICAL COMPLICATIONS

The incidence and frequency of complications in stroke rehabilitation are influenced by several factors. Most studies show that the frequency of complications increases with age of patients and the severity of neurologic or functional deficits (Table 28.3). Prestroke disability, urinary incontinence, vascular risk factors such as diabetes and hypertension, markers of poor nutritional status (e.g., hypoalbuminemia), and length of hospital stay also identify patients at higher risk of developing infections (8,10,11). Factors that predict transfer to acute medical facilities from rehabilitation settings include elevated admission white blood cell counts, low admission hemoglobin levels, greater neurologic deficit, and a history of cardiac arrhythmia (8).

The relationship reported in some studies between increased length of hospital stay and increased prevalence of complications raises important issues. It remains unclear whether prolonged hospitalization is a cause or a result of stroke-related complications, but it is likely that complications are both a cause and an effect of prolonged hospitalization. The setting in which patients are managed also has an important influence on the frequency and type of complications. Kalra et al. (7) have shown that although there are no differences in the frequency of complications between generic and specialist settings, there is a significant difference in the type of complications between the two settings. This difference may be one of the reasons for better outcomes and shorter lengths of hospital stays reported in specialist settings. It is likely that patients cared for in a dedicated stroke unit are under more scrupulous observation by experienced staff and may experience fewer severe or life-threatening complications, whereas less-severe complications may appear to be more frequent simply because of better recognition and documentation in case records (10). This explanation is supported by a study on processes of care on specialist units, which showed that patients on a stroke unit were monitored more frequently than those in general units and that more patients received antipyretics, measures to reduce aspiration, and early nutrition (12). Complications were less common in the specialized setting, with fewer patients suffering from chest infection or dehydration, which was associated with reduced mortality, fewer instances of institutionalization, and shorter length of hospital stay. Similar findings have been reported from the most recent Stroke Unit Trialists Collaboration meta-analysis of medical complications data from seven trials, which included 3327 patients and showed significantly lower complications arising from immobility and infections in patients managed on specialist units (13).

SPECIFIC MEDICAL COMPLICATIONS

Aspiration and Pneumonia

Aspiration and swallowing impairment are common after stroke; a recent meta-analysis has shown that their incidence ranges from 51% to 55% on clinical tests and 64% to 78% on videofluoroscopy or other instrumental tests (5). Dysphagia is associated with a three-fold increase in the risk of chest infections, which increases to eleven-fold in those with definite aspiration (14). Large stroke registries across the world have shown pneumonia to be the single most important cause of death in the entire stroke population, accounting for 23% of deaths in the Japanese registry (15) and 31% in the German Stroke Registers Study (1). In addition, as many as two out of three stroke patients who appear to be able to swallow safely on clinical assessment have been shown to aspirate using instrumental diagnostic techniques (16). Aspiration is associated with a higher risk of chest infections and mortality (17).

Although aspiration is common after stroke, not all patients who aspirate will develop chest infections. It is likely that there are several mechanisms that protect the lower airways, ranging from physical processes that clear the airways of the aspirated material, to cellular and immunological processes that combat infection. Of these, voluntary expiration and cough are particularly important for maintaining the patency of airways. Cough, whether voluntary or reflex, generates high expiratory flows with laminar flow in the smaller airways, which dislodge and eject foreign material from the pulmonary system. The relationship between cough and aspiration has not been explored in detail, but the few studies available

Low admission hemoglobin	1.9 (1.3–2.7)
Greater neurologic deficit	2.5 (1.4–4.4)
History of cardiac arrythmia	1.8 (1.2–2.7)

Source: Data from Davenport et al. (10), Roth et al. (8), and SUTC (13).

show that absent or weak cough in stroke patients is associated with a higher incidence of aspiration and chest infections (18,19). Several aerodynamic measures of voluntary cough are impaired in stroke patients compared to nonstroke control subjects, and in aspirating compared to nonaspirating stroke patients (19). More recent studies suggest that stroke patients also have impaired reflex cough, increasing the likelihood of aspiration (20). The final common pathway for the production of effective cough is the ability to generate high intra-abdominal pressure by strong contraction of the abdominal muscles. Recent studies have shown diaphragmatic involvement on the affected side, disruption of cortico-respiratory neuronal outflow, and decreased expiratory muscle excitation from the affected hemisphere in patients with stroke (21). It is quite likely, but remains unproven, that the impairment of expiratory muscle function may impair voluntary cough efficacy and contribute to increased susceptibility to chest infections after stroke.

The CNS modulates the immune system through humoral and neural pathways, and it has been suggested that stroke may induce an immunodeficient state at the time of maximal deficit by affecting hypothalamic pituitary adrenal (HPA) axis activity and resulting in impairments of the sympathetic nervous system and various neurohumoral mechanisms (22). Experimental studies have shown long-lasting depression of cell-mediated immunity, reduced spleen cellularity and response to mitogens, and increased production of inflammatory factors on sympathetic stimulation in stroke models. This is supported by findings of reduced peripheral blood lymphocyte counts, impaired T- and natural killer cell activity, reduced mitogen-induced cytokine production, rapid increase of circulating cytokines in plasma, and sympathoadrenomedullary activation with infection in stroke patients.

Despite several studies showing strong associations between dysphagia and chest infections, there are few intervention trials of antibiotics used to prevent chest infections. A meta-analysis of 5 studies that included 506 stroke patients showed that preventive antibiotic therapy reduced infection rate from 36% to 22% overall (relative risk, 0.58; 95% confidence interval, 0.43–0.79), but there was no effect either on mortality or the likelihood of good outcomes (23). Major limitations in existing literature include small studies based on the assumptions of high frequencies of chest infections (30%–45%), much higher than those encountered in clinical practice; inclusion of nondysphagic stroke patients in whom the risk of aspiration and pneumonia is significantly lower than in those with dysphagia and more severe stroke (typical of those undergoing rehabilitation); and very short treatment duration. In addition, end points were inconsistent and consisted of infarct size and bladder temperature rather than mortality or chest infections. The use of antibiotics is associated with increased risk of serious adverse events such as *Clostridium difficile* and methicillin-resistant staphylococcus aureus colonization, which were not addressed.

Existing guidelines have evidence-based recommendations on the assessment, positioning, and feeding of acute stroke patients to prevent chest infections, but there is not enough evidence to support a clear strategy for antibiotic use for prevention (24). The current policy is to adopt a "wait and watch" approach for identifying early signs of chest infection and treat aggressively with appropriate antibiotics if any of these are present. Additional risk factors for aspiration and chest infection in patients undergoing rehabilitation include age over 65 years, speech or cognitive impairment, stroke severity and residual disability, decreased level of consciousness, brainstem strokes, and multiple infarcts (25); patients identified at high risk should be monitored closely for early signs of aspiration and chest infection. Preventive measures to reduce chest infections include assessment for dysphagia, aspiration risk, and cough; positioning and regular suctioning, dietary modifications, and dental and oral hygiene. It should be emphasized that nasogastric tubes or percutaneous gastrostomies do not reduce the risk of aspiration in dysphagic patients. For further reading on the management of dysphagia, see Chapter 14.

Cardiac Complications

Cardiac disease is not only a risk factor for stroke but also a common complication encountered during stroke rehabilitation. As stroke and heart disease share several risk factors, a recent stroke may be caused by a concomitant acute myocardial infarction, valvular heart disease, heart failure, or arrhythmias—and these conditions may also be exacerbated by stroke. The involvement of the right insula in stroke is of particular importance in predisposing to cardiac complications, because of its rich connections with the limbic system and involvement with autonomic control (26). The

occurrence of serious cardiac events and nonstroke vascular death in stroke patients varies between 1.1% to 2.1%, and most of these events tend to occur in the first two weeks after stroke (27,28). Factors that predispose to the risk of cardiac disease in recovering stroke patients include stroke severity, diabetes, congestive heart failure, and a prolonged QTc interval (28).

Cardiac arrhythmias are the commonest complication after stroke and include atrial fibrillation, supraventricular tachycardia, ventricular ectopic beats, and ventricular tachycardia (29). Cardiac arrhythmias can lead to hemodynamic instability, increase the risk of cardiac death, and be associated with cerebral and systemic thromboembolism. Subclinical ECG abnormalities in stroke patients are frequent, but their relevance to outcomes remains controversial. Of these, only prolongation of the QTc interval has been independently associated with ventricular arrhythmias and vascular death (30).

A systematic review of myocardial infarction in stroke patients suggests a 2% incidence for both myocardial infarction and nonvascular death in stroke patients (27). A subthreshold increase in cardiac enzymes is more common and thought to be indicative of brain-induced myocardial damage (myocytolysis) (31). Worsening of congestive heart failure is frequently seen in stroke patients, largely because of iatrogenic complications such as fluid overload or changes in medications. Occasionally, congestive heart failure may be precipitated by new-onset myocardial infarction or arrhythmia. Very rarely, patients with severe strokes may develop Takotsubo syndrome, a characteristic cardiomyopathy with left ventricular apical ballooning. Takotsubo syndrome is usually self-limiting, but has been associated with sudden death, congestive heart failure, and recurrent thromboembolism (32).

Identification of high-risk patients and surveillance on the stroke unit can help to prevent such complications. As these complications may be life threatening, patients may need to be transferred to acute facilities with intensive monitoring and specialist input as appropriate to their needs.

Falls

Falls during rehabilitation are common, and a high prevalence has been reported in many studies (Table 28.1). In a study by Davenport et al., falls were the most common individual complication and occurred in 22% of patients (10). An even higher proportion of falls during the hospital stay was reported by patients discharged from rehabilitation, with nearly 46% claiming to have fallen at least once during their hospital stay and 73% experiencing a fall within the first six months of discharge (33). In most instances, these falls are benign; soft-tissue damage or need for further investigations is seen in about 10% of fallers and only 1% to 3% of patients who fell suffered a fracture as a result of the fall. An important consideration is falls occurring in patients receiving anticoagulation for secondary-stroke prevention while undergoing rehabilitation. Despite falls being a relative contraindication to anticoagulant therapy because of percieved risks, Stein et al. have shown that although falls in patients on anticoagulation were as frequent as in nonanticoagulated patients undergoing rehabilitation, the risk of injury, major bleeding, or intracranial hemorrhage was comparable to those not receiving anticoagulation (34).

The great paradox of rehabilitation is that most therapy activity is geared toward increasing mobility in stroke patients; yet patients who have some ability to mobilize are most prone to falling (11). The main reason for falls is stroke-related disability, with most patients losing balance while attempting to undertake basic activities such as transferring, walking, or reaching. Factors associated with increased risk of falls include age, severity of stroke deficit, neglect, cognitive impairments, comorbidity, and a tendency to "push" from the unaffected side (35). Patients who have had one fall are at a greater risk of suffering further falls. The Berg balance test has been suggested as a reliable, objective test for identifying potential fallers in rehabilitation settings, but its use in clinical practice remains to be validated (36).

The greatest risk of falling in rehabilitation settings is during unsupervised activity, but it may neither be feasible to monitor patients on a 24-hour basis nor desirable to lower their optimism and perceptions of recovery by severely restricting activity. The answer may lie in effective therapy techniques and strategies to prevent falls, good communication with patients to provide a clear understanding of stroke-related problems and their abilities, safe environments, toileting programs, and use of aids and technology. Individuals with evidence of balance difficulties, neglect, seizures, cognitive impairments, or use of CNS-depressant medication are at high risk and these risks should be minimized by careful attention to environment and medication (9). The use of hip protectors as shock absorbers to prevent fractures after a fall has been advocated in stroke patients and supported by a pooled analysis of 15 trials, which has shown benefit in the older patient (37). However, there must also be acceptance, by both patients and professionals, of the small element of risk of falling, which is inherent to promoting independence and self-confidence in stroke patients undergoing rehabilitation.

Urinary Dysfunction

The most frequently occurring urinary problems associated with stroke are frequency, incontinence, retention, and infection. Urinary incontinence has a reported incidence ranging from 37% to 79% (9) and is one of the most commonly encountered medical complications in rehabilitation settings. Elderly patients with stroke can have pre-existing difficulties with micturition, which are worsened even by mild strokes. Any urinary problem can adversely affect self-esteem and motivation of patients, leading to delayed discharge from hospital, increased caregiver burden after discharge, or institutionalization. Patients who are incontinent on admission to rehabilitation suffer additional complications and have greater morbidity, both during their hospital stay and at three months after stroke (38). Many stroke

patients who are initially incontinent regain continence in two weeks, but 15% to 20% patients may have persisting problems at six months after stroke (39). The main predictors of incontinence in the 935 patients included in the Copenhagen Stroke Study were age, severity of stroke, diabetes, and pre-existing functional comorbidity (39). Factors associated with increased risk of urinary tract infections included older age, a history of prior stroke, greater stroke severity, use of beta-blockers or antidepressants, and a postvoid bladder residual of greater than 150 mL.

Several mechanisms contribute to incontinence in stroke patients (40). Patients may present with incontinence because of impairments of bladder function resulting from an "uninhibited bladder" and/or hyperreflexia from disrupted neuromicturition pathways. Other patients have normal bladder function but may still be incontinent because of stroke-related motor, cognitive, and language deficits. In some patients, incontinence may result from bladder hyporeflexia caused by concurrent neuropathy associated with age or diabetes or from concurrent medications, which are unrelated to the acute stroke. In addition, there may be many nonphysiological factors that contribute to increased prevalence of reported incontinence in stroke patients. These include other stroke-related problems such as depression, apathy, confusion, or speech difficulties, which may affect the desire or the ability to communicate voiding needs. Some patients who are dependent on caregivers for transfers and mobility may find it difficult to void in a socially appropriate manner. Lack of caregiver support may also make it difficult for stroke patients to use the toilet quickly enough. Medications (such as diuretics) can increase the frequency of the need to void, whereas others (such as those with anticholinergic effects, and beta-blockers in particular) can increase confusion or affect the autonomic nervous system, leading to incontinence or retention.

There are a wide range of interventions, including bladder training, continence nurse practitioner care, pharmacological treatments, and sensory–motor biofeedback techniques, to manage continence in stroke patients. Many of these behavioral and pharmacotherapy interventions are supported by small studies, but the heterogeneity in patient populations, study design, and times of enrollment between studies limits their ability to influence practice (41). There are no large well-designed randomized controlled trials that provide conclusive evidence of benefit, and no single treatment has been shown to be superior to any other in improving continence. In the absence of conclusive evidence, a stepwise approach beginning with behavior intervention, progressing to medication only if these measures fail, and considering surgical interventions as a last resort has been recommended (36).

The use of indwelling catheters in patients with incontinence is an important issue in stroke management. It is generally believed that early use of indwelling catheters will inhibit regaining continence in stroke patients, and that the use of indwelling catheters should be limited to patients with incontinence who cannot be treated with other means, patients with urinary-outlet obstruction, severely impaired patients with skin breakdown in whom frequent bed or clothing changes would be difficult or painful, and patients in whom incontinence interferes with monitoring of fluid and electrolyte balance (36). Chronic use of indwelling catheters also increases the risk of urinary tract infection and inflammatory bladder wall changes, which contribute further to incontinence and infection.

Deep Vein Thrombosis

There is wide variability in the reported incidence of deep vein thrombosis (DVT) following stroke. The overall incidence of clinically apparent and silent DVT may be as high as 45% in acute stroke patients. This rate falls to 10% or lower in patients in the subacute phase of stroke who are receiving rehabilitation (36,42,43). The incidence of pulmonary embolism (PE) varies between 9% and 15% in patients who have DVT and, like DVT, is lower in those undergoing rehabilitation. DVT and PE account for 1% to 2% of mortality in stroke patients in rehabilitation settings (36), but PE has been implicated as a cause of death in 12% to 20% of patients in acute settings and in up to 50% of stroke patients with sudden death (44,45). Most fatal PEs occur between the second and fourth weeks after a stroke, when patients are most likely to be undergoing rehabilitation. Clinical symptoms of DVT (pain, swelling, erythema) may often be absent in stroke patients, even when diagnostic tests are positive. The risk of DVT and PE is high in patients with advanced age, more severe strokes, lower-limb plegia, reduced consciousness, obesity, history of a previous DVT, and longer duration of hospital stay (46). Many reports show that the prevalence of DVT appears higher in patients with hemorrhagic compared with ischemic strokes, which has partially been attributed to the use of anticoagulant medications in ischemic stroke patients (47).

Prophylaxis with low-dose subcutaneous unfractionated heparin (UFH) or low molecular weight heparin (LMWH) can be effective in preventing DVT and PE, but can also increase the risk of major bleeding, intracranial hemorrhage (ICH) or hemorrhagic transformation, especially in patients with large infarcts (9). There is a difference of opinion on their management, and guidelines for thromboprophylaxis in stroke vary between countries. North American guidelines strongly recommend early use of anticoagulants, heparin, or other antithrombotic measures to prevent DVT in immobilized stroke patients (48). In contrast, UK guidelines warn against the routine use of heparin or anticoagulation and recommend the use of aspirin and elastic compression stockings in stroke patients (24).

There is very strong, good-quality evidence in literature that anticoagulation significantly reduces the incidence of DVT. A pooled analysis of 16 trials involving 23,043 patients showed that treatment doses of UHF decreased DVT and PE but increased ICH in stroke patients. UHF used in preventive doses decreased DVT but had no effect on PE or ICH. LMWH (>6000 IU) decreased DVT and PE but increased the risk of ICH, but low-dose LMWH (<6000 IU) reduced both

DVT and PE without increasing the risk of ICH (49). It was not possible to identify optimum candidates for DVT/PE prophylaxis therapy from these studies, and it has been suggested that prophylaxis is used for stroke patients identified as being at high risk (based on the factors described earlier) during rehabilitation. There is also no evidence or consensus on the duration of treatment required in these patients, so a pragmatic approach based on individual patient characteristics has been recommended. The use of anticoagulants to prevent DVT or PE in patients with hemorrhagic stroke presents a greater challenge and remains controversial. A small randomized study in ICH patients has shown that low-dose heparin prophylaxis initiated on the second day after stroke was safe and effective in preventing PE and that early treatment started within two days was more effective than treatment started at an average of one week after stroke onset. However, these results remain to be confirmed by larger, better-designed studies (50).

The alternate approach of using graded compression stockings has been recommended in some guidelines, but a very large randomized controlled trial has shown no benefit in reducing DVT, PE, or mortality in stroke patients (51). Compression stockings were associated with a four-fold increase in skin ulcers and a small increase in lower-limb ischemia, suggesting harm, and should be avoided in stroke patients undergoing rehabilitation.

Regardless of the robustness of evidence on these interventions, a major challenge in stroke management is the translation of good research evidence into good clinical practice. In the Post-Stroke Rehabilitation Outcomes Project, Zorowitz et al. (42) showed that despite the strength of evidence and support from clinical guidelines, nearly 33% of patients without DVT and 1% of patients with DVT had no documented orders for anticoagulant medications. The study concluded that although much is known about the prevention and treatment of poststroke DVT, clinicians need to learn to apply prevention protocols to prevent interruptions to the rehabilitation process.

Edematous Limbs

Swelling of the limbs on the affected side is common after stroke. A recent study in 88 stroke patients on a rehabilitation unit showed that some degree of hand swelling was present in 73% and edema in 33% of patients (52). These problems are more common in patients with hypertonic fingers and impaired sensation, and have been associated with worse outcomes for arm and hand function. Limb edema also causes considerable discomfort and concern to stroke survivors, especially because it may never resolve in some patients. Elderly patients and those with more severe strokes are likely to suffer from these problems and have an increased risk of venous thrombosis.

The precise etiology of edema of the hand of the paralyzed arm is not known, but various mechanisms such as complex regional pain syndrome (formerly called reflex sympathetic dystrophy), posture, and lack of muscle activity have been suggested in the past. Geurts et al. (53) undertook an extensive review of studies on the etiology and treatment of poststroke hand edema and shoulder–hand syndrome. This review included etiological studies on lymph scintigraphy in hand edema, bone scintigraphy, putative risk factors, and the existence of autonomic dysregulation or peripheral nerve lesions. Therapeutic studies included investigations of continuous passive motion and neuromuscular stimulation in hand edema as well as oral corticosteroids, intramuscular calcitonin, and trauma prevention. They concluded that hand edema is not lymphedema but is rather associated with increased arterial blood flow, possibly resulting from autonomic dysregulation, and is probably worsened by trauma-causing aseptic inflammation of the joints. Furthermore, no specific pharmacological treatment had any advantage over physical methods for reducing hand edema (54). Available treatment modalities include elevation of the hand, massage, application of elastic bandages, immersion of the hand in cooled water, and pneumatic compression, all of which remain debatable.

MEDICAL MANAGEMENT IN REHABILITATION

The medical management of patients with stroke requires the skills of a well-coordinated multidisciplinary team because of the number of problems associated with stroke (e.g., impaired sensation or cognition, paresis, dysphagia), the high risk of stroke-related complications (e.g., aspiration pneumonia, venous thrombosis), the specialized needs of stroke patients (e.g., communication problems, visuospatial impairment), and patients' dependence on others for basic activities of daily living.

Most of the medical treatment during stroke rehabilitation is supportive, allowing time for neurologic injury to settle with minimization of further risk from potential complications. This includes maintaining stable respiratory and cardiovascular function, with particular attention to oxygenation and appropriate blood pressure; correcting fluid electrolyte imbalances and optimizing blood glucose levels; ensuring adequate nutrition; and preventing complications such as aspiration pneumonitis, urinary retention or infection, venous thromboembolism, pressure sores, and falls. Of particular importance is the maintenance of nutrition and hydration, because stroke is often associated with disturbances of water, glucose, and salt mechanisms. These conditions may be a result of impaired consciousness, inability to perceive or respond to hunger and thirst, or hypothalamic disturbances causing salt-losing or salt-retaining syndromes. Although stroke patients also have high metabolic needs, factors such as metabolic impairments, renal function, and glycemic status must be taken into consideration while planning nutrition regimens. Poor nutrition, dehydration, and electrolyte imbalance are the precursors of many—and contribute to the severity and consequences of almost all—complications encountered in stroke (see also Chapter 29). Meticulous attention to managing these often "silent" derangements is often rewarded by fewer complications,

better participation in rehabilitation, and better functional and psychological outcomes.

The key message emerging from several research studies and years of clinical experience is that the best intervention to reduce stroke-related complications and optimize rehabilitation outcomes is to manage stroke patients on specialized dedicated units where staff, who are knowledgeable about stroke and stroke-related complications, monitor patients regularly and institute measures that can proactively prevent the occurrence of such complications or provide early aggressive interventions to mitigate consequences once complications occur.

RESEARCH FRONTIERS

Although considerable literature is available on outcomes, rehabilitation, and service organization in stroke rehabilitation, research into the prevalence, management, and consequences of medical complications has merited relatively little attention (54). Studies that can measure the independent impact of complications on recovery and the benefits of prevention of individual complications are difficult to design because of the interactions between different processes of care in determining stroke outcome. There is still no satisfactory longitudinal representative cohort study with a large enough number of patients for accurate estimation of the incidence and prevalence of stroke-related medical complications and their temporal profile during various stages of stroke management. Similarly, there are no robust intervention studies on the prevention or treatment of these complications that can guide clinical practice for the specific management of these problems. There are several small ongoing studies that investigate various aspects of medical management of stroke patents, but small sample sizes and design heterogeneity will limit the impact of their findings and their potential for inclusion in meta-analyses.

Physiology and Management of Spasticity After Stroke

Gerard E. Francisco and John R. McGuire

Spasticity is commonly defined as "a motor disorder characterized by a velocity-dependent increase in tonic stretch reflexes with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex, as one component of the upper motor neuron syndrome" (1). It magnifies weaknesses and other motor abnormalities and thus worsens the functional impairments commonly associated with stroke, such as difficulty with gait and upper-limb use. In more severe states, it causes pain and leads to contractures and permanent joint deformities. Unfortunately, this often-quoted definition does not describe commonly observed clinical findings such as the intermittent nature of spastic hypertonia. It also does not consider the other abnormalities associated with the upper motor neuron syndrome (UMNS), of which spastic hypertonia is but one component: dystonia, co-contraction of agonists and antagonists, clonus, weakness, and incoordination (2–8). Lastly, this definition does not acknowledge the role of the sensory system in causing motor abnormalities. A proposed alternate definition is spasticity as "a disordered sensorimotor control, resulting from an upper motor neuron lesion, presenting as intermittent or sustained involuntary contraction of muscles" (9).

Because spasticity presents with related motor and neurologic disorders, a thoughtful clinical assessment should tease out the underlying dysfunction for a particular component of the clinical presentation in order to design an appropriate treatment plan that will address all impairments that contribute to the functional problem. For instance, even as pharmacologic interventions can effectively reduce hypertonia, they may either uncover or cause motor weakness and incoordination, which will have to be addressed through strengthening exercises.

Current estimates of the prevalence of spasticity range from 4% to 42.6% (2,10–21). The wide range of these estimates can be attributed to various factors such as the interval between stroke onset and assessment, sample size, assessment method, duration of follow-up, and study setting. In fact, many studies involved stroke survivors recruited from institutions rather than the community, thereby limiting knowledge of the population-based incidence of spasticity. Although certain conditions have been implicated as risk factors for poststroke spasticity, such as degree of paresis, sensory deficits, pain, and lower Barthel index (BI) scores, many patients in epidemiological studies also had severe motor, language, and cognitive impairments that may be related to more severe spastic hypertonia, raising the possibility that these conditions are comorbidities rather than causative factors.

ASSESSMENT AND GOAL SETTING

When assessing poststroke hypertonia, it is important to understand that spasticity is only one component of the muscle overactivity seen as part of the upper motor syndrome (Table 29.1). Abnormal co-contraction of agonist and antagonist muscles, spastic dystonia, synergistic limb patterns (synkinesis), weakness, and soft tissue contractures are important considerations in the assessment of poststroke patients (3–6,13,14). Upper motor neuron lesions cause motor dysfunction that result in a "convoluted mixture of obligatory and compensatory motor behaviors that are difficult to interpret" (16). Simple bedside testing is usually an inadequate determinant of an overall treatment strategy; a description of the problem in different circumstances is of far more value than a single examination (11). Assessments from physical, occupational, and speech therapists, as well as input from the patient and their caregivers, are essential for establishing patient-specific goals and an optimal treatment plan (17).

Perhaps the most systematic method of setting treatment goals is goal attainment scaling (GAS), initially developed in the mental health domain. Over the years, it has been applied to rehabilitation, and recently, to spasticity management (22). Using GAS, individual goals are identified and mutually agreed upon by the patient and clinician, and are weighted based on importance. Over the course of the treatment, the degrees to which goals are reached are compared to expected likelihood of achievement set a priori. Unlike other measures, the GAS method allows a patient to identify meaningful goals rather than relying on a standardized set of items.

Clinical, electrophysiological, and biomechanical measures have been used to quantify poststroke spasticity (Table 29.2). The most commonly used clinical measures of poststroke spasticity are the Ashworth (AS) and Modified Ashworth (MAS) Scales. The AS grades muscle tone from

TABLE 29.1 Upper Motor Neuron Syndrome

Positive symptoms
Spasticity
Spastic co-contraction
Spastic dystonia
Synergistic muscle patterns
Reflex release phenomena
Negative symptoms
Weakness, fatigue
Loss of dexterity, balance
Loss of selective muscle control
Rheologic changes
Contracture, fibrosis, atrophy

TABLE 29.3 Ashworth Scale and Modified Ashworth Scales

0. No increased tone
1. Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end of the range of motion when the affected part is moved in flexion or extension (the modified Ashworth scale includes: 1+)
2. More marked increase in muscle tone through most of the range of motion, but affected part(s) easily moved
3. Considerable increase in muscle tone, passive movement difficult
4. Affected part(s) rigid in flexion or extension

0 (normal) to 4 (severe) and is shown in Table 29.3 (10). The MAS adds an additional intermediate grade (1+) but has less interrater reliability than the AS (12,23,24). Despite their widespread use, the AS and MAS have marginal intrarater and interrater reliability (23–26). The reliability of the AS for upper-limb spasticity can be improved if the examiner completes a standardized training program and testing is done in a similar format (25). Another limitation of the AS is its "clustering" effect of the patients in the middle grades; also, the measure does not differentiate contracture from hyperexcitable stretch reflexes (26). Caveats in the clinical use of these scales include the nonstandardized speed with which passive stretching is performed and scoring of joints with very limited range (i.e., less than 50% of expected range) due to muscle contracture. The Tardieu scale has advantages over the AS because it not only quantifies muscle reaction to stretch, but also accounts for the velocity of the stretch and measures the angle at which the catch, or clonus, occurs (Table 29.4) (27–29). The quality of muscle reaction to passive stretch at certain velocities is scored between 0 (no resistance with passive movement) and 4 (clonus greater than 10 seconds). The spasticity angle is the difference between the angle at the end of passive range of motion (PROM) at slow speed (V1) and the angle of catch at fast speed (V2 or V3). The spasticity angle provides an estimation of the relative contribution of neural mechanisms (spasticity) and the mechanical restraint of the soft tissues. Grading is performed at the same time of day and in a constant position of the body for a given limb (27). The Tardieu scale is a valid clinical measure of spasticity after stroke (30). To increase the internal consistency, validity, and reliability of clinical assessment of muscle tone using the AS or MAS, Platz et al. developed REPAS (REsistance to PASsive movement), a 32-point summary scale that provides detailed guidelines for the performance of different passive joint motions and scoring (31).

Electrophysiologic tests such as the H-reflex, H/M ratio, F-wave, and tonic vibration reflex (TVR) have been used to quantify spasticity in stroke patients (32,33). Historically, these measures tend to correlate poorly with the degree of spasticity (34). Recently, Pizzi and colleagues demonstrated a positive correlation between the flexor carpi radialis H/M ratio and the MAS scores at the wrist in 65 poststroke spastic, hemiparetic patients (35). The correlation was strongest with the higher AS scores (3 and 4). The soleus H/M ratio can be used to confirm the effects of intrathecal baclofen (ITB) during an ITB trial and potentially for troubleshooting (33,36). In a prospective case series involving 9 stroke, 17 traumatic brain injury, and 4 anoxic brain-injured subjects treated with 50 mcg intrathecal bolus of baclofen, there was a reduction of the H/M ratio from 62% ± 28% to 14% ± 19% and Ashworth scores from 2.4 ± 0.7 to 1.5 ± 0.6 on the more involved side 5 hours after bolus (36). This study suggests that the soleus H/M ratio may be more sensitive than the AS score in detecting a physiologic response to ITB bolus.

TABLE 29.2 Examples of Measures of Spasticity, Motor Control, or Function

	MEASURES OF SPASTICITY	MEASURES OF MOTOR CONTROL OR FUNCTION
Clinical	Ashworth Scale Modified Ashworth Scale Tardieu Scale REPAS Spasm frequency scale Tone Assessment Scale	Fugl-Meyer Wolf Motor Function Test Timed walk Timed Up & Go Box and Block Test Action Research Arm Test
Electrophysiological	H/M ratio	Dynamic EMG
Biomechanical	Servo-control device	Motion Analysis Systems

TABLE 29.4 Tardieu Scale

Quality of muscle reaction
0. No resistance
1. Slight resistance
2. Catch followed by a release
3. Fatigable clonus (less than 10 seconds)
4. Sustained clonus (greater than 10 seconds)
Angle of muscle reaction
Velocity of stretch
V1. As slow as possible
V2. Speed of limb falling under gravity
V3. As fast as possible

Biomechanical measurements of spasticity using a servo-controlled, motor-driven device can provide a more reliable measure of spasticity, but use of these devices is limited to the research laboratory. The device can provide a controlled stretch of a limb while measuring torque, joint angle, and reflex EMG activity (37,38). Large-amplitude perturbations have been used to quantify spastic stretch reflexes at a joint (37–39). These reflex measures were shown to be reliable measures of elbow spasticity in 16 chronic stroke patients with upper-limb spasticity (40). In this study, elbow stretch reflexes were assessed using a custom-made device attached to a Biodex System™. Movements into elbow flexion and extension were imposed at four speeds: 6, 30, 60, and 90 degrees per second. Ninety percent reliability in the measurement of peak torque, peak stiffness, and reflex threshold angle was obtained when at least two days of testing were performed. The biomechanical measures correlated well with the AS (Spearman rho = 0.84, $P < .005$) (40).

The assessment of patients with poststroke hypertonia should also include measures of motor control (Table 29.2). The Fugl-Meyer Scale (FMS) is a reliable and validated measure of the upper- and lower-extremity motor impairment based on the natural progression of functional return after a stroke (41). The FMS has been demonstrated to have high intrarater and interrater reliability and can be completed in 10 to 20 minutes. Decline of the function on the FMS has been shown to correlate closely with the severity of spasticity (42).

Given the complex relationship of spasticity, impairment, and disability, it is not always easy to ascertain the functional impairment of spasticity. Yet, it is worth assessing the functional changes after intervention because patients and caregivers set goals that favor functional improvement over reduction in impairment. The functional test for the hemiparetic upper extremity was developed at Rancho Los Amigos Hospital and consists of 17 graded tasks with 7 levels of difficulty. The test is based on the Brunnstrom scale, and each task is timed and graded pass/fail (13,37–39,43). The patient has three opportunities to try each task and can work no longer than three minutes on each item. The test is functionally based and has good interrater reliability, and the timing of each task allows detection of more subtle changes (44). Other tests of motor skills, such as the Action Research Arm, Jebsen-Taylor, Frenchay, and Box-and-Block, can be utilized as part of the overall assessment.

The BI is an ordinal scale of global function and mobility that may not be sensitive to the functional implications of spasticity (18,45). Francis and colleagues proposed a "Composite Functional Index" (CFI) that was shown to correlate well with reduction of arm spasticity (46). The index (range 0–17) uses the dressing, grooming, and feeding sections of the BI, and adds three subjective measures: putting arm through sleeve, cleaning palm, and cutting fingernails. In a meta-analysis of two randomized controlled trials, 26 of 47 had improved arm function (CFI) and reduced spasticity (MAS) after injections of abobotulinumtoxinA (Dysport™) (46). The disability assessment scale (DAS) (range 0–12) was developed to assess functional impairment in patients with poststroke upper-limb spasticity (i.e., dressing, hygiene, limb position, pain) and has shown good intra and interrater reliability (25).

Dynamic polyelectromyographic (PEMG) recordings can be used to identify the timing and duration of muscle overactivity in poststroke spastic hypertonia. These EMG recordings can be helpful in understanding muscle involvement when assessing for treatment with chemodenervation, chemical neurolysis, or surgical release of individual muscles (47). For example, in the patient with a spastic flexed elbow, PEMG can be used to identify spastic co-contraction of the elbow flexors and extensors (47). By combining PEMG with kinematic data from a motion analysis lab, the primary upper- or lower-extremity motor dysfunction can be localized (48,49). Quantitative gait analysis can differentiate quadriceps overactivity from hip flexor weakness or poor ankle mechanics as the cause of stiff-legged gait (50).

IMPACT ON REHABILITATION AND RECOVERY

Health care costs are four times higher for stroke survivors with spasticity compared to those without spasticity (21). Other investigators have suggested that the importance of spasticity may be overstated (18,51). Despite a lack of good epidemiological data, most clinicians would agree that treating spasticity "just because it's there," as suggested by Landau, is not the best practice (51). There are potential benefits of increased muscle tone. Increased extensor tone of the legs can assist with standing and transfers (52). Reflex muscle activity may preserve muscle bulk and slow osteoporosis (53).

When spasticity interferes with active or passive function or becomes painful, then appropriate interventions must be considered (54). Even though limb weakness may be the more important factor when considering active function, spasticity or spastic co-contraction can impede limb movement (6,54). Upper-limb spasticity, such as the adducted, internally rotated shoulder or flexed elbow, can make activities such as reaching overhead more difficult. Spastic co-contraction of elbow flexors and extensors can limit active elbow extension and flexion (54). Increased tone of the wrist and finger flexors can interfere with releasing objects after grasping them. Lower-extremity spasticity such as the adducted hip, flexed or extended knee can interfere

FIGURE 29.1 Finger flexor spasticity as shown in the "clenched fist" condition.

with standing, transferring, or walking. The inability to obtain a flat foot position during the stance phase of gait, as in the equinovarus foot, can lead to gait instability and make stair climbing more difficult.

Spasticity may play a more important role by interfering with passive functions such as hygiene in the axilla, elbow, and palm of the hand. Finger flexor spasticity, as in the "clenched fist" condition, can lead to skin breakdown and nailbed infections (47) (Figure 29.1).

Lower-extremity passive function such as perennial care, bladder catheterization, toileting, and bathing can be more difficult with spasticity of the hip adductors. Overactivity of the hip flexors or extensors can interfere with wheelchair positioning.

The pathophysiology of pain in spasticity is not well understood, but it has been proposed that it may involve an interaction between dysfunction of nociceptive pathways and thalamocortical projections, tonic muscle overactivity, structural changes in muscles and tendons, and biomechanical problems including joint malalignment. For instance, the poststroke shoulder pain that is associated with spasticity in 31% to 57% of cases (5,36,55–61) may result from the interplay between central poststroke pain, adhesive capsulitis, rotator cuff tendinitis, and muscle shortening and spasm (62). Pain associated with spasticity is characterized as nonradiating and sharp as in the case of spasms, present at rest and worsening during passive or active movement of the involved body part (63).

In an uncontrolled observational study of 13 patients with spastic hemiplegia, subjects had reduced shoulder pain and improved ROM after phenol injection of the nerve to the subscapularis muscle (64). In a randomized double-blind, placebo-controlled study, 10 spastic poststroke patients had reduced spasticity, improved ROM, and decreased shoulder pain after onabotulinumtoxinA injections to the subscapularis muscle (65).

Early treatment of spasticity may lead to improved outcomes in motor recovery. Windows of opportunity may exist in the early management of spasticity (66). If one takes "a wait and see" approach, optimal treatment benefits may be lost. Twitchell noted that severe proximal spasticity at one month after stroke was a predictor of poor motor recovery (67). In some stroke survivors, spasticity may be a constraint on motor recovery, and early treatment may improve their motor recovery. Although not all stroke survivors will have improved motor recovery, early spasticity treatment may affect the clinical course of the increased tone. A double-blind, placebo-controlled trial of three treatments for lower-extremity spasticity in 28 patients with acute TBI demonstrated improved ROM and reduced MAS in the patients treated with serial casting and saline or onabotulinumtoxinA (Botox™), when compared to physical therapy alone (68). Despite the limited number of subjects, this study suggests that early intervention may have a beneficial effect on the long-term consequences of spastic hypertonia. A recent controlled study reported significant reduction of finger flex or stiffness six months after early treatment with botulinum toxin, possibly due to prevention of contractures. Wrist and finger flexors were injected with 150 units of incobotulinumtoxinA versus placebo at 6 weeks after stroke. Each group had nine subjects who received four weeks of therapy. The treated group had reduced Ashworth scores, pain, and passive nail trimming at one and six months after injection (69). Further investigation is needed to identify which patients may benefit most from early spasticity treatment.

ORAL MEDICATIONS

Stroke survivors generally have a poor tolerance for oral medications because of the central nervous system (CNS) side effects. Of the oral antispasticity medications currently available in the United States, only baclofen, tizanidine, Valium, dantrolene sodium, and clonazepam have been evaluated in persons with stroke (70–73). In 2004, Montané et al. completed a systematic review of double-blind randomized controlled trials of antispastic oral medications for stroke and reviewed six trials (71,72,74–78). Because of the small numbers, lack of quality of life measures, and high incidence of adverse drug effects (drowsiness, sedation, and muscle weakness), they concluded that the evidence supporting use of oral antispastic medications in stroke is weak (72) (Table 29.5).

Baclofen is a structural analog of gamma-aminobutyric acid (GABA), which is one of the main inhibitory neurotransmitters in the CNS (79). The half-life of oral baclofen is 3.5 hours, and, although 15% is metabolized in the liver (70), it is excreted primarily by the kidney. In a double-blind, placebo-controlled crossover trial of 20 stroke patients, those treated with up to 30 mg/day of baclofen for 1 month had reduced Ashworth scores, no functional improvement, and higher adverse events (50% vs. 15%) versus those on a placebo (80). The most common adverse effects were sedation, dizziness, and weakness. In a retrospective review of 35 subjects with acquired brain injury that included

TABLE 29.5 Oral Spasticity Medications

AUTHOR (YEAR)	STUDY DESIGN	SUBJECTS AND INTERVENTION	RESULTS
Basmajian (1984) (202)	Randomized, double-blind, placebo-controlled, crossover	24 stroke survivors out of 50 subjects, but only 19 completed study 3 treatment conditions: Ketazolam 10 and 20 mg/day (1 week each) Diazepam 5 and 10 mg/day (1 week each) Placebo (2 weeks)	Ketazolam and diazepam conditions better than placebo on most outcomes ($P < .05$) but no significant difference between ketazolam and diazepam
Bes (1988) (74)	Randomized, double-blind, parallel group	N = 105 hemiplegics (89 stroke, 16 cranial trauma) 2 groups well-matched for sex, age, height, and body weight: Tizanidine (46 stroke) started at 6 mg/day and titrated up to maximum of 24 mg/day within 2 weeks (mean dosage at week 8: 17.08 mg/day) Diazepam (43 stroke) started at 7.5 mg/day and titrated up to maximum of 30 mg/day (mean dosage at week 8: 19.52 mg/day)	15 subjects on tizanidine and 6 on diazepam dropped out due to side effects Tizanidine group improved walking distance on flat ground; 3 of 11 bedridden subjects on tizanidine, and 2 of 4 bedridden subjects on diazepam became ambulatory
Cocchiarella (1967) (203)	Randomized, double-blind, placebo-controlled, multiple crossover	Mixed diagnoses; 16 stroke survivors out of 19, but were not identified in data analysis 5 treatment conditions: Placebo Diazepam 6 mg/day Diazepam 15 mg/day Phenobarbital 45 mg/day Phenobarbital 90 mg/day	No significant difference in leg drop and straight leg raise tests, and total steps taken Slower ambulation while on diazepam 15 mg/day compared to placebo
Glass (1974) (204)	Double-blind, placebo-controlled, crossover	24 stroke survivors out of 62; 16/62 participated in crossover phase, but only 11/16 completed (unknown number of stroke survivors in crossover phase or among dropouts) 4 treatment conditions: Dantrolene (100 mg qid) Diazepam (5 mg qid) Dantrolene (100 mg qid) and diazepam (5 mg qid) Placebo	Combined dantrolene and diazepam was superior to diazepam or dantrolene alone or placebo in clinical measures
Meythaler (2001) (71)	Randomized, double-blind, placebo-controlled, crossover	9 stroke survivors among 17 subjects 2 treatment conditions: Placebo Tizanidine 4 mg qHS titrated to goal of 12–36 mg/day	Only 6 tolerated up to 9 pills of tizanidine (36 mg/day), even as 11 tolerated all 9 placebo pills Somnolence in 41% on tizanidine and none in placebo
Meythaler (2004) (81)	Retrospective	35 acquired brain injuries (7 stroke) Average oral baclofen dose 57 mg/day	Decreased lower, but not upper limb spasticity 17% complained of sleepiness

Source: Adapted from Francisco GE. Pharmacologic management of lower-limb spastic hypertonia in stroke: what is the evidence? In: Condie E, ed. *Report of a Consensus Conference on the Orthotic Management of Stroke Patients*. Copenhagen: ISPO; 2004:137–147.

7 stroke patients, those treated with an average dose of 57 mg/day of baclofen had reduced lower-extremity spasticity and no change in the upper extremity (81). No functional measures were reported, and 17% of the patients had sleepiness, which limited dose increases (81).

Dantrolene sodium is a hydantoin derivative that acts primarily on the muscle fiber. It exerts its effect by blocking the release of calcium from the sarcoplasmic reticulum, which reduces the force of the muscle contraction (70). Recent studies suggest that this phenomenon results from an alteration in the relationship between calcium channels and ryanodine receptors within the sarcoplasmic reticulum (82). The half-life of dantrolene sodium is 4 to 15 hours after oral dose and 12 hours after intravenous dose; it is metabolized primarily by the liver (70). The most common side effects are drowsiness, nausea, paresthesias, and weakness. Even though the risk of hepatic toxicity is rare (1%–2%), it is recommended to monitor liver function tests before and during treatment (70). In a double-blind, placebo-controlled crossover study of 31 stroke patients treated with 50 to 200 mg per day of dantrolene, subjects showed no change in AS or Barthel scores while reducing strength in the unaffected

limb, but not the paretic limb, based on isokinetic testing (11). In a double-blind parallel study, 14 stroke patients who achieved reduced spasticity with dantrolene for 6 weeks were randomized to either a placebo or continued dose of dantrolene for 6 more weeks (83). The placebo group noted increased deficits, and 13 of the 14 chose to continue dantrolene (average dose 165 mg/day) after the 6-week trial had ended. Side effects were mild and transient (83).

Tizanidine is an alpha-2 adrenergic agonist that binds to spinal and supraspinal imidazoline receptors and prevents the release of excitatory neurotransmitters (70). The half-life of tizanidine is 2.5 hours, and it is metabolized by the liver. The most common side effects are drowsiness, dry mouth, weakness, hypotension, and elevated liver function tests (5%) (70). Because of this, liver function tests should be monitored before treatment, and at one, three, and six months and then annually after initiating treatment. In a small double-blind placebo-controlled crossover study that included 9 stroke patients treated with 12 to 36 mg/day of tizanidine, subjects demonstrated dose-dependent reduced upper- and lower-extremity AS scores. No functional measures were reported. The most common adverse events were somnolence (41%), increased liver function tests (18%), and dry mouth (12%) (71). In a double-blind comparative study of 30 stroke patients treated with tizanidine (8–20 mg/day) or baclofen (20–50 mg/day), both groups had similar improvements in AS scores. The side effects in the tizanidine group were mild and transient, and no patients discontinued the study. For the baclofen, three patients discontinued the study due to severe side effects (78). In an open-label dose titration study of 47 chronic stroke patients treated with tizanidine (2–36 mg/day), total upper-extremity AS score improved with no decline in strength. Pain intensity, quality of life, and physician assessment also improved. The maximum average daily dose was 20 mg/day, and 10 out of 47 patients were able to tolerate the maximum dose of 36 mg/day. The most frequent side effects were somnolence (62%), dizziness (32%), asthenia (30%), dry mouth (21%), hypotension (13%), and elevated liver function tests (4%) (84).

Cyproheptadine, a serotonin receptor antagonist, has been demonstrated as effective in reducing delay in the relaxation of finger flexors immediately after grip in a small group of stroke patients, suggesting a role of monoaminergic brainstem pathways in poststroke spasticity (85).

Despite limited evidence in the literature to support the use of oral antispasticity medications in stroke patients, and frequent adverse effects, there is a role for them. Because somnolence is a common side effect of oral medications, low doses at night may be useful in select patients who have difficulty sleeping because of muscle spasms. As with most medications in stroke survivors, it is suggested to "start low and go slow." Rather than higher doses of one medication, a combination of lower doses of two medications may be better tolerated (86). Also, these medications should be tapered off slowly, especially baclofen, because abrupt withdrawal can result in seizures and other life-threatening situations.

NERVE BLOCKS

Injection of a local anesthetic near a motor nerve or diagnostic nerve block (DNB) is a useful tool in the management of poststroke spasticity. DNB can determine the potential benefits of longer-lasting interventions such as botulinum toxin chemodenervation, neurolysis, or surgery; assist in the diagnosis of contractures; facilitate serial casting; and reduce painful spasms to allow participation in therapy (87). Neurolytic procedures using phenol or alcohol are effective in treating focal spastic hypertonia from various etiologies, including cerebral palsy, traumatic brain injuries, and stroke (64,88–96) (Table 29.6).

In sufficiently high concentrations, phenol (5%–6%) and alcohol (35%–60%) work by denaturing proteins, leading to neurolysis, while at lower concentrations (i.e., 3% and lower), phenol acts as an anesthetic (97). Phenol appears to control muscle hypertonia as a result of denervation and degeneration of muscle spindles (98). Phenol injures afferent and efferent nerve fibers, and the damage to the axons and membranes can be extensive (99,100).

Following injection of either agent, muscle relaxation is almost immediate due to the anesthetic effects. The neurolytic effect sets in about an hour after injection and lasts for a few months. The effect may last for as long as a year or longer, depending on the degree of nerve blockade. Hypertonia usually recurs due to muscle reinnervation, but this recovery is incomplete (98). Common side effects include pain at the injection site, postinjection dysesthesia, localized swelling, and excessive weakness (97,101). If inadvertently injected into vessels, or if systemic absorption occurs, CNS effects, such as tremors, convulsions, and CNS depression may result.

There is a paucity of well-designed studies on the use of phenol or alcohol in the treatment of spastic hypertonia. For one, these drugs are rarely used in the upper limb because of concerns with complications, most especially dysesthesia. Most published studies reported treatment of spasticity of the finger flexors, elbow flexors, and other muscle groups in the traumatic brain injury population (88,91,92,102). Hecht treated 11 patients with painful shoulder attributed to hypertonia of the subscapularis muscle (64). Three to 6 mL of aqueous phenol 6.7% was percutaneously injected into the subscapular nerve branches. This resulted in improvement in shoulder flexion, abduction, and external rotation, presumably because of a decrease in pain and hypertonia.

One investigation reported effective treatment of hip flexor spasticity by injecting up to 3.5 mL of phenol 5% into the belly of the psoas major and minor muscles under ultrasonic monitoring (94). Nine of the twelve patients had spasticity from stroke. In addition to increased range of motion, improvement in sitting position, standing and walking posture, and pain relief were noted. No complications occurred. Another study reported the beneficial effects of phenol in reducing spasticity of tibial-innervated muscles (103).

An investigation demonstrated significant reduction of quadriceps muscle tone with use of etidocaine 1%, 2 cm^3 after a femoral nerve block (104). The primary intent of this study was

TABLE 29.6 Phenol, Alcohol, and Anesthetic Nerve Blocks

AUTHOR (YEAR)	STUDY DESIGN	SUBJECTS AND INTERVENTION	RESULTS
Albert (2000) (104)	Case series	7 stroke survivors out of 12 subjects with hemiplegia disabled by quadriceps overactivity Etidocaine 1%, 2 cm^3 was injected to block the branch of the femoral nerve to either the vastus intermedius or lateralis	Decrease in quadriceps spasticity, but results were difficult to interpret, based on the data reported
Chua (2000) (90)	Case series	5 stroke survivors out of 8 subjects with hemiplegia and severe knee flexor spasticity Ethyl alcohol 50%–100% (with 1% lidocaine) injected to sciatic nerve using repetitive monopolar electric stimulation	MAS scores of knee flexors improved significantly at 1 ($P < .005$), 3 ($P < .01$), and 6 ($P < .02$) months after injection
Kirazli (1998) (105)	Randomized, double-blind (?), parallel group	N = 20; onabotulinumtoxinA 400 units injected to lower-limb muscles using electromyographic guidance versus phenol 5% tibial nerve block	Significant improvement in AS in both groups ($P < .05$) for ankle plantar flexor; toxin group had more improvement in AS of ankle invertors than phenol ($P > .05$); AS and clonus duration more improved in toxin group than phenol at weeks 2 and 4, but not at weeks 8 and 12

to demonstrate an anatomical injection technique, and thus it used an anesthetic, the effect of which on muscle tone was transient. Chua and Kong used ethyl alcohol of varying concentrations (50%–100%) to block the sciatic nerve and found that the decrease in hamstring muscle tone lasted up to 6 months after intervention and, in some subjects, improved the quality of ambulation and facilitated wheelchair positioning (90).

The popularity of phenol and alcohol has been eclipsed by botulinum toxin chemodenervation. The latter is easier to administer and appears to have a better side-effect profile, but phenol and alcohol are much less expensive and may last longer. Although both treatments are effective, there has been no convincing evidence as to the superiority of one over the other in treating spastic hypertonia. Only one attempt has been made to compare the effects of phenol 5% and botulinum toxin type-A (BTX type A) in controlling clonus and hypertonia. In the investigation, both phenol and BTX-type A improved muscle tone (as measured by AS scores) of ankle plantar flexors and invertors, but it appeared that the BTX group had superior efficacy over phenol ($P < .05$), both in decreasing muscle tone and ankle clonus at 2 and 4 weeks, but not at 8 and 12 weeks, after treatment (105). The study result may have been affected by the relatively low dose of phenol used, because the amount injected was not adjusted based on clinical response after the first few injections, as is commonly done in clinical practice. Table 29.7 presents further comparison of the clinical characteristics of these two medications.

BOTULINUM TOXINS

BTXs are arguably the most commonly used intervention for spastic hypertonia. Derived from the bacterium *Clostridium botulinum*, it has seven types, designated A through G, which are antigenically and serologically distinct but structurally similar (106). The toxin molecule is formed by heavy and light polypeptide chains that are linked by a disulfide bond. BTXs act by binding on presynaptic cholinergic nerve terminals. Once in the nerve terminal, it blocks the release, but not the synthesis, of acetylcholine into the neuromuscular junction, thereby disallowing muscular contraction. In addition to its reduction of alpha motor neuron activity on extrafusal muscle fibers, BTXs exert their effects on reduction of Ia afferent signal from muscle spindles at the gamma motor neuron level. The decreased signal from Ia afferents will then result in a reduction of feedback to alpha motor neurons, resulting in decreased muscle activity. The duration of clinical effect is three to four months, and is most likely due to axonal sprouting and muscle reinnervation when new neuromuscular junctions are established.

DePaiva et al. suggested that previously blocked junctions undergo functional repair (107).

In the past decade, two BTX serotypes, A and B, have emerged as an important treatment for focal poststroke spastic hypertonia. A recent consensus paper supported the use of BTX for focal spastic conditions in adults (108). Its popularity is due to the impressive clinical outcomes experienced by stroke survivors and clinicians, despite the relative lack of convincing scientific evidence of its effects on function. For a variety of reasons, such as study design limitations, sensitivity of outcome measures, and appropriateness of patient selection criteria, published literature has yet to demonstrate that BTXs lead to functional enhancement, although significant improvement in muscle tone has been shown.

BTXs also have the advantage of target treatment specificity (i.e., exerting significant changes only in injected muscles), as opposed to the systemic effects of oral medications, and have a better adverse event profile. For instance, the incidence of drowsiness and sedation, which are commonly associated with oral spasmolytics, are practically nonexistent with toxins. BTXs also appear to be favored by many clinicians over phenol and alcohol, which are more technically challenging and have a higher incidence of complications, such as dysesthesia.

Evidence of Efficacy of Botulinum Toxin Type A (BTX-A)

Upper Limb

Various studies have demonstrated significant improvement of upper-limb poststroke spastic hypertonia (Table 29.8). Simpson investigated the effect of three total doses of onabotulinumtoxinA as compared to placebo in 39 subjects (109). Saline or one of three doses of onabotulinumtoxinA (75 units, 150 units, or 300 units) were injected to the biceps, flexor carpi radialis (FCR), and flexor carpi ulnaris (FCU). At two, four, and six weeks after injection, all treatment groups had better outcomes than placebo, but the group that received the highest dose had the most robust improvement in hypertonia reduction in the elbow and wrist flexors. The effects lasted for about 16 weeks. This dose-dependent effect of BTX was also demonstrated in a later study (110). Ninety-one stroke survivors received either onabotulinumtoxinA or placebo to spastic finger, wrist, and elbow flexors. Participants were randomized to one of the following groups: placebo, 90, 120, and 360 units of onabotulinumtoxinA. All treatment groups demonstrated improvement in MAS scores ($P < .05$), but the group that received the highest dose also had the most improvement.

Brashear et al. compared onabotulinumtoxinA 200 to 240 units to placebo injected into the wrist, finger, and thumb flexors. At 4, 6, 8, and 12 weeks, the onabotulinumtoxinA group had superior improvement in muscle tone over the placebo group (25). Additionally, this study also measured changes in various impairment and functional domains, including pain, deformity, hygiene, and orthotic fit, using the DAS. At week 6, the treatment group had more significant improvement on the DAS in the principal target of treatment ($P < .001$). As in the Simpson study, no major adverse event was reported (110).

A large-scale Japanese study demonstrated efficacy of onabotulinumtoxinA in treating upper-limb spasticity. In a multicenter study involving 109 subjects, higher-dose onabotulinumtoxinA (200–240 units) injected to wrist and finger flexor muscles was superior to lower dose (120–150 units) when compared to placebo. Higher-dose onabotulinumtoxinA also resulted in significant improvement in limb position as measured by the DAS at 6, 8, and 12 weeks after injection (111).

Experience with the use of abobotulinumtoxinA has been similar. In one study, 59 subjects were randomized to receive either placebo or 1000 units of abobotulinumtoxinA divided between the biceps, FCR, FCU, flexor digitorum superficialis (FDS), and flexor digitorum profundus (FDP). At 4 weeks after injection, the abobotulinumtoxinA group had a more significant improvement in muscle tone (as measured by MAS) when compared to the placebo ($P = .004$) group. The same investigators also conducted a dose-ranging investigation involving 83 stroke survivors, who were randomized to one of three abobotulinumtoxinA doses (500, 1000, or 1500 units) or placebo. Muscles injected included the biceps, FCR, FCU, FDS, and FDP (112,113). The treatment groups demonstrated more significant improvement in tone than the placebo group. Weakness was observed in the 1500-unit group.

Another investigation compared the efficacy of abobotulinumtoxinA 500, 1000, and 1500 units with placebo in treating spastic hypertonia of the biceps, wrist flexors, finger flexors, and thumb adductors/flexors (114). When compared to placebo at 6 weeks, improvement in muscle tone in the elbow and wrist flexors ($P < .05$) and passive elbow range of motion ($P < .02$) were noted in all treatment groups. Consistent with Bakheit et al.'s findings, the group that received higher doses had greater hypertonia reduction than the placebo group but did not have an advantage in terms of duration of effect (114).

Prior to its recent introduction in the United States, incobotulinumtoxinA (Xeomin™) was studied in upper-limb poststroke spasticity (115). One hundred forty-eight patients with wrist and finger flexors spasticity and at least moderate disability on the DAS were treated either with incobotulinumtoxinA (median, 320 units) or placebo for up to 20 weeks. The incobotulinumtoxinA group had better reduction in AS scores at week 4 and up to week 12. There was no significant difference in the incidence of adverse events in both groups. After completion of the double-blind, placebo-controlled phase, 145 subjects continued in an open-label extension for up to 69 weeks (116). During that time the subjects received up to five additional incobotulinumtoxinA injections. Throughout the duration of the open-label period, there was significant improvement in AS scores of elbow, wrist, finger and thumb flexors, and forearm pronators, and DAS. Neutralizing antibodies were not detected during the study period.

TABLE 29.8 Randomized, Controlled Botulinum Toxin Trials for Upper Limb Spasticity

AUTHOR (YEAR)	STUDY OBJECTIVE	SUBJECTS	INTERVENTION	OUTCOME MEASURES	FOLLOW-UP	RESULTS
Simpson (1996) (109)	To evaluate the safety and efficacy of local treatment of upper-extremity spasticity in chronic stroke patients	N = 39; At least 9 months post stroke; Mean 2.5 on AS at elbow and wrist with minimum 2 at either joint	OnabotulinumtoxinA (300 units; n = 9); OnabotulinumtoxinA (150 units; n = 9); OnabotulinumtoxinA (75 units; n = 9) or placebo (n = 10) to biceps, FCR, or FCU	MAS; FIM, Rand 36 Item Health Survey, Fugl Meyer Scale, caregiver dependency, function and pain assessment, motor task/function rating scale, grip strength, global assessment of spasticity scale	2, 4, 6, 10, 16 weeks	Decreased AS score of elbow and wrist flexors at weeks 2, 4, and 6 in high-dose group versus placebo Decreased AS score of wrist flexors at week 6 in low-dose group versus placebo
Hesse (1998) (132)	To investigate comparative efficacy of abobotulinumtoxinA plus electrical stimulation (ES) versus abobotulinumtoxinA alone in the treatment of chronic upper limb spasticity after stroke	N = 24; 6–12 months post stroke; MAS at least 3 at elbow, wrist and fingers	AbobotulinumtoxinA 1000 units + ES (n = 6); AbobotulinumtoxinA 1000 units only; placebo + ES (n = 6); placebo only (n = 6), to biceps, brachioradialis, FCU, FCR, FDP, FDS	MAS, limb position at rest, three functional activities, pain	2, 6, 12 weeks	MAS not significantly different, but cleaning the palm was better in abobotulinumtoxinA + ES group compared with abobotulinumtoxinA alone or placebo alone at all time points
Smith (2000) (114)	To assess dose response relationships to a single dose of BTX in upper limb spasticity associated with stroke or head injury	N = 21; At least 1 year post stroke	AbobotulinumtoxinA 1500 units (n = 6); AbobotulinumtoxinA 1000 units (n = 7); AbobotulinumtoxinA 750 units (n = 6); placebo (n = 6); Different muscles injected based on clinical pattern of spasticity	MAS, passive and active range of movement, time to dress upper body, FAT, finger curl, global clinical assessment score, gait (if mobile)	2, 6, 12 weeks	Decreased wrist and finger flexor MAS scores and greater number of patients improved on global clinical assessment at week 6 when all abobotulinumtoxinA groups were combined and compared with placebo Decreased MAS score in abobotulinumtoxinA 500 units group versus placebo at week 6; Improved passive range of movement in abobotulinumtoxinA 1500 units group versus placebo at weeks 6 and 12
Bakheit (2000) (113)	To define an effective and safe dose of abobotulinumtoxinA for the treatment of upper limb spasticity in stroke patients	N = 83; At least 3 months post stroke; MAS 2 or more at elbow, wrist and fingers	AbobotulinumtoxinA 1500 units (n = 19); AbobotulinumtoxinA 1000 units (n = 22); AbobotulinumtoxinA 500 units (n = 22); placebo (n = 20) to biceps, FDS, FDP, FCU, FCR	MAS, range of movement, pain, Rivermead Motor Assessment, Barthel ADL index, three functional activities	2, 4, 8, 12, 16 weeks	Decreased MAS score at any joint in all abobotulinumtoxinA groups versus placebo at week 4; Decreased MAS of elbow and wrist flexors in all abobotulinumtoxinA groups and of finger flexors in abobotulinumtoxinA 1000 units group versus placebo over 16 weeks

Bhakta (2000) (205)	To investigate whether reduction in spasticity after BTX treatment translates into reduction in disability and carer burden	N = 40; At least 6 months after stroke; Elbow or finger MAS > 2	AbobotulinumtoxinA 1000 units (n = 20); placebo (n = 20) Different muscles injected based on clinical pattern of spasticity	Patient disability scale, carer burden scale, MAS, range of movement, pain, grip strength	2, 6, 12 weeks	Improved patient disability scale score in abobotulinumtoxinA group at 2 and 6 weeks versus placebo. Improved carer burden at 12 weeks. Decreased MAS of finger flexors in abobotulinumtoxinA group versus placebo at all time points and of elbow flexors at week 2. Decreased grip strength in abobotulinumtoxinA group compared with placebo at week 6
Bakheit (2001) (112)	To study the efficacy and safety of BTX in the treatment of upper-limb spasticity caused by stroke	N = 59; At least 3 months after stroke; MAS 2 or more in at least two of elbow, wrist, fingers and 1+ in remaining area	AbobotulinumtoxinA 1000 units (n = 27); placebo (n = 32) to biceps, FDS, FDP, FCU, FCR	MAS, range of movement, pain, Barthel ADL index, Goal Attainment and subjective global assessment scales	4, 8, 12, 16 weeks	Decreased MAS score at all joints in abobotulinumtoxinA group versus placebo at week 4, and finger and wrist flexors over 16 weeks. Improved elbow passive range of motion in abobotulinumtoxinA group versus placebo over 16 weeks
Brashear (2002) (25)	Assess the effects of one set of injections of botulinum toxin on muscle tone and measures of disability with respect to self-care, limb position, and pain	N=126; At least 6 months after stroke; Wrist AS 3 or more, fingers AS 2 or more	OnabotulinumtoxinA 200–240 units (n = 64); placebo (n = 62) to FCU, FCR, FDP, FDS =/- FPL or AP	AS, DAS, global assessment scale	1, 4, 6, 8, 12 weeks	DAS principal target and AS scores improved in onabotulinumtoxinA group versus placebo at all time points. Greater number of patients in onabotulinumtoxinA group improved by at least one point on global assessment versus placebo at all time points
Childers (2004) (110)	To test the hypothesis that intramuscular BTX reduces excessive muscle tone in a dose-dependent manner in the elbow, wrist, and fingers after stroke	N = 91; At least 6 weeks after stroke; Wrist AS 3 or more, elbow AS 2 or more	OnabotulinumtoxinA 360 units (n = 21); OnabotulinumtoxinA 90 units (n = 21); OnabotulinumtoxinA 180 U (n = 23); placebo (n = 26) to biceps, FCU, FCR, FDP, FDS. A second injection with same dose was given at >12 weeks if AS 2 or higher at wrist and/or elbow flexors	MAS, pain score, and functional disability measure SF-36, FIM, physician and patient global assessments	1, 2, 3, 4, 5, 6, 9, 12, 18, 24 weeks	Decreased AS score of elbow and wrist flexors in all onabotulinumtoxinA groups versus placebo at most time points up to week 9. Global response scores higher in 360- and 180-units groups versus placebo at some time points

(*continued*)

TABLE 29.8 Randomized, Controlled Botulinum Toxin Trials for Upper Limb Spasticity (*continued*)

AUTHOR (YEAR)	STUDY OBJECTIVE	SUBJECTS	INTERVENTION	OUTCOME MEASURES	FOLLOW-UP	RESULTS
Suputtituda (2005) (206)	To define the lowest effective dose and safety of BTX in the treatment of adult patients with upper-limb spasticity	N = 50; Any cause spasticity (but only stroke included); "Upper limb spasticity"	AbobotulinumtoxinA 1000 units (n = 5); AbobotulinumtoxinA 500 units (n = 15); AbobotulinumtoxinA 350 units (n = 15); placebo (n = 15) to biceps, FCU, FCR, FDP, FDS	MAS, ARAT, Barthel ADL index, visual analogue pain scale	2, 4, 8, 16, 24 weeks	Decreased MAS scores in all abobotulinumtoxinA groups versus placebo at week 8. Improved ARAT score in abobotulinumtoxinA 500-units group versus placebo at weeks 8 and 24. Decreased ARAT scores in abobotulinumtoxinA 1000 units versus placebo at weeks 8 and 24
Jahangir (2007) (207)	To assess the effectiveness, safety, and impact of BTX on ADLs and quality of life in poststroke hand spasticity in Malaysian patients	N = 52; At least 1 year after stroke; MAS at least 2 at wrist and fingers	OnabotulinumtoxinA 80 units (n = 27); placebo (n = 25) to FCR, FCU, FDS, FDP	MAS, Barthel ADL Index, Euroqol EQ-5D	1, 12 weeks	Decreased MAS scores at wrist and fingers in onabotulinumtoxinA group versus placebo at weeks 1 and 12
McCrory (2009) (208)	To examine the effect of BTX type A on quality of life and person-centered outcomes in patients with upper-limb spasticity following stroke	N = 96; >6 months after stroke; MAS at least 2 in two out of three of elbow, wrist, fingers and 1+ remaining area	AbobotulinumtoxinA 750–1000 units (n = 54); placebo (n = 42); Different muscles injected based on clinical pattern of spasticity; a second injection was given at week 12, choice of muscles and dose based on response to first injection	Assessment of quality of life measure, 100-point pain VAS, anxiety and depression rating scale, goal attainment scale, MAS, Modified Motor Assessment Scale, Carer Burden scale	8, 12, 20, 24 weeks	Decreased MAS scores in abobotulinumtoxinA groups versus placebo in all joints at weeks 8 and 20. Goal attainment score higher in BTX group compared with placebo at week 20. Higher proportion of participants with global benefit at weeks 12 and 24 in abobotulinumtoxinA group versus placebo
Kanovsky (2009) (115)	To assess the impact of incobotulinumtoxinA on muscle tone, functional disability, and caregiver burden in patients with poststroke upper-limb spasticity	N = 148; >6 months after stroke; AS score 2 or higher in wrist and finger flexors and at least 2 (moderate disability) in a subject-selected domain of the DAS	IncobotulinumtoxinA group (dose not fixed; maximum 400 units; median 320 units) versus placebo to various upper-limb muscles causing any of five clinical patterns (flexed wrist, clenched fist, flexed elbow, pronated forearm, thumb-in-palm)	AS: DAS: Carer Burden Scale; Global Assessment Scale of Treatment Benefit	2,4,8,12 weeks	Significantly higher proportion of incobotulinumtoxinA group had at least 1-point drop in AS in the wrist flexors versus placebo at week 4

Kaji (2010) (117)	To evaluate the efficacy and safety of one-time injection of botulinum toxin in Japanese patients with poststroke upper-limb spasticity	N = 109; >6 months after stroke; MAS 2 or higher in finger flexors and 3 or higher in wrist flexors; Score of 2 or 3 in DAS for at least one domain (hygiene, pain, dressing, limb position)	High-dose onabotulinumtoxinA (200–240 units; n = 51); High-dose placebo (n = 26); Low-dose onabotulinumtoxinA (120–1550 units; n = 21); Low-dose placebo (n = 11) to FCR, FCU, FDS, FDP =/- FPL	AUC of the change from baseline in MAS wrist flexor in high-dose group; DAS	1, 4, 6, 8, 12 weeks	Decreased MAS scores in wrist flexors in high-dose onabotulinumtoxinA versus high-dose placebo. No difference between low-dose onabotulinumtoxinA versus low-dose placebo. DAS (limb positioning and dressing) more improved in onabotulinumtoxinA versus placebo groups
Shaw (2010) (209)	To compare the clinical effectiveness and cost-effectiveness of treating upper-limb spasticity due to stroke with botulinum toxin type A plus an upper-limb therapy program with the upper-limb therapy program alone	N = 333 adults; upper-limb spasticity at the shoulder, elbow, wrist, or hand; reduced upper-limb function due to stroke more than 1 month previously	OnabotulinumtoxinA plus a 4-week upper-limb therapy program; Control group enrolled in upper-limb therapy program only	ARAT; MAS; Motricity Index; grip strength; Nine-Hole Peg Test; upper-limb basic functional activity questions; Barthel Activities of Daily Living (ADL) Index; Stroke Impact Scale, European Quality of Life-5 Dimensions (EQ-5D), and the Oxford Handicap Scale. Numerical pain rating scales; Canadian Occupational Performance Measure. EQ-5D data were used to calculate the quality-adjusted life-years (QALYs) associated with intervention and control treatments, and the incremental cost per QALY gained of botulinum toxin type A plus therapy compared with therapy alone was estimated	3, 6, 9, 12 months	No significant difference between the groups for primary outcome (arm function) at 1 month. No significant differences in arm function at months 3 and 12. Decreased MAS scores in elbow flexors in onabotulinumtoxinA group versus controls at 1 month only; higher incidence of general malaise/flu-like/cold symptoms in onabotulinumtoxinA group versus controls

Lower Limb

Kaji et al. randomized 120 patients with lower-limb spasticity to receive either onabotulinumtoxinA 300 units or placebo to ankle plantar flexors and invertors (117). The drug group had significant decline in the MAS score of ankle plantar flexors at 12 weeks after injection. Although the treated group showed a trend towards improvement of gait speed, this was not significantly different from the placebo group. In both studies, there was no marked difference in the frequency of treatment-related adverse events between the onabotulinumtoxinA and placebo groups (111).

A study on the effect of abobotulinumtoxinA involving 23 stroke survivors showed that 1000 units to various lower-limb muscles was significantly superior to the placebo in improving AS scores in the ankle plantar flexors ($P < .0002$) and invertors ($P = .0002$) (118). Muscles injected included the gastrocnemius, soleus, tibialis posterior, and flexor digitorum longus. Another investigation of the impact of abobotulinumtoxinA injected to both heads of the gastrocnemius and soleus showed similar results (119). In this study, 234 subjects were randomized to one of four groups (placebo, abobotulinumtoxinA 500, 1000, and 1500 units) (119). Similar to previous findings, the most significant improvement in spasticity was in the group that received the highest dose (1500 units).

A randomized, double-blind, dose-ranging trial by Mancini et al. on 45 spastic feet due to stroke demonstrated the efficacy and safety of about 300 units of BTX-A injected in various lower-limb muscles (120). Subjects were randomized into three groups: Groups 1 (mean total BTX dose, 167 units), 2 (mean total BTX dose, 320 units), and 3 (mean total BTX dose, 540 units). Even as all three groups improved on various outcome measures, including the modified AS, Medical Research Clinical Scale, gait assessment, ankle clonus, and visual analog scales for gait and pain, groups 2 and 3 had more improvement at 4 months after injection. Group 3 reported the highest incidence of adverse events 4 weeks after treatment, suggesting a dose–response relationship.

Evidence of Efficacy of BTX Type B (BTX-B)

There is limited published research on the use of rimabotulinumtoxinB (marketed as Myobloc™ in the United States, and as Neurobloc™ in Europe and elsewhere), for spastic hypertonia. An open-label study reported that Myobloc™ effectively decreased upper-limb tone in 10 subjects with acquired brain injuries (9 of whom had a stroke) (121). A total dose of 10,000 units was injected into various muscles, including the biceps (3750 units), FCR (2500 units), FCU (2500 units), FDS (625 units), and FDP (625 units). AS scores improved significantly from baseline in the elbow ($P = .016$), wrist ($P = .004$), and finger flexors ($P = .02$) at week 4. The most commonly reported adverse event was dry mouth.

Clinical Issues in the Use of BTX

In the United States, BTX dosing for spastic hypertonia is neither standardized nor based on scientific data. Instead, dosing is based on recommendation by experts and unique experience of clinicians (122). The optimal dose of BTX is the most effective amount required to achieve a predetermined outcome such as reduced hypertonia, increased range of motion, and/or improved hygiene and function, without causing an adverse event (e.g., weakness). Several factors affect the outcome of BTX therapy and influence clinical decision regarding choice of dose. These are summarized in Tables 29.9, 29.10, and 29.11.

TABLE 29.9 Factors That Affect Dose Selection of BTX

Patient-related factors

BTX is usually not administered more frequently than every three months because of theoretical concern for antibody development (122). This cautionary measure is based on findings in earlier studies on the use of BTX in cervical dystonia, where frequent injection, administration of "booster" injections, and initial high doses appeared to contribute to the development of BTX antibodies (123,124). It is estimated that the incidence of antibody to BTX in the spastic hypertonia population is less than 1%, but there are as yet no published data based on a prospective investigation (125,126). Repeated injection of BTX appears to be effective and safe (127,128). Lagalla et al. studied the effects of repeated injections every 3 to 5 months over a 2-year period to various upper-limb muscles in 28 stroke survivors (127). Muscle tone, range of motion, and satisfaction and functional measures (e.g., putting on gloves, axillary hygiene) improved after each treatment, and this response was sustained over time. Additionally, there was no significant increase in treatment doses, and treatment intervals increased from a mean of 3.9 ± 1.2 months between the first two sessions to 6.4 ± 1.7 months between the fourth and fifth doses.

The preparation of onabotulinumtoxinA for injection has not been standardized, but a common practice is to dilute a 100-unit vial with 1 to 2 mL of preservative-free saline. A small prospective study comparing dilution of 100 units of onabotulinumtoxinA with 1 and 2 mL of saline did not show a difference in improving hypertonia of wrist and finger flexors (129). Another small trial suggested that dilution of onabotulinumtoxinA with 5 mL of preservative-free saline is superior to more concentrated solution for decreasing spastic hypertonia of elbow flexor muscles (130). This is not an issue with Myobloc™, which already comes in a solution. No published information is available regarding dilution of abobotulinumtoxinA.

Little has been published in the literature on the role of adjunctive therapy modalities with BTX. Small, uncontrolled trials claim that the combination of BTX and various therapy modalities enhances clinical outcome. These include electrical stimulation of muscles injected with onabotulinumtoxinA or abobotulinumtoxinA, ankle taping, and casting (131–133). A "low dose" of onabotulinumtoxinA plus casting resulted in improved ankle range of motion and foot positioning similar to that obtained with a "high dose" (190–320 units) but without subsequent taping. The combined effect of BTX and physiotherapy and other therapeutic modalities in the stroke population has yet to be systematically investigated.

The reviewed studies have demonstrated that BTX is an effective therapy for focal poststroke spastic hypertonia, but no persuasive evidence has been published on its impact on generalized spastic hypertonia and function. Only a few studies attempted to investigate the effect of BTX on the functionality of upper limb (e.g., changes in hygiene and use of orthosis; decrease in caregiver burden) (25,132,134). The same observation is true for lower-limb studies, which primarily addressed spastic hypertonia reduction. Only one

study investigated gait as a main outcome measure (119). The lack of a systematic substantiation of the influence of BTX on poststroke recovery may be due to study design, patient selection, and choice of study outcome measures.

INTRATHECAL BACLOFEN

ITB therapy differs from the oral form of the medication in that it provides direct infusion of baclofen into the intrathecal space, thereby bypassing the blood–brain barrier. In contrast to oral baclofen, ITB is delivered in close proximity to the drug's site of action in the dorsal horn of the spinal cord. Therefore, only a small concentration of the drug is required to exert therapeutic effects; this avoids increasing the risk of side effects commonly associated with oral baclofen, such as sedation, drowsiness, and weakness. A programmable pump that infuses baclofen includes a small titanium disk containing a refillable reservoir for the drug and houses a computer chip that regulates the battery. A flexible silicone catheter, connected to the pump, delivers the drug into the intrathecal space. Prior to ITB pump implantation, a screening trial consisting of a bolus injection of 50 to 150 micrograms of baclofen is customarily performed to determine responsiveness of hypertonia to the medication.

ITB was initially used in persons with stroke and severe multilimb spastic hypertonia (135,136). Typical goals were facilitation of hygiene, positioning, and comfort. Lately, more clinicians have been utilizing ITB therapy chiefly to enhance upper-limb function and gait (137,138). When applied in the appropriate clinical setting and combined with a rehabilitation program, ITB therapy is an effective means of managing poststroke spastic hypertonia in individuals at various functional levels.

The body of literature supporting the efficacy of ITB in poststroke spastic hypertonia is limited. Thus far, no randomized, controlled study has been published. Much of what is known is based on a handful of open-label trials and case series (Table 29.12) and a consensus statement of experts (135–137,139–142). Two small investigations were conducted using a randomized, double-blind, placebo-controlled, crossover design during the first part of the study (ITB bolus injection during the screening trial), which then assumed an open-label design during the continuous ITB infusion phase (135,136). These patients showed a significant improvement in spastic hypertonia. A much larger series involving 94 subjects suggested that ITB therapy can positively enhance function and quality of life based on significant changes in functional independence measure (FIM) and

TABLE 29.12 Intrathecal Baclofen in Poststroke Spastic Hypertonia

STUDY/AUTHOR	SUBJECTS	STUDY DESIGN	OUTCOME
Meythaler et al. (1996) (135)	Stroke = 3 TBI = 3	Randomized, double-blind, placebo-controlled, crossover (screening phase only); open label after ITB pump implantation 3 months follow-up	Improved AS, SFS, and reflex scores No effect on motor strength on the normal side
Meythaler et al. (2001) (71)	Stroke = 21	Randomized, double-blind, placebo-controlled, crossover (screening phase only); open label after ITB pump implantation 12 months follow-up	Improved AS, SFS, and reflex scores No effect on motor strength on the normal side Three subjects recovered ability to ambulate
Francisco and Boake (2003) (137)	Stroke = 10, all ambulatory	Open label Mean 8.9 months follow-up	Improved modified AS scores and gait speed. Preserved strength in unaffected limbs.
Remy-Neris et al. (2003) (142)	Stroke = 4 TBI = 3	Case series, open label; bolus intrathecal baclofen only	Improved AS scores and maximal walking speed, but preferred walking speed was unchanged Minimal knee extension and maximal ankle flexion were the only kinematic data that significantly improved
Horn et al. (2005) (140)	Stroke = 13 TBI = 12 HE = 3	Case series; open label 2, 4, and 6 hours post-ITB bolus injection	Improved AS scores and gait velocity Significant correlation between baseline gait velocity and peak change in velocity after ITB bolus No significant correlation between AS and change in temporospatial outcome gait measures
Ivanhoe et al. (2006) (141)	Stroke = 74	Open label Post-ITB follow-up at 3 and 12 months	Significant improvement in AS, FIM, and SIP scores at both follow-ups No effect on muscle strength on unaffected side Largest study in stroke

Abbreviations: AS, Ashworth Scale; FIM, functional independence measure; HE, hypoxic encephalopathy; ITB, intrathecal baclofen therapy; SFS, spasm frequency scale; SIP, sickness impact profile; TBI, traumatic brain injury.

sickness impact profile (SIP) scales, respectively (141). The limitation of study design and choice of outcome measures, however, prevent interpretation of the results and correlation with clinically significant functional changes. Thus far, only three investigations have suggested actual functional improvement. Two small case series demonstrated significant improvement in gait speed, whereas one demonstrated increased upper-limb use following ITB and physical or occupational therapy (137,140).

A consensus statement suggested that ITB therapy be considered in stroke survivors whose spastic hypertonia did not respond adequately to other pharmacologic and nonpharmacologic management interventions (139). ITB should also be considered regardless of the severity of hypertonia, as long as the spastic condition is significant enough to cause other problems, such as pain, joint deformities, postural abnormalities, and functional deficits like impairment in gait and inability to adequately perform activities of daily living. It should also be considered in persons whose progress in a rehabilitation program is hindered by spastic hypertonia that failed to respond to other treatment strategies. Table 29.13 summarizes typical goals for the application of ITB in stroke.

In spite of the potential benefits of ITB, less than 1% of stroke patients with severe disabling spasticity are treated with ITB (143). Possible reasons for ITB underutilization include surgical risks, excessive weakness, less effect on upper limbs, and limited functional improvement.

Concerns regarding the early use of ITB therapy after a stroke are based on animal studies, where early use of baclofen and other medications that mimic or enhance the effects of GABA after experimentally induced cerebral lesions slowed neurologic recovery (144,145). Reports also suggest that certain drugs, including baclofen and other GABA agonists, may have a negative impact on cognitive and motor recovery after a stroke (146). However, it is widely acknowledged that delayed or inadequate treatment of spastic hypertonia may result in costly complications such as contractures, persistent pain, and failure to benefit from rehabilitation efforts. Thus, the same consensus statement recommended that ITB therapy should be considered as early as three to six months after stroke, whenever it causes significant functional impact or hinders progress in rehabilitation (139).

Although not unique to persons with stroke, certain clinical issues warrant thoughtful consideration before institution of ITB therapy, such as concomitant use of antiplatelet agents and anticoagulants. There is insufficient evidence regarding the risk of withdrawing these medications prior to ITB screening or implantation to guide treatment. Thus, the decision whether to withdraw antiplatelet and anticoagulation treatment, its timing, and reinstitution, will have to be made in consultation with the implanting surgeon and other specialists (cardiologists, hematologists, neurologists) involved in the patient's care. Seizures are also known to occur during ITB therapy in other patient populations, but their occurrence among stroke survivors with ITB is not known (147,148). Changes in gastrointestinal motility associated with ITB therapy have also been described (149). This may aggravate constipation, which commonly occurs during the acute and subacute phases of recovery from a stroke, when individuals are relatively immobile. Sexual dysfunction associated with ITB has been reported in the spinal cord injury population but has yet to be reported in stroke survivors (150).

TABLE 29.13 Goals for ITB Therapy in Poststroke Hypertonia

High-level patient
Mobility
Increased speed of gait
Increased safety of gait
Improved quality of gait
Prevent long-term injury due to alteration in joint biomechanics
Activities of daily living (ADLs)
Dressing
Independence in hygiene
Decreased time to accomplish ADLs
Others
Discontinuation of oral spasmolytic drugs (and avoidance of drug side effects)
Decreased time spent on stretching as part of an exercise program
Low-level patient
Improved positioning
Facilitation of hygiene
Decreased caregiver burden and time
Prevention of complications (i.e., contractures and nonuse of paretic limb)
Increased orthotic fit and compliance
Decreased pain due to nighttime spasms
Improved quality and duration of sleep

Source: From Ref. (139). Francisco GE, Yablon SA, Schiess MC, Wiggs L, Cavalier S, Grissom S. Consensus panel guidelines for the use of intrathecal baclofen therapy in poststroke spastic hypertonia. *Top Stroke Rehabil*. 2006;13(4):74–85. Thomas Land Publishers.

The Impact of BTX and ITB on Functional Recovery

BTX and ITB therapies are effective treatments for poststroke spastic hypertonia, but their influence on function has not been fully demonstrated by well-designed studies. Even though it is tempting to dismiss their therapeutic impact on functional recovery due to the dearth of published evidence, common clinical experiences dictate otherwise. Perhaps the lack of scientific evidence does not accurately reflect the effect of BTX and ITB on function, but rather results from limitations in study design and methods. Likewise, it is also possible that it is incorrectly assumed that spastic hypertonia is the chief cause of a functional deficit, whereas other abnormalities associated with the UMNS, such as incoordination and co-contraction of agonist and antagonist muscles, are the primary reason for impaired function. Often, an erroneous assumption is made that a decrease in spastic hypertonia alone will automatically translate to enhanced function. Doing so oversimplifies function, which is a complex and multifaceted phenomenon that depends not only on muscle tone but also on muscle strength, coordination, and endurance, as well as the influence of behavior and cognition. Some have suggested

that tonic stretch reflex activity does not meaningfully contribute to active motor function after stroke (2).

Inappropriate patient selection may also explain poor functional outcomes in BTX and ITB studies. Patients with no or poor potential for motor and functional recovery could not be expected to demonstrate further functional improvement despite significant reduction of spastic hypertonia. Moreover, BTX injections and ITB therapy may worsen residual function by transiently inducing or uncovering latent weakness if too high a dose is used. Sheehan and Francis et al. have discussed this issue in greater detail in their excellent reviews (46,151).

ROLE OF SURGICAL INTERVENTION

Surgical procedures are typically reserved for those stroke patients with muscle or tendon shortening who have not responded to the less invasive procedures, or as a "last resort." Tendon transfer, release, or lengthening are the most common orthopedic procedures (152). The split anterior tibial tendon transfer (SPLATT) and tendon Achilles lengthening (TAL) have been used to manage the spastic equinovarus foot (153–157). In a retrospective review of 73 operated feet in patients with stroke, cerebral palsy, and brain injury, there was improved ability to ambulate, decreased need to wear orthosis, and increased ability to wear normal shoes with minimal complications (158). In a study of 21 stroke patients 1 year after a SPLATT, 83% reported good or excellent results. All ambulatory patients had improved gait, and 35% were able to discontinue their orthosis. Poor surgical outcomes were associated with nonambulatory status (159). The additional transfer of the flexor hallucis longus and flexor digitorum longus to the os calcis with the SPLATT and TAL improved calf strength, and patients had less reliance on orthotics (70% vs. 40%) (160). Pinzur et al. reported improved prehension after brachioradialis to finger extensor tendon transfer in four patients with spastic hemiplegia (161). Eighteen patients with spastic hand deformities had improved prehension after release of the flexor-pronator origin and step-cut lengthening of flexor pollicis longus (162). Polyelectromyography may be useful in identifying which patients would benefit most from orthopedic procedures (163). Other procedures, such as neurotomy, have also been shown to benefit spastic conditions (75,93,164).

NONPHARMACOLOGIC MODALITIES

Collaboration with physical and occupational therapists is critical to the effective management of poststroke spasticity (66). The therapist can help with patient evaluations, education, and establishment of patient-specific goals (17). A number of conventional therapies have been used to manage spasticity and improve function (17,165) (Table 29.14). These therapies are aimed primarily at providing prolonged stretch to shortened muscles and tendons, reducing muscle overactivity, strengthening weak muscles, potentiating medications, restoring biomechanics, improving endurance, integrating into functional tasks, and improving motor control (166,167).

TABLE 29.14 Rehabilitation Interventions for Spasticity

Neurofacilatory techniques
Electrical stimulation
Aquatic therapy
EMG biofeedback
Constraint-induced movement therapy
Robotic training
Partial weight support treadmill training

Unfortunately, there is a significant variation in the use of these therapies, and lack of controlled trials (168). The reader is referred to three reviews on the benefits of stretch and physical modalities in the management of spasticity (168–170). In a randomized, controlled study of 44 stroke patients, those treated with 20 sessions of Bobath treatment for 4 weeks had improved motor function and reduced spasticity, compared with the orthopedic treatment group (171,172).

Surface electrical stimulation in stroke survivors has been shown to reduce atrophy, enhance strength, and possibly reduce spasticity (7,173–180). The antispastic effect has been suggested to involve facilitation of Renshaw cell recurrent inhibition, antagonist reciprocal inhibition, cutaneous sensory habituation, and augmentation of Ib fiber activation (181). Unfortunately, these studies have shown limited functional improvement, and many patients are unable to tolerate the electrical stimulation (175,182). Initial work with an upper-limb neuroprosthesis used to improve function was limited to the laboratory, and stimulation was limited to hand opening (57,178).

A new approach is a device that combines a wrist-hand orthosis with neuromuscular electrical stimulation (NMES) of wrist and finger flexors and extensors during a repeated prehension exercise paradigm. The NESS H200™ is a neuroprosthesis that is well tolerated and has been shown to reduce impairments and improve function (180,183–185). The major advantage of this system is that the device is custom-fitted to the patient's forearm, assuring that the electrodes always stay in the correct place and provide consistent activation of the targeted muscles. The device is easy to don and doff and can be activate with one hand. The integrated NMES system provides reproducible stimulation of both wrist and finger flexors and extensors. The NESS 200 is intended to be self-administered and allows NMES-assisted exercises involving prehension. The simplicity of using the system improves compliance with the treatment program (74). Improved function can be obtained when NMES is combined with a home exercise program. In a multicenter, multicountry nonrandomized study, 77 stroke survivors completed a 5-week daily home training program with the NESS H200. Subjects trained two to three times each day for seven days a week, and all enrolled subjects completed the study. The Jebsen-Taylor simulated feeding time improved

35%, the light object lift improved 45%, and the nine-hole peg test improved 59%. Mean spasticity reduction was 0.87 at the elbow and 0.78 at the wrist as measured by the AS. Thirty-three of the 77 patients had persistent upper-limb pain with mean reduction 3.5 to 1.9 (74). Although this study is promising, it did not include a control group, so it is difficult to determine whether the benefits resulted from the NMES or from the regular exercise program.

Whole-body vibration in chronic stroke patients appears to decrease spasticity, but studies with larger sample size and long-term follow-up are needed to better understand its role in managing poststroke spasticity (186,187).

LOOKING AHEAD: THE FUTURE OF SPASTIC HYPERTONIA MANAGEMENT

Spastic hypertonia and the UMNS, being complex and multifaceted conditions, create opportunities for innovative therapies for the future. Drugs that have been used for indications other than stroke have the potential to alleviate spastic hypertonia and other abnormalities. 4-amino-pyridine, an orally administered medication touted to alleviate symptoms in multiple sclerosis by improving impulse conduction along damaged nerve fibers, has been reported to have antispasticity properties (188). Clonidine, already used as an adjunctive oral therapy for spastic hypertonia, can also be delivered intrathecally (189,190). Its use is more common in Europe than in the United States. The use of intrathecal tizanidine has also been described in painful conditions, although its effect on spasticity, similar to that of the oral preparation, is yet to be shown (191). Another intrathecally administered drug, ziconotide, a neurotoxin that is an emerging treatment for severe pain, has been shown to have spasmolytic properties in the spinal cord injury population (192). An ancient therapy, acupuncture, has been used to treat spastic hypertonia, but its efficacy has yet to be established (see Chapter 37) (193–196). Earlier studies have suggested that spinal cord stimulation decreases spasticity, but clinical application of this modality has become more common for pain (197,198). Interest in the use of direct motor nerve stimulation appears to have been revived, judging by the recent publication of the results of animal investigations (199,200). Neuromodulation, through brain and spinal cord stimulation, is also a promising avenue for the future treatment of spastic hypertonia, as is gene therapy (201). Being able to control muscular overactivity through genes capable of specifically inducing synaptic inhibition and suppressing neuromuscular transmission offers the advantage of addressing the root of the neuromuscular dysfunction (201).

Decisions on the treatment of spasticity after stroke depend on the severity of spastic hypertonia and its impact on function and well-being. Other factors to consider include disease etiology and duration, previous response to therapies, topographical involvement, response to medication side effects, and cost. Therapeutic efforts have focused on peripheral (e.g., altering muscle properties through physical techniques) and central (e.g., influencing neurotransmission through GABA-mediated medications and modifying reciprocal inhibition through chemodenervation) strategies. Spastic hypertonia and the other UMNS signs and symptoms result in physical deformities and performance deficiencies. Thus, it is logical for interventions to target not only the underlying CNS pathology but also the ensuing physical abnormalities. Consequently, it is a widely held belief that concurrent use of various pharmacologic and nonpharmacologic treatment modalities results in a more optimal management outcome.

Musculoskeletal Complications After Stroke

Richard D. Wilson, David T. Yu, and John Chae

Musculoskeletal complications are common after stroke, with a quarter or more of stroke survivors experiencing them (1–4). The consequences of musculoskeletal complications can range from an annoyance to a major hindrance during and after stroke rehabilitation. Most of the musculoskeletal complaints are related to pain, yet some are not painful but interfere with function. It is not surprising that musculoskeletal complications are prevalent among hemiparetic stroke survivors. Biomechanics in these patients can be altered by weakness, sensory loss, spasticity, neglect, impaired motor control, and maladaptive compensatory strategies. This chapter addresses musculoskeletal complications that are commonly reported in the literature. Hemiplegic shoulder pain is one of the most common musculoskeletal complaints after stroke, and is a major focus of this chapter. Other complications include arthralgias, joint contractures, complex regional pain syndrome (CRPS), and heterotopic ossification (HO). It is important to note that musculoskeletal pathologies that are common in the general population, such as low back pain, are also common in those with stroke. This chapter focuses on musculoskeletal complications of stroke.

PAIN

Pain is one of the top complications after stroke. In fact, after the first week, pain has been found to be the most common cumulative complication in stroke survivors (1). Studies in stroke survivors have shown that pain is associated with lower health-related quality of life (5–7), lower function (8,9), and higher mortality (10). Guidelines highlight the importance of prevention, assessment, and treatment of pain throughout rehabilitation (11) to provide the greatest chance of recovery and to obtain the highest level of independence possible.

Pain is prevalent, affecting more than 25% of stroke survivors in the first week after stroke (12) and more than 33% of stroke survivors during hospitalization and acute rehabilitation (1,13,14). The prevalence of pain in the first 2 years after a stroke is estimated to be between 15% and 50% (15), which is similar to the estimated prevalence of chronic pain in community-dwelling adults (15%–51%) (16–19). It appears that the development of new pain complaints is higher in stroke survivors than community samples. The only population-based study that included a matched reference group found that the proportion of pain related to the stroke is 10% (20), which is similar to the estimates of 10% to 21% in other studies (15,21). The most common musculoskeletal stroke-related pain complaints are related to the shoulder, other arthralgias, and muscle stiffness and spasms (15,20,22–24).

That the prevalence of pain is so high in stroke survivors likely is the result of multiple factors. First, pain is undertreated in older adults, many of whom tend to have other illnesses that may be prioritized more highly for treatment by providers (25). Second, pain is undertreated in those who have communication or cognitive impairments because of their inability to express their needs (26,27). Finally, there are many chronic pain syndromes without adequate treatments that result in prolonged suffering and frustration for patients and providers (28–30). It is important for providers who care for stroke survivors to inquire about the presence of pain and to adequately address complaints. This chapter provides information germane to providers caring for stroke survivors and primarily focuses on musculoskeletal conditions that are directly related to the stroke.

Shoulder Pain

Shoulder pain is a common complication after stroke that can inhibit functional recovery and reduce quality of life (31,32). Many types of shoulder pathology after stroke have been reported in the literature, including shoulder subluxation, impingement syndrome, rotator cuff injury, tendonitis, bursitis, capsulitis, peripheral nerve injuries, CRPS, spasticity, central hypersensitivity, and contractures. No single type of pathology accounts for all shoulder pain after stroke. Conversely, it is important to recognize that more than one type of shoulder pathology may cause pain in an individual.

Among hemiplegic stroke survivors, the reported prevalence of shoulder pain ranges from 5% to 84%, reflecting differences in study methods and samples (33,34). Population-based studies estimate the prevalence of shoulder pain to be 17% at 1 week and 20% to 24% at 1 to 16 months after stroke (35,36). The estimates of prevalence in rehabilitation settings are 37% to 55% (37–40), likely because of the greater number of associated risk factors in this population compared to the general population of stroke survivors.

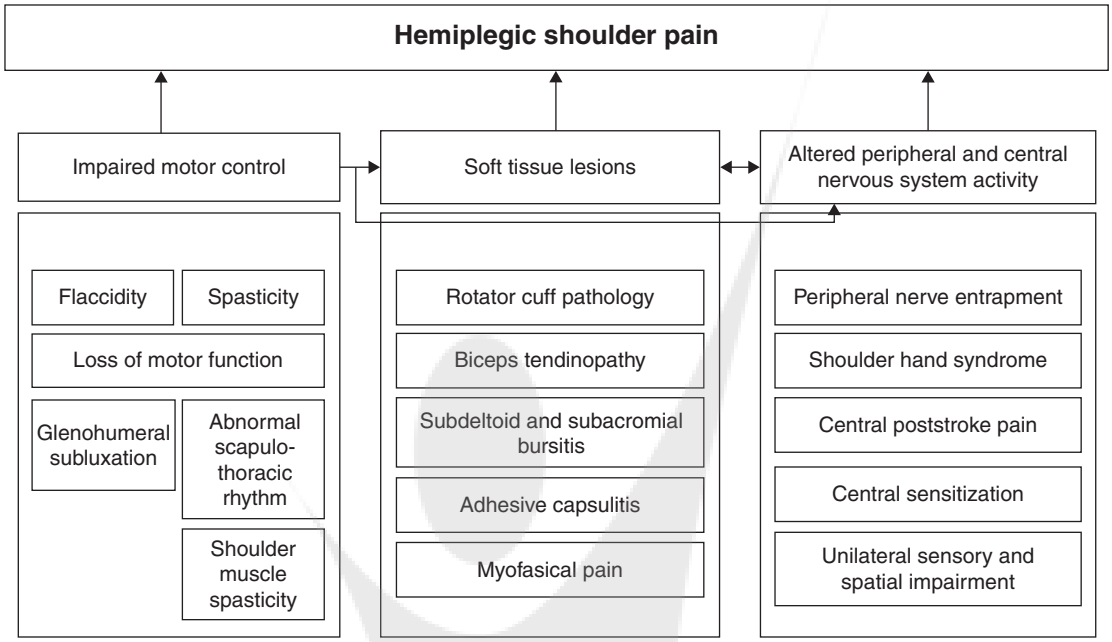

FIGURE 30.1 Systematic organization of pathologies underlying hemiplegic shoulder pain.

Source: Adapted from Ref. (52). Kalichman L, Ratmansky M. Underlying pathology and associated factors of hemiplegic shoulder pain. *Am J Phys Med Rehabil*. 2011;90(9):768–780.

Gamble et al. reported resolution of pain in 80% of cases when management included prompt diagnosis and early, appropriate intervention (41). However, studies consistently report a significant number of cases that do not resolve, with 20% of moderate to severely impaired stroke survivors reporting pain 4 years after stroke (42). The data suggest that poststroke shoulder pain can improve in many cases with prompt diagnosis and appropriate intervention, but that a significant number of cases become chronic and refractory to available treatments.

Many potential risk factors for shoulder pain after stroke have been cited in the literature and have been most consistently correlated with severity of motor impairment (35,36,41–43). Other commonly reported risk factors include duration of motor impairment (44), sensory impairment (36,43,45), reduced range of motion (43,44), spasticity (46), central sensitization (47,48), soft tissue injuries (49–51), and comorbidities such as diabetes mellitus (36,43). A systematic approach to integrating potential underlying pathologies has proposed three categories of pathology: (a) impaired motor control, (b) soft tissue lesions, and (c) altered peripheral and central nervous activity (see Figure 30.1) (52).

Shoulder Subluxation

Subluxation is defined as partial dissociation or increased translation between two articulating surfaces of a joint (53). Subluxation may be contrasted to dislocation, defined as complete dissociation between two articulating surfaces of a joint. By convention, shoulder subluxation resulting from hemiparesis after stroke refers to increased translation of the humeral head relative to the glenoid fossa. Generally, in clinical practice and in research, shoulder subluxation after stroke is measured in the inferior direction with the upper limb in a dependent position, allowing the weight of the limb to distract the humeral head from the glenoid fossa (38,44,46,54–65). Though these methods have become the standard by convention, the content validity of measuring only inferior subluxation is questionable and may contribute to the inconsistent correlation between subluxation and pain reported in the literature.

Shoulder subluxation is common in hemiplegia. Though subluxation has been reported to occur in up to 81% of cases (61), one of the largest cohorts of hemiplegic subjects followed over months reported an incidence of approximately 50%(46). However, even in this case, an overestimation resulting from selection bias toward more impaired hemiplegic subjects cannot be ruled out. Though shoulder subluxation is one of the most commonly cited causes of shoulder pain in the literature, the relationship between subluxation and pain remains controversial. Although a number of studies suggest a correlation between subluxation and pain (33,46,66–68), others have demonstrated absence of correlation (38,42,69–72). Many differences in study methods may underlie the disparity in the literature, although the lack of correlation between subluxation and pain in several studies suggests that subluxation may not be a direct cause of pain in many cases. It is also possible that subluxation predisposes the shoulder to other types of painful pathology. Several studies have corroborated this notion by demonstrating a correlation between

shoulder subluxation after stroke and the development of other causes of shoulder pain, including CRPS, peripheral neuropathies, and rotator cuff injury (33,73–75).

Shoulder subluxation in hemiplegia occurs because of the paralysis of active restraints that play a critical role in maintaining glenohumeral stability (76–79). Shoulder subluxation tends to occur early after stroke, with most cases occurring within the first three weeks, particularly in patients with flaccid hemiplegia (55). Spasticity develops in most hemiplegic patients and may have an effect on reducing shoulder subluxation. An inverse correlation between shoulder subluxation and spasticity has been reported in two studies in which the authors attribute the reduction of subluxation to return of muscle tone or volitional activation (55,58). In another study, subluxation was reduced only when shoulder muscles became spastic within the first week after stroke, but was not reduced when spasticity occurred at three weeks or later. This suggests that there may be a critical, brief time window for spasticity to have an effect on reducing subluxation (55). The results of this study also suggest that the passive restraints of the shoulder may only be sufficient for maintaining joint stability for a short period of time. Stretching of the joint capsule and ligaments may not be reversible after a point. In only one study, a higher incidence of shoulder subluxation was found when spastic and flaccid hemiplegic subjects were compared (46). Studies of electric stimulation (ES) of shoulder muscles to reduce subluxation after stroke also suggest that changes in muscle properties can reduce subluxation. However, it is not clear if relevant changes in muscle properties are a result of the improvement in muscle tone, improvement in purely passive mechanical properties, or (less likely) improvement in voluntary muscle contraction. The majority of ES studies have shown that stimulation-induced muscle contraction can reduce subluxation. Several of these studies have shown that the reduction of subluxation is maintained for months after muscle stimulation has been discontinued, suggesting an effect of passive muscle properties (54,57,65,80). Though a few studies have shown that subluxation can be reduced in chronic stroke patients, a 2002 meta-analysis of the data suggests that ES for reducing poststroke shoulder subluxation is most effective when applied early after stroke (81).

The clinical diagnosis of shoulder subluxation can be made without imaging studies. The most commonly used clinical measure of shoulder subluxation in hemiplegia quantifies inferior subluxation by determining the number of fingerbreadths that can be inserted between the inferior border of the acromion and the superior border of the humeral head while the patient is seated with the upper limbs hanging passively. The patient is seated because muscle tone may increase in the standing position, reducing the subluxation. Comparison to the unaffected shoulder is recommended, but care should be taken to palpate only the bony landmarks to avoid misinterpreting a unilateral flaccid or atrophied deltoid muscle as the difference between shoulders. The clinical fingerbreadth measure detects abnormal translation in the inferior direction only. This clinical measure has a resolution of a half fingerbreadth and does not detect small changes in glenohumeral displacement that may be significant. Despite anatomical variability in finger widths, the reliability of the fingerbreadth measure has been established (82). The reliability of this technique may be in part a function of its limited resolution. Imaging studies such as plain radiographs, computed tomography, ultrasound, and magnetic resonance imaging also show subluxation, often with greater resolution and the ability to detect abnormal translation in other dimensions. Because the clinical significance of subluxation in multiple dimensions is not known, the significance of small amounts of subluxation is not known. Because the role of subluxation as a cause of pain is controversial, these additional studies are not currently standards for diagnosing shoulder subluxation.

Despite the controversial relationship between shoulder subluxation and pain, treatment of subluxation continues to be the standard of care in rehabilitation facilities, for several reasons. First, shoulder subluxation may be painful in some cases, particularly when manual reduction of the subluxed joint diminishes pain. Second, shoulder subluxation may predispose hemiplegic patients to the development of other painful conditions. If chronic shoulder pain develops, it is often refractory to available treatment, warranting prevention for at-risk patients and prompt treatment in patients with subluxation. Third, subluxation may inhibit functional recovery by limiting the range of motion. Support of the hemiplegic upper limb in the seated and standing positions remains the standard of care for stroke survivors with shoulder subluxation and those with flaccid paralysis of shoulder muscles who are at risk for developing shoulder subluxation.

Upper-limb support includes the use of wheelchair adaptations and judicious use of selected supports. When seated in the wheelchair, hemi-trays are appropriate for patients with sufficient motor function to maintain the upper limb in a resting position on the tray. A trough, in some cases with Velcro enclosures, attached to the wheelchair is suited to patients who lack sufficient motor control to prevent the upper limb from sliding from a tray. It should be mentioned, however, that wheelchair arm troughs and trays have not been shown to reduce subluxation or pain, and occasionally have been thought to predispose the affected shoulder to impingement syndromes (83,84). Selected supports may be used to support the affected upper limb during transfers and ambulation, though findings have been mixed and there is little evidence to recommend their use (83,85,86). If a sling-type support is used, a neoprene cuff-type hemisling is recommended. Slings that place bulky material, such as a roll, under the axilla may cause lateral subluxation. Swathe-type slings that hold the shoulder in adduction and internal rotation and the elbow in flexion should be avoided because they can rapidly lead to capsulitis, cause contractures over time, and promote undesirable synergistic patterns of muscle activation (84).

The use of tape to support the subluxed glenohumeral joint, known as *strapping*, has been evaluated in randomized, controlled trials with mixed results (87–89). A Cochrane

review of external supports suggests that strapping may delay the onset of shoulder pain but does not reduce pain severity or associated disability (86).

The limitations of orthotic applications such as strapping, slings, and wheelchair adaptations have prompted investigators to evaluate the efficacy of ES for reducing poststroke shoulder subluxation and pain. The stimulation is most commonly delivered through electrodes placed on the skin surface (i.e., transcutaneous ES). Electrodes are typically placed over the posterior deltoid and supraspinatus muscles. Baker et al. proposed that placing the cathode over the deltoid and the anode over the supraspinatus would reduce undesirable stimulation to the upper trapezius and resultant shoulder shrugging (54). Stimulation is typically delivered for six hours daily for six weeks. Transcutaneous ES reduces shoulder subluxation when applied within weeks of stroke onset (56,57,80,81,90), though one trial did not find improvement (91).

Clinical trials evaluating the efficacy of transcutaneous ES for reducing subluxation in chronic hemiplegia (54) and for reducing shoulder pain have yielded mixed results (56,57). Clinical application of transcutaneous ES has been limited for several reasons. First, stimulation of cutaneous nociceptors results in stimulation-induced pain. Pain with transcutaneous ES is a well-recognized entity, and methods to improve tolerance by gradually increasing stimulation time or intensity until tolerance for therapeutic stimulation develops has been described (54,92). However, this strategy does not promote tolerance in all cases. Furthermore, it is time-consuming for the therapist and patient; the previously reported clinical trials were conducted in the context of inpatient rehabilitation and may not be practical under the economic pressures of the present health care environment. Approximately 30% of hemiplegic patients do not tolerate transcutaneous ES even when methods to enhance tolerance are employed (59). Second, activation of deep muscles cannot be achieved without stimulation of more superficial muscles. Third, clinical skill is required to place the electrodes and adjust stimulation parameters to provide optimal treatment. Treatment is typically administered daily by a skilled therapist. Few patients are able to administer treatments at home by themselves or with the assistance of a caregiver. Fourth, transcutaneous ES may interfere with the user's daily activities. Surface electrodes can be displaced from the skin during movement and connecting leads can be accidentally pulled during activity. The significance of this limitation is obvious when considering that most treatment regimens require stimulation over hours, daily, for weeks.

Newer technologies permit direct stimulation of target peripheral nerve or motor points through percutaneously placed electrodes. Electrical stimulation delivered through electrodes implanted near the target nerve has several potential advantages over transcutaneous ES. First, percutaneous ES is less painful than transcutaneous ES for reducing shoulder subluxation after stroke (93). The stimulating surface of the electrode is placed near the peripheral nerve or muscle motor point so that stimulation of cutaneous nociceptors can be avoided. This method permits the use of lower stimulus intensities than when the current has to cross the skin, which is a poor conductor. Stimulation frequencies as low as 12 Hz, which minimize muscle fatigue and facilitate muscle conditioning, can be used. These lower frequencies are associated with significant pain when using surface ES. Undesirable stimulation of adjacent muscles not intended for stimulation also can be avoided. Second, implanted electrodes are placed optimally at the beginning of treatment and remain in place for the treatment duration. Thus, the system is more reliable, can be administered by the user or caregiver at home, and obviates the need for daily application by a therapist. This percutaneous intramuscular system also permitted users to perform typical daily activities while receiving treatment. The efficacy of six weeks of ES delivered directly to peripheral nerves of four shoulder muscles using this partially implanted system for treating shoulder pain in chronic stroke patients with hemiparesis and subluxation was demonstrated in a multicenter randomized clinical trial (94,95). In this trial, pain reduction remained significant for at least one year after completing treatment. However, the reduction of subluxation between treatment and controls was not significant, calling into question the mechanism of pain reduction (94–96). This approach was simplified to a single-lead percutaneous intramuscular electrode that stimulates the axillary nerve at the middle and posterior deltoid muscles of the painful shoulder for three weeks (97). In a case series of subjects with shoulder pain with or without subluxation, a reduction in pain occurred after a three-week stimulation period and remained throughout the three-month follow-up period (98).

An alternative to the percutaneous intramuscular system is a fully implanted ES system comprised of a percutaneously injected microstimulator, battery, and electrode housed within a titanium and ceramic cylinder. The device has been investigated in small case studies and has shown success in reduction of subluxation and shoulder pain (99–101). The potential advantages of this fully implanted system are numerous. It obviates the need for users to wear external components, making it easier to use; in addition, reliability is improved, infection risk posed by percutaneous hardware is avoided, and the risk of accidental electrode displacement is reduced. The system is designed to remain in the body for the life of the user. Thus, chronic or repetitive treatment is facilitated.

In summary, shoulder subluxation tends to occur early after stroke in patients with flaccid hemiplegia and may be reversible through facilitation of muscle tone, motor recovery, or stimulated muscle contraction. There may be a brief, critical time window for reducing subluxation during the acute phase after stroke. The use of external upper-limb support, including judicious use of slings and wheelchair adaptations, is indicated for patients with subluxation or those with flaccid hemiparesis who are at risk. Electrical stimulation reduces subluxation in acute stroke, but the effect on subluxation in chronic stroke is less clear. The effect of ES in treating shoulder pain after stroke appears to be a reduction of pain regardless of improvement in subluxation.

Capsulitis and Related Conditions

Capsulitis, also known as *adhesive capsulitis* or *frozen shoulder*, is a common complication after stroke and refers to shortening and thickening of the glenohumeral joint capsule. Several studies have found a high prevalence of joint capsule thickening and synovial membrane contrast enhancement on magnetic resonance imaging for those with shoulder pain after stroke compared to controls (102,103), indicative of capsulitis (104,105). The inflammatory response seen in this condition probably results from irritation and injury to shortened capsular fibers. The term *adhesive* refers to adhesions of the capsule during surgery found by Neviaser et al. (106). Other authors report fibrosis of the capsule but no adhesions at the time of surgery (107). Fibrosis most likely occurs in the chronic phase of this condition if inadequately treated. There is an association of the development of capsulitis after stroke with immobility (108,109), impingement (110), and subluxation (111), which raises the question of whether capsulitis has a causative role or is a result of shoulder-related sequelae of stroke (52). Ultimately, the cause of capsulitis remains unknown.

On physical examination, decreased shoulder external rotation and abduction associated with pain is the hallmark of capsulitis. Because many patients with spastic hemiparesis have tonic adduction and internal rotation of the shoulder, shortening of shoulder internal rotators is common. Thus, palpation of these muscles during the exam is useful to determine whether musculotendinous shortening contributes to decreased range of motion and pain. It is also useful to measure passive shoulder rotation with the shoulder in adduction, because shoulder internal rotators have more slack than in abduction. In practice, shortening of capsular fibers often coexists with spasticity and shortening of the internal rotators of the shoulder (i.e., subscapularis, pectoralis, anterior deltoid, teres major, and latissimus dorsi muscles). In such cases, treatment of all contributing entities affords better and longer-lasting outcomes than treatment of only one. In the stroke literature, decreased shoulder abduction and external rotation resulting from end range of motion or pain often is considered diagnostic of capsulitis, making it difficult to assess the relative contribution of spastic or shortened shoulder muscles in many published studies.

Keeping in mind the potential contribution of spastic shoulder muscles, the diagnosis of capsulitis can, in most cases, be made by physical exam alone. Contrast-enhanced magnetic resonance imaging is a noninvasive method for diagnosis of capsulitis, with findings of increased thickness and enhancement of the joint capsule and synovial membrane in the axillary recess and rotator interval (104,108). Occasionally, intra-articular injection of an anesthetic agent can corroborate the diagnosis or help to evaluate the relative contribution to shoulder pain when multiple diagnoses are suspected. Usually, there is already a high index of suspicion, and the diagnostic injection is combined with therapeutic steroids. Arthrography can also be diagnostic but usually is not warranted. Typical findings on arthrography include a scalloped appearance of the joint space border or a capsule that accommodates significantly less than the expected 12 mL of contrast. Contrast seen in the subacromial bursa after intra-articular injection typically indicates a rotator cuff tear.

Generally, idiopathic capsulitis tends to resolve over 15 to 20 months and treatments do not offer different long-term endpoints compared to no treatment. However, treatments may offer relief sooner than watchful waiting, thus decreasing the time patients spend in pain and with limitations in shoulder range (112). Treatment of capsulitis is comprised of restoration of range of motion and reduction of inflammation. If spasticity or shortening of shoulder muscles contributes to pain, limits function, or predisposes to recurrent capsulitis, additional measures may be indicated. When possible, management of inflammation, spasticity, and pain should be performed concurrently with restoration of motion. Range-of-motion restoration often is done under the supervision of a therapist with close communication between therapist and physician, although the results of physical therapeutic interventions are mixed (113,114). If range of motion does not improve as expected, underlying biomechanical barriers, such as spasticity, or medical barriers, such as pain, may have to be addressed. Care should be taken to avoid impingement problems caused by excessive shoulder abduction without concomitant shoulder external rotation and scapular rotation. As mentioned previously, swathe-type slings that hold the shoulder in adduction and internal rotation should be avoided. Caregiver training and home supervision are important in most cases because stroke survivors with hemiplegia often have some degree of neglect that may require cues for performing the appropriate range-of-motion exercises; there is also a need to promote attention to upper-limb positioning in bed. Caregivers often are able to assist with range-of-motion exercises that patients have difficulty performing independently. Caregiver involvement becomes more critical in the setting of more pronounced unilateral neglect or cognitive impairment.

More aggressive interventions should be considered in patients for whom pain or range of motion is limiting recovery or ability to function, though the evidence is mixed. One study of a series of three intra-articular corticosteroid injections over three weeks in subjects with shoulder pain and restricted range of motion after stroke found a reduction in pain without a significant change in range of motion (115), whereas a randomized controlled trial of three intra-articular injections did not find a significant difference compared to placebo in pain, range of motion, or function (116). In a randomized trial in nonstroke subjects, a single injection of intra-articular corticosteroid provided faster relief of pain and an improvement in range of motion as compared to placebo (117). Another randomized trial in nonstroke subjects found equal improvement among different locations of the corticosteroid injection (subacromial, glenohumeral, or combined), and faster pain relief and improvement in range of motion compared to oral medications, although there was no difference in range of motion or function at 24 weeks (118). Although arthroscopic release

and manipulation under anesthesia have been described in adhesive capsulitis in the nonstroke population, it is not clear that these treatments offer any better long-term outcomes than corticosteroid injection; in fact, they possibly offer a slower recovery (119). Additionally, manipulation under anesthesia is less appealing because of the small risk of humeral fracture, dislocation, rotator cuff injury, labral tears, and brachial plexus injury (120).

Impingement Syndrome and Rotator Cuff Injury

Impingement syndrome refers to injury to the supraspinatus muscle or tendon resulting from repetitive compression between the inferior border of the acromion and the greater tuberosity of the humerus. The greater tuberosity of the humerus rotates under the acromion with internal shoulder rotation, diminishing space for the supraspinatus muscle and tendon during shoulder abduction. Repetitive compression of the supraspinatus muscle occurs when the shoulder is abducted more than 90 degrees without concomitant shoulder external rotation. Though not adequately studied, biomechanical changes after stroke such as laxity of passive restraints because of subluxation, weakness of muscles that stabilize the joint, abnormal muscle tone, and motor recovery in a proximal-to-distal gradient may place stroke survivors at greater risk for impingement syndrome. Inflammation of the supraspinatus muscle and tendon, and the surrounding subacromial bursa, are common sequelae. Though rotator cuff injury can occur because of trauma and may include any of the four rotator cuff muscles, after stroke, rotator cuff injury is more common from injury to the supraspinatus muscle or tendon that occurs as a result of impingement that has not been adequately addressed (33,72).

The roles of impingement syndrome and rotator cuff injury have not been studied rigorously as a cause of shoulder pain after stroke. In some circles their contribution to poststroke shoulder pain is well accepted, though in others it remains controversial. In one cross-sectional study, half of 28 subjects with chronic hemiplegia and functionally limiting shoulder pain experienced pain reduction after injecting lidocaine near the subacromial region of the affected shoulder (72). A similar proportion also was shown to have signs of supraspinatus tendinopathy and impingement syndrome in a different cross-sectional study of patients in acute rehabilitation with shoulder pain (37). Although the prevalence rates of rotator cuff tears and tendinopathies have been found to be high in those with shoulder pain after stroke, it also has been noted that the presence of tears and tendiopathies is not related to the severity of pain (121). These results indirectly suggest that impingement syndrome, supraspinatus tendonitis, or subacromial bursitis are common causes of pain in hemiplegic stroke survivors. However, recent magnetic resonance imaging studies comparing those with shoulder pain to a pain-free group found no differences in the prevalence of rotator cuff pathology or subacromial bursitis (102,103). Studies in which the painful hemiplegic shoulder is compared to the contralateral shoulder by arthrography have produced mixed results on the prevalence of rotator cuff tears (33,109). It is likely that impingement syndrome and rotator cuff injuries are common in those with stroke because they are common in the general population and have a higher incidence with increasing age (122,123). Unfortunately, the high prevalence of rotator cuff pathology in patients without shoulder pain increases the risk of misdiagnosis in those with shoulder pain after stroke (123).

Prevention is the critical component of impingement syndrome management, and includes measures to prevent the syndrome from occurring as well as preventing further injury once it exists. Shoulder flexion or abduction, whether during passive or active exercise, always should be accompanied by external rotation. Altered biomechanics of the shoulder in hemiplegia resulting in displacement of the arc of the humeral head and tubercle may predispose the shoulder to impingement (124). Overhead passive range-of-motion exercises with shoulder internal rotation and the use of overhead pulleys that promote similar movement have been implicated as causes of impingement syndrome (33). Wheelchair arm supports also have been implicated (84). Care also should be taken to ensure that inadequate trunk control does not result in weight bearing through the elbow to the glenohumeral joint, particularly when it causes shoulder pain or occurs in the presence of hemisensory loss, unilateral neglect, or severe cognitive impairment. Ultimately, as in able-bodied patients, treatment should attempt to enhance shoulder posture, particularly in retraction and elevation, and restore active restraints by strengthening the external and internal rotators of the shoulder. However, an adequate strengthening regimen may not be possible because of severity of hemiparesis. A subacromial steroid injection also can be considered, particularly if shoulder pain is interfering with therapy or recovery, as it has been shown to improve pain, disability, and active range of motion for those with a painful shoulder after stroke and rotator cuff disorder (125).

Complex Regional Pain Syndrome

Much of the literature discussing CRPS after stroke predates the introduction of more accurate nomenclature, and thus refers to reflex sympathetic dystrophy (RSD) or shoulder hand syndrome. Generally, CRPS after stroke refers to type I (CRPS I) because it follows central nervous system injury rather than damage to a peripheral nerve (126). However, as discussed later in this section, root-level injury or peripheral nerve injury may result from traction to neural tissue from persistent shoulder subluxation or possibly compression of nerve between bones. Thus, it is possible that type II (CRPS II), which occurs after a peripheral nerve injury, may also occur, although there are no reports in the literature.

The reported prevalence of CRPS I in hemiplegia ranges from 12.5% (127) to 70% (128). The variability in reported prevalence of CRPS I may result from differences in the diagnostic criteria used. It also has been suggested that the incidence likely is lower than previous estimates that were made prior to

the routine treatment in rehabilitation facilities (129). Tepperman documented increased radionuclide uptake in the wrist, metacarpophalangeal (MCP), or interphalangeal joints of the hemiplegic upper limb on delayed images using scintigraphy in 25% of 85 hemiplegic subjects. The incidence of shoulder pain in these subjects was not reported. In their study group, the authors reported 100% sensitivity and specificity for MCP tenderness relative to their scintigraphic diagnostic criteria for CRPS I (130). VanOuwenaller found that 50 (23%) of 157 hemiplegic subjects with shoulder pain had clinical findings of CRPS I. The majority of these subjects had radiographic evidence of shoulder subluxation (92%) or spasticity (94%), suggesting that these may have played a role in the pathogenesis of CRPS I (46). Other studies of stroke cohorts over time also correlate early subluxation with the development of CRPS, suggesting traction injury to vaso nervorum as a possible etiology (46,75). It also is possible that shoulder subluxation and CRPS I are related coincidentally rather than causally. One prospective study evaluating the prognostic factors associated with CRPS I found that motor impairment, rather than subluxation, was clinically predictive, which also would explain the association between subluxation and CRPS I (131). Two reviews found that trauma related to altered shoulder biomechanics likely was the causative etiological factor (132,133). The pathophysiology of CRPS I remains a mystery, although multiple theories exist (134).

The diagnosis of CRPS I after stroke is made clinically. There have been attempts to standardize the diagnostic criteria for CRPS I to improve clinical care for patients and to improve comparability of scientific studies. The most recent iteration of diagnostic criteria from the 2004 Budapest International Association for the Study of Pain (IASP) consensus group set forth both clinical and research diagnostic criteria (see Tables 30.1 and 30.2) (135). Triple-phase bone scan has been recommended as a diagnostic tool (129,136–138). However, the sensitivity and specificity of triple-phase bone scanning has caused its utility as a diagnostic tool to be doubted (139). The typical presentation includes pain and limited range of motion at the shoulder, wrist, and hand, but not at the elbow. These findings often are accompanied by edema, warmth, and redness primarily involving the wrist and hand. Three subtypes have been identified within CRPS I: (a) a relatively limited syndrome predominated by vasomotor signs, (b) a relatively limited syndrome predominated by neuropathic pain or sensory abnormalities, and (c) a florid CRPS syndrome of high levels of motor or trophic signs and possible disuse-related changes (140). Interventions specific to each subgroup have not yet been identified.

Although no definitive treatments for CRPS I exist, goals of treatment include edema reduction, pain control, maintenance of range of motion, maintenance or increase in muscle strength, and restoration of function (139,141). Approaches to treatments often are empirical and based on presenting symptoms. Oral steroids appear to have the highest level of evidence. Other treatment options include sympathetic blocks; membrane stabilizers; edema control, mobilization, strengthening, and physical modalities; motor imagery and mirror therapy; and psychological and behavioral interventions (134). The specifics of these studies are beyond the scope of this chapter, and additional literature review is recommended if these treatments are pursued.

Brachial Plexopathy and Axillary Nerve Injury

Brachial plexus injury and other peripheral nerve injuries as causes of shoulder pain after stroke are controversial primarily because of the lack of a diagnostic gold standard. Although electromyography (EMG) is considered the diagnostic gold standard for brachial plexus injuries, electrodiagnosis of brachial plexopathy in hemiplegia is confounded

TABLE 30.1 Clinical Diagnostic Criteria for Complex Regional Pain Syndrome

1. Continuing pain that is disproportionate to any inciting event
2. Must report at least one symptom in *three of the four* following categories
   Sensory: Reports of hyperalgesia and/or allodynia
   Vasomotor: Reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry
   Sudomotor or edema: Reports of edema and/or sweating changes and/or sweating asymmetry
   Motor or trophic: Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
3. Must display at least one sign[a] at time of evaluation in *two or more* of the following categories
   Sensory: Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement)
   Vasomotor: Evidence of temperature asymmetry and/or skin color changes and/or asymmetry
   Sudomotor or edema: Evidence of edema and/or sweating changes and/or sweating asymmetry
   Motor or trophic: Evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)
4. There is no other diagnosis that better explains the signs and symptoms

[a]A sign is counted only if it is observed at the time of diagnosis.

by loss of motor units that result from loss of descending input from upper motor neurons after central nervous system injury (142). Further, proximal nerve conduction studies lack reliability because volume-conducted potentials from nontarget muscles affect recorded potentials from target muscles. The studies using advanced imaging techniques to evaluate nerve injury have yet to be reported.

Prolonged nerve conduction latencies in the proximal upper limb of hemiplegic subjects have been reported by several investigators (73,74,143). Interpretations of these findings differ based on the diagnostic criteria used. Chino et al. documented significantly delayed latencies of the suprascapular, axillary, musculocutaneous, and radial nerves compared with published normative values and evidence of denervation on needle EMG in 21 hemiplegic subjects with shoulder subluxation. They postulated that shoulder subluxation may lead to traction injury to the brachial plexus (73). Kingery et al. documented delayed mean central latencies across the brachial plexus and spontaneous activity during needle EMG in hemiplegic subjects when compared with the unaffected limb. Subjects also had to meet strict physical examination criteria for brachial plexus injury. Although the findings in both studies were similar, in contrast to Chino, Kingery interpreted his results to reflect loss of motor units secondary to cortical injury rather than injury to the brachial plexus (143).

Based on available data, brachial plexopathy or peripheral nerve injury should be considered in the diagnosis of hemiplegic shoulder pain when (a) a mechanism for brachial plexus injury exists or (b) muscle tone, reflex changes, weakness, or sensory loss are not consistent with a CNS lesion, especially in the setting of pronounced shoulder subluxation. Because shoulder subluxation has been postulated as the cause of nerve injury, measures to prevent and reduce shoulder subluxation are warranted.

Bicipital Tendonitis

Bicipital tendonitis has not been well described in the stroke literature. However, it bears inclusion in the differential diagnosis of hemiplegic shoulder pain. The prevalence in those with shoulder pain after stroke has been estimated at 54% (37). Bicipital tendonitis should be suspected particularly in hemiplegic patients with spasticity or movement synergies that result in overactivation of the biceps as elbow flexors or forearm supinators.

The diagnosis is suggested when there is greater tenderness to palpation of the long head of the biceps as it originates from the anterior glenoid labrum on the affected side compared to the unaffected side (144). Provocative maneuvers such as Yergason's test, which provokes pain at the biceps origin with resisted forearm supination, are useful when cognition and motor abilities are adequate. An examination under ultrasound may improve diagnostic ability, though sensitivity is only 49% (145). Injection of an anesthetic agent at the point that is most painful over the bicipital groove, often combined with a therapeutic steroid, can corroborate the diagnosis and provide treatment (146). As with all paratendon injections, care must be taken to avoid injecting steroid directly into the tendon because of the risk of rupture. Long-term benefit usually requires alleviation of the underlying biomechanical stresses through use of spasmolytic medications, botulinum toxin, chemical neurolysis, or (rarely) tendon release, depending on the clinical scenario.

Central Hypersensitivity

A more recent theory as to why there may be persistent pain in the shoulder of some stroke survivors is based on evidence implicating alteration in pain perception because of peripheral and central hypersensitivity (43,48,147). It is possible

that an injury at the paretic shoulder, whether from a fall, poor handling by caregivers, or repetitive microtrauma, results in an initial injury and acute pain, but maladaptive changes from central hypersensitivity may allow the pain to persist or worsen beyond the initial injury, even after the initial injury has healed (43,48,147). Central hypersensitivity is a change in the central nervous system that results in an enhancement in the function of neurons and circuits in nociceptive pathways. The manifestation of this plasticity of the somatosensory nervous system in response to inflammation and neural injury can lead to pain from innocuous stimulation or exaggerated perception of pain from low-level painful stimuli (148). One of the primary methods of demonstrating central hypersensitivity is through generalized hyperalgesia or a higher sensitivity to pain at unaffected tissues remote to the site of injury (149). In one study of stroke survivors with chronic shoulder pain compared to pain-free stroke survivors, a higher sensitivity to pain was found not only at the hemiparetic shoulder but also at the nonhemiparetic shoulder and leg, suggesting that a central process may affect the perception of pain over the whole body of those with chronic shoulder pain (47). Further evidence of a central hypersensitivity was shown in a comparison of somatosensory functioning between those with chronic shoulder pain after stroke, pain-free stroke survivors, and a healthy population in which greater allodynia to cold and sharpness were found when comparing ratios of affected to unaffected arms of those with hypersensitivity and pain-free stroke survivors (43,48).

Evidence of central hypersensitivity in those with shoulder pain after stroke suggests that new targets for treatment should be explored. Rather than attempting to design treatments addressing a painful response to a noxious stimulus, greater success might be achieved through addressing changes within the nervous system that result from central hypersensitivity. Electrical stimulation has been suggested as a neuromodulatory treatment for chronic shoulder pain after stroke, but no trials have confirmed the efficacy of this (95,100).

Spasticity

The principles of assessment and management of spasticity following stroke are presented in Chapter 29. The association between spasticity and hemiplegic shoulder pain has been recognized for some time (46). However, whether spasticity actually causes shoulder pain is uncertain. As noted earlier, spasticity can coexist with adhesive capsulitis, impingement syndrome, rotator cuff disease, bicipital tendonitis, and CRPS. Associated deleterious biomechanical effects on the glenohumeral joint may contribute to the pathogenesis of these conditions. Some also have postulated that spasticity, especially of the subscapularis and other internal rotators of the shoulder, directly causes pain by traction on the periosteum of the muscle insertion (150). Examination typically demonstrates hypertonia of the shoulder adductors, flexors, and internal rotators. Treatment intervention may include stretching, strengthening of antagonist muscles, and oral spasmolytics (151). However, there are no controlled trials to demonstrate the efficacy of these interventions in reducing hemiplegic shoulder pain.

Given the prominence of hypertonia of the shoulder internal rotators, adductors, and flexors, botulinum toxin injections to these muscles have received considerable attention. Yelnik and associates demonstrated the initial feasibility of botulinum toxin injection to the subscapularis in reducing hemiplegic shoulder pain (152). However, subsequent randomized clinical trials of botulinum toxin injections to subscapularis, pectoralis, and biceps muscles have yielded inconsistent results. Although some showed significant benefit (153–155), others did not (156–158). Quantitative reviews have also yielded inconsistent conclusions (159,160). Botulinum toxin injections may be beneficial for a select group of stroke patients with shoulder pain and hypertonia. However, because of the inconsistency in the literature, specific recommendations must await additional data from larger, well-defined clinical trials.

Contractures

As with all upper motor neuron syndromes, contractures are common complications after stroke. Spasticity, paralysis, and muscle imbalance can result in joint immobilization and fixed positioning of limbs. Prolonged joint immobilization results in collagen deposition and organization of fibrous structures in surrounding soft tissues, affecting muscle belly rather than tendon (161,162). Stiffness and loss of elasticity occur with associated shortening of soft tissues. Changes in the joint also take place. Animal and human studies have shown proliferation of intra-articular fibrofatty connective tissue, and adhesion formation between the fibrofatty connective tissue and cartilaginous surfaces also takes place after immobilization (163). The fibrous connective tissue capsule surrounding synovial joints undergoes compositional change that further affects biomechanics (163). The primary effect of these changes is an increase in resistance to stretch that is independent of muscle activity (164). A number of deleterious effects can result, including loss of functional movement, pain, interference with hygiene, and development of pressure sores (165). In general, the clinical goal is prevention of permanent muscle shortening or contracture, and is typically approached with passive and active range-of-motion work and treatment of spasticity. In some cases, reversal of contracture can be accomplished with surgical or nonsurgical interventions, but restoration of movement and function often is challenging and incomplete. As with all rehabilitation interventions, management must be considered within the context of functional restoration for the individual patient. It has been estimated that about half of stroke survivors will develop a contracture within six months, with the most commonly affected joints being the shoulder and hip (166). However, after stroke, contractures can involve any joint affected by spastic paralysis.

Prevention of contractures requires prompt initiation of daily management beginning 24 to 48 hours after stroke

onset. Spasticity evolves in the majority of hemiplegic patients within one week of stroke onset (55). Assessment of joint range also should be performed daily so that more aggressive treatment can be initiated if range of motion declines. Passive range-of-motion exercises, splinting, and positioning are the mainstays of contracture prevention. After stroke, voluntary and involuntary muscle activations generally are split into extensor or flexor synergy patterns. Preventative measures must consider these muscle synergies in assessing contracture risk for a given joint, and efforts should be apportioned according to risk. Joints should be moved through their complete range at least daily, and ideally several times daily. Adherence to a consistent regimen of aggressive stretching is thought to prevent contractures after stroke (167,168), although this is not supported in the literature (169,170). If pain occurs during passive range-of-motion exercise, analgesic medications should be given to minimize pain during exercise.

When impairment in range of motion occurs in the setting of associated spasticity, spasmolytic medications should be considered. The use of oral spasmolytics is common, but their effectiveness is limited by several factors. First, titration to the optimal dose can take time. Second, sedative side effects can limit use, particularly in the acute phase after stroke and in elderly patients. Temporary chemodenervation with short-acting local anesthetic agents has been advocated to facilitate passive range-of-motion exercises (171), but the need for repeated injections or multiple injections when several muscle groups require reduction of tone can be impractical. Focal chemodenervation using injected botulinum toxin may be a more practical approach. However, the potential effects of weakening voluntary muscle on motor recovery should be considered carefully. The major advantages of botulinum toxin are that individual muscles can be targeted, the effect lasts for about three months, and sensory innervation is not affected. The use of botulinum toxin has a significant role in promoting functional movement in the upper limb (see Chapter 29) and in preventing contractures and their sequelae in the upper limb. However, permanent neurolysis using phenol should be considered only after motor recovery has reached a plateau, when there is a very high level of confidence that paralyzing the muscle(s) will not have any negative consequences on functional movement at that time or in the future and that effects on sensation will not reduce function or increase the risk of pressure sores. That said, permanent neurolysis can be effective in improving hygiene, reducing the risk of pressure sores, and improving functional movement. Muscle groups innervated by a single nerve, such as the hip adductor group innervated by the obturator nerve, are particularly amenable to neurolysis. Obturator neurolysis most often is performed to improve perineal hygiene or to reduce pressure sores at the medial knee, but have also been used to improve gait by reducing scissoring. When innervation of target muscles cannot be isolated to a single nerve, or when the sensory component of the nerve should not be sacrificed, motor point blocks can be considered.

Splinting is commonly considered in joints that are at high risk for contracture or when passive range-of-motion exercises are insufficient to maintain range (172). Contractures of wrist and finger flexion and ankle plantar flexion are common. Thus, preventative splinting of these joints in neutral position has been recommended when abnormal muscle tone or movement synergies put them at risk. In spite of frequent use, a systematic review of upper-limb splinting after stroke and other brain injuries found that the use of splinting does not affect upper-limb disability, range of motion of the wrist or thumb, or pain (173). A randomized controlled trial of nighttime ankle splinting compared to the use of standing at a tilt-table for 30 minutes per day early in stroke rehabilitation also failed to show a difference in the splinted group and tilt-table group in contracture prevention (174). These findings call into question the current practice of splinting, yet technological advances and the shift in focus to considering function and activities in the design, prescription, and evaluation of splints in the context of rehabilitation programs may offer benefits in the future (175). One randomized pilot trial found that the combination of botulinum toxin injection and splinting might reduce contracture formation and facilitate maintenance of range of motion (176).

Surgery, in general, should be considered only when no further motor recovery is anticipated and after other less-invasive management options have failed. The preoperative objectives should be clear to the clinicians, caregivers, and patients and are broadly directed at improving function or reducing the risk of medical complications. The physiologic objective typically is restoration of muscle balance. Successful outcomes require close attention to rehabilitation management following surgery. Clinical benefits have been reported in nonrandomized clinical trials in stroke survivors for a number of procedures, including release or lengthening of tight adductor tendons for hip adduction contractures (177), selective release or fractional tendon lengthening for knee flexion contractures (167), Achilles tendon lengthening for ankle equinus deformities, split tibialis anterior tendon transfer combined with Achilles tendon lengthening for ankle equinovarus deformities (178), and capsular release plus resection of subscapularis and pectoralis tendons for shoulder capsulitis (179).

Arthralgia

Arthralgia is common in the general population and is the number one comorbidity for stroke survivors (180,181). The association of arthralgia related to stroke is complex. One prospective study identified the acute poststroke phase as a period of increased risk for acute arthritis, primarily associated with the paretic limbs (182). There is evidence for a higher prevalence of joint pain in community-dwelling adults with stroke than those without stroke (183). However, the relationship between arthralgia and pain resulting from the stroke is less clear. An increasing prevalence of new-onset joint pain was described at 3 months (7.4%) and at 6 months after stroke (11.7%) in one cohort study (23). Yet, a matched population

study found no difference in the poststroke development of pain from joints, other than shoulder pain, in stroke patients in 2 years following stroke and reference subjects (22.0% vs. 18.5%, $P = .14$) (20). One possible explanation for the lack of agreement is a variable expression of arthralgia that is influenced by severity of paralysis and age. Ascribing new joint symptoms to a stroke is difficult given the varying nature of joint pains relative to the paretic side. In stroke survivors who have paresis on one side, there is a greater likelihood of having joint pain on the affected side, yet estimates of having joint pain solely on that side limit it to 1.8% (23,183). A radiographic study of hands of paretic subjects and controls found that the severity of paralysis was correlated with the extent of osteoarthritic asymmetry between the paretic and unaffected sides. Interestingly, hemiparalysis reduced ipsilateral expression of osteoarthritis and increased expression of osteoarthritis in the unaffected hand (184). One reason for these findings may be the additional stresses put on the unaffected side by prolonged use of walking aids or the use of upper limbs during transfers (183). Similarly, the unaffected leg may experience more stress because of difficulty in normal foot placement in hemiparetic gait.

It is clear that the comorbid arthralgia has a detrimental effect on stroke survivors, regardless of whether it arises before or after the stroke. Stroke survivors with osteoarthritis have longer lengths of stay and lower functional gains in acute rehabilitation settings than those without osteoarthritis (185). Stroke survivors with comorbid osteoarthritis experience daily pain, frustration, and activity limitations that interfere with participation in prescribed therapies, thereby reducing the potential for recovery (28). Even after the acute period of recovery, arthralgia interferes with daily function, and the cumulative effect of having disability related both to stroke and arthralgias is greater than the sum of either one alone (183). It also appears that the pattern of arthralgia relative to hemiparesis is important. Having arthralgia opposite to a hemiparetic upper limb is much more disabling than having arthralgia in the hemiparetic upper limb. In contrast, having arthralgia in the hemiparetic lower limb is much more disabling than having it in the opposite limb (183). Such findings may be important in consideration of therapeutic plans, although this has not been studied. Providers should evaluate stroke survivors routinely for arthralgias, and provide treatment so that recovery and function can be maximized.

Heterotopic Ossification

HO is a pathological process by which lamellar bone is formed in soft tissues that do not typically ossify. It is often observed after surgery, neurological injury, burns, and trauma (186). The prevalence of HO in stroke is lower than that in spinal cord injury or traumatic brain injury, estimated to be 0.5% to 1.2% (187), and is not as well studied. Although uncommon in stroke, HO is a complication that can interfere with mobility and recovery in addition to the damage caused by the stroke, and should be considered in stroke survivors with unexplained joint immobility and pain (188,189). Early symptoms of HO may be mistaken for deep venous thrombosis, arthritis, cellulitis, or central pain (190–194). Awareness among providers who treat stroke survivors is necessary to allow early identification and the timely initiation of appropriate treatment.

Typical presenting signs and symptoms of HO include pain, skin erythema, fever, swelling around the affected joint, and gradual joint ankylosis (195). The primary complications are loss of function because of loss of joint mobility. Potentially, HO can occur in any soft tissue and around any joint. However, the joints most commonly involved are the hip, knee, and elbow, and the ossification tends to occur 4 to 12 weeks after the injury (186,195).

The etiopathogenesis of HO after neurologic injury is not known. The bone formation does not occur within the muscle, but rather in the para-articular connective tissue between muscle planes (194). It is thought that local inflammation may induce the formation of ectopic bone in those with spinal cord injury (196). The local inflammation causes release of prostaglandins that transform soft tissue mesenchyma into osteoblasts (197). The osteoblasts produce tropocollagen and alkaline phosphatase that are responsible for the formation of the bone matrix, calcium deposition, and mineralization of the bone matrix (197). The mineralized bone matrix has a histological appearance similar to that of the callus formation of healing bone (186). Although the exact mechanism is unclear, other important factors appear to be hypercalcemia, tissue hypoxia, changes in sympathetic nerve activity, immobilization, remobilization, and disequilibrium of parathyroid hormone and calcitonin (195).

Diagnosis of HO begins with identification of the clinical symptoms and signs. Often, because of the overlapping presentation with other complications such as deep venous thrombosis, multiple studies must be obtained to rule out other causes. Laboratory studies are limited in their ability to diagnose HO in the early stages. Alkaline phosphatase may show abnormally high levels in the presence of ectopic bone formation, but is not useful initially, as levels may not become elevated in the first two weeks of active ossification and may not peak until months after (198). If the ossification is limited in scope, alkaline phosphatase levels may not change at all. Nevertheless, the test is inexpensive and easily obtained and often used as a screening tool for HO. The association of prostaglandin production and HO has raised interest in the use of 24-h PGE_2 urinary excretion as a diagnostic tool, as a sudden increase may signify active ossification even before clinical symptoms arise (199). Unfortunately, serial testing is required to detect elevations, and the presence of seminal fluid or urinary tract infection may make interpretation unreliable. The 24-h PGE_2 urinary excretion also may be used to monitor treatment effectiveness, as there is a positive association between the magnitude of PGE_2 elevation and extent of active disease.

The triple-phase bone scintigraphy study is the most sensitive diagnostic imaging study for HO and also can be used to assess maturity of ossification and to monitor therapeutic effectiveness (186,195). The first two phases are indicative of

blood flow and pooling that are consistent with HO in about the second week. The third phase shows abnormality about a week later. Other imaging modalities, such as plain radiography, computed tomography, and magnetic resonance imaging are not as sensitive in detecting the early stages of HO and thus are not used as often for these purposes (186,195). Plain radiographs may not show abnormality until four to six weeks after ossification has been demonstrated on triple-phase bone scintigraphy. There is evidence that ultrasound may be useful for identifying HO earlier than radiographic appearance and with higher specificity than triple-phase bone scintigraphy (200,201). Ultrasound may be the test of choice, given its sensitivity and specificity for the early diagnosis of HO, and its concomitant use for evaluation of deep venous thrombosis.

In subjects with spinal cord injury, early prophylactic treatment with indomethacin 75 mg/day for 3 weeks resulted in a lower incidence of clinical, scintigraphic, or radiographic evidence of HO (25.0%) compared to those on placebo (64.7%) (202). Those receiving indomethacin also had later onset and lower severity of symptoms. Another study of rofecoxib compared to placebo also resulted in lower incidence of HO, but rofecoxib has been withdrawn from the market because of safety risks (203). Because of their deleterious side effects, nonsteroidal anti-inflammatory drugs are not recommended as prophylactic treatment for HO.

The use of bisphosphonates generally has been found to be effective in the treatment of HO in spinal cord injury (204–207). Successful treatment of HO with pharmaceuticals is dependent on the timing of initiation, although no randomized controlled trials have been completed. In a case series, subjects who had scintigraphically diagnosed HO received intravenous etidronate for three days, followed by six months of oral etidronate. In this case series, 78% of subjects who did not develop radiographic evidence of HO at baseline did not progress to radiographic HO. Of those who had both scintigraphically and radiographically evident HO at baseline, only 46% experienced a halting of progression (208). There also is evidence that oral etidronate is as effective as intravenous followed by oral etidronate (206), although the use of intravenous etidronate was associated with a lower severity of swelling.

Surgical excision is indicated in patients who have severe restriction in range of motion, intractable pain, or a risk of nerve or vessel involvement from HO (186,209). Studies in spinal cord and traumatic brain injuries have shown an improvement in range of motion and function following surgery, with those who had greater motor control having better outcomes (210,211). Recent studies have not shown a relationship between the extent and duration of HO, or severity of neurologic injury with recurrence rates (209,212,213). In those with established HO that causes severe functional loss or pain, surgical excision should now be considered sooner rather than later to allow greater chance for recovery.

SUMMARY

Musculoskeletal conditions are common complications in poststroke hemiplegia that have significant impact on functional recovery and quality of life. Mechanical abnormalities that underlie musculoskeletal complications always should be considered and corrected or mitigated when possible. Long-term outcomes often depend upon the degree to which biomechanical abnormalities can be addressed. Treatments that address acute as well as biomechanical issues potentially are most effective. The most common conditions include shoulder pain and contractures that can affect any joint affected by spastic paralysis. Of musculoskeletal complications after stroke, shoulder pain has been by far the most studied. Many types of shoulder pathology have been suggested as causes of shoulder pain in hemiplegia, including shoulder subluxation, capsulitis, tendinitis, rotator cuff injury, bursitis, impingement syndrome, spasticity, CRPS, and central hypersensitivity. Electrical stimulation for treating shoulder pain serves as an example of treatment in which sensory neuromodulation, reduction of subluxation, and promotion of motor recovery are potential benefits.

To allow stroke survivors to reach their full potential of recovery, providers need to be aware of the musculoskeletal complications and provide appropriate and timely treatment. Experienced clinicians recognize that numerous musculoskeletal complications can arise that are not discussed in this chapter or reported in the literature. In these cases, treatment should address acute issues as well as underlying causes.

Depression and Other Neuropsychiatric Complications

Victoria M. Wilkins and George S. Alexopoulos

Stroke ushers in the potential for not only physical and cognitive impairments but also neuropsychiatric syndromes. They may arise immediately after stroke or develop later; they may dissipate, fully remit, or continue for many years. Depending on their nature and severity, stroke-related neuropsychiatric symptoms or syndromes increase suffering, promote disability, interfere with rehabilitation efforts, and cause family disruption. This chapter provides an overview of common and some rare neuropsychiatric syndromes after stroke and summarizes options for their treatment.

POSTSTROKE DEPRESSION

Epidemiology

Depression is the most common psychiatric syndrome after a stroke (1,2). Poststroke depression has been described by medical writers since the fifth century BC and likely even earlier. Poststroke depression received attention approximately 30 years ago with the work of investigators at Johns Hopkins University (3,4). Combined studies of 2178 patients hospitalized for acute stroke documented that 22% had major depression and 17% developed minor depression (5–7). In a sample of 80 patients admitted to an acute hospital unit (i.e., within a week of stroke), major depression occurred in 25% during the acute phase, 31% at 3 months, 16% at 1 year, 19% at 2 years, and 29% at 3 years after stroke (5). Kouwenhoven and colleagues' (8) review of hospitalized and community subjects found that the prevalence of depressive disorders ranges from 11% to 55% and that of depressive symptoms from 5% to 54%. However, precise prevalence rates are difficult to estimate because of a variety of factors, including what setting is used for patient recruitment, how depression is assessed, and who conducts the assessment. The poststroke depression literature often conflates depressive disorder and depressive symptoms (9). Only a few of the studies that used diagnostic criteria reported on the qualifications and training of the individuals making the assessment. Some studies made the diagnosis of major depression in the acute phase of stroke, disregarding the requirement of a two-week syndrome duration of the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5*) (10) and the *International Statistical Classification of Diseases and Related Health Problems*, tenth revision (ICD-10) (8,11). Many studies have focused exclusively on depression after ischemic stroke samples (12). However, the overall prevalence rates of depression are similar in ischemic and hemorrhagic stroke patients (8). Likewise, prevalence rates were similar among patient settings (i.e., hospital, rehabilitation, and outpatient). Other issues that complicate the estimation of prevalence are the exclusion of individuals with severe aphasia, in whom assessment of depression is difficult, as well as the inconsistency in cut-off scores used on depression scales (1).

Diagnosis

The syndrome of depression consists of various physical, cognitive, emotional, and behavioral signs and symptoms. The *DSM-5* syndrome of depression is based on experience derived from psychiatric patients. The *DSM-5* criteria for an episode of major depression consist of nine symptoms: depressed mood, anhedonia, significant weight change, changes in sleep, psychomotor changes, fatigue, feelings of worthlessness or guilt, poor concentration or indecisiveness, and recurrent thoughts of death or suicide (10). At least five of these symptoms must be present for a two-week period, with at least one of the symptoms being depressed mood or anhedonia. Symptoms that do not meet full criteria for major depression are often considered minor depressive disorder (at least two, but less than five symptoms lasting more than two weeks). Robinson and Spalletta (1) advocated for major depressive disorder and minor depression as the two most appropriate ways to classify depressive symptoms following stroke. Beyond categorization of depression, assessment of an individual who has suffered a stroke is further complicated by the physical and cognitive sequelae of the brain lesion. Cohen-Cole and Stoudemire (13) outlined four approaches to the assessment of poststroke depression: inclusive (ruling in depressive symptoms regardless of whether they are related to medical illness), etiologic (ruling in those depressive symptoms that do not stem from

Kessler Psychological Distress Scale-10 (24)

medical illness), substitutive (ruling in only psychological symptoms of depression), and exclusive (ruling in only the symptoms that are seen more in depressed patients than in those who are not depressed). Despite the concerns of stroke-related physical symptoms masquerading as depressive symptoms, the results of studies investigating the various types of depressive symptoms (e.g., somatic, cognitive, psychological) supported use of the inclusive approach for the assessment of poststroke depression and the use of *DSM* criteria without modification (14–17). Finally, a recent study found that some of the most common depression screening tools used (Table 31.1) performed favorably in identifying depression when compared to the structured clinical interview for *DSM-5* in stroke patients without severe aphasia (18). The Stroke Aphasic Depression Questionnaire (Hospital version) is an observational instrument with satisfactory psychometric properties and performance in identifying depression within the aphasic subgroup of stroke survivors (19).

Course of Depressive Disorders After Stroke

The timing of depression onset after stroke varies. It has been suggested that the risk of depression is similar during the early, middle, and late phases of recovery after stroke (2). However, several studies documented greatest risk for developing a depressive syndrome in the first month after stroke, with lower, but persistent, risk during the ensuing year (25–28). Robinson et al. (29) reported that approximately 34% of those who did not develop depression acutely after stroke went on to develop depression within a two-year period.

A high percentage of patients who develop depression soon after stroke improve during the next two years. Improvement of symptoms or remission from depressive disorder has been observed in 50% to 100% of samples (5,29–31), and spontaneous remission is more common in those with depression arising immediately after stroke (32). However, chronicity of depressive symptoms remains high in stroke survivors, especially in those whose symptoms emerged late in the acute phase or had minor depression early on (6,33–35). Findings from longitudinal studies paint a dual picture. Stroke survivors with early and more severe depressive symptoms may fare better as time goes on, whereas survivors with less severe early symptoms or who develop depression later on appear to have worse recovery (1).

RISK FACTORS

Several demographic and clinical characteristics increase the risk for depression after stroke. These include female gender (35–38), younger age (4,37), previous psychiatric illness (35–40), neuroticism (25), family history of psychiatric illness (41), greater disability (42,43), medical comorbidity (36), fatigue (44), and lower education and socioeconomic status (35,37,38). Asian stroke survivors may be at lower risk for poststroke depression than Caucasians (30,45).

There is debate as to whether the location of lesion increases the risk for poststroke depression. One analysis found no difference in the risk for depression for lesions in either hemisphere (9). However, another analysis found increased risk for those with left anterior lesions (7). Shorter distance of the left-hemispheric lesion's anterior perimeter from the frontal pole (46–48) as well as shorter time (i.e., first few months) from stroke are influential factors in the association between lesion location and depression (49,50). Other biological risk factors for depression after stroke include a history of previous stroke (35) and elevated serum leptin levels (51).

Relationship to Functional and Cognitive Impairment

A complex relationship exists between depression, functioning, and cognitive impairment after stroke. Impairment in activities of daily living (ADLs) is the single strongest correlate of depression after stroke (1,7). Specific physical problems are associated with depression after stroke, such as incontinence (42), ambulation (42,52), sleep apnea (53), stomach pain and physical discomfort (54). Depression can negatively impact the neurological recovery process (40,55,56). Depressed patients have greater impairment in ADLs at one-month follow-up than those who are not depressed (57) and less improvement in functional impairment at two-year follow-up, despite equivalent ADL impairment at baseline (58). Depression and functional dependence are associated with poor quality of life, social support, physical functioning, self-esteem, perceived control, and pessimism in stroke patients (59,60). History of depression prior to stroke is associated with increased risk of new stroke (61,62).

In studies including 17,934 stroke patients, depression was consistently associated with cognitive impairment, disability, and stroke severity (55). Patients with poststroke depression are more likely than nondepressed stroke patients to have impairments in executive functioning, problem solving, psychomotor speed, attention, and memory (63). Depression is also correlated with neglect and deficits in visual perception, abstract reasoning, and language (64). Severity of depression is associated with severity of cognitive impairment (65), especially in women who had psychiatric disorders prior to stroke (37). Depression was found to be a predictor of cognitive impairment after stroke (66) mainly in those with left-sided lesions (65,67–69). Aphasia has been linked to depression after stroke, but the evidence is mixed, as many studies on poststroke depression exclude aphasic patients (12). In those

studies that do include patients with aphasia, the prevalence of depression was not significantly influenced by aphasia (8).

Poststroke depression increases mortality. Patients who were depressed during the first month after stroke had greater risk of mortality at one-year follow-up than patients who did not become depressed after stroke (31,42). The mortality risk of patients with poststroke depression remained greater at follow-up assessments of 2 years (42), 8 years (70), and 10 years (71).

Mechanisms

Both biological and psychological explanations for the development and persistence of poststroke depression have been proposed (72). One biological mechanism implicates disruption of ascending norepinephrine fibers and was based on the early observation that stroke of the left frontal pole or left basal ganglia posed the highest risk for depression (48,63,68,73–77). However, the original findings have not been consistently replicated (6,9,49,64). A related biological mechanism postulates decreased production of norepinephrine and serotonin as a result of lesions involving the transmission of biogenic amines in axons projecting through the basal ganglia (78). This view has been supported by studies documenting a reduction of the cerebrospinal fluid serotonin metabolite 5-hydroxy-indoloacetic acid (5-HIAA) in poststroke depression (79,80).

Inflammatory responses may also contribute to poststroke depression. Increased levels of cytokines, including interleukins IL-1, IL-6 (81–85), IL-18 (86), and tumor necrosis factor-alpha (TNF-alpha) (87,88) have been reported after stroke. Heightened inflammatory response activates the enzyme indoleamine 2,3-dioxygenase, leading to decreased serotonin. High levels of leptin may contribute to poststroke depression, either independently or as part of the poststroke inflammatory response (51). Stroke patients homozygous for the short allele of the serotonin transporter 5-HTTLPR are more likely to develop poststroke depression than those with at least one long allele (89). Individuals with short 5-HTTLPR alleles may thus have decreased 5-HT uptake and be more vulnerable to poststroke stress.

Conflicting results related to these biological hypotheses have led others to propose a psychosocial mechanism for poststroke depression (90,91). This hypothesis postulates a link between severity of disability (55,92,93), psychosocial risk factors (35,37,38,94), and poststroke depression. More research is needed to better understand the specific mechanisms of poststroke depression and their potential interplay.

We proposed a conceptual model that integrates biological and psychosocial contributors to poststroke depression (95,96). According to this model, stroke increases vulnerability to depression by compromising frontolimbic circuitry (1) and by initiating inflammatory (72,97) and resculpting (98) brain responses. The "psychosocial storm" to which the stroke patient is exposed magnifies these events by increasing inflammatory responses, producing reactive oxygen species, interfering with dendrite remodeling and neurogenesis, and disrupting functional connectivity (99–113). The "psychosocial storm" originates both from the patient's sudden disability and the resulting change in the patient's needs and family life. The "storm" can be conceptualized as a result of the interaction between the severity of the patient's clinical state and the strengths of the environment in which the patient lives. The patient becomes deskilled by the abrupt loss of strength, coordination, language, executive functions, behavioral disorganization, lack of motivation, fear for his or her life, and hopelessness caused by stroke and poststroke depression, as well as by the tasks of a demanding rehabilitation. These factors, combined with lack of readiness, often lead to a feeling of incompetence and helplessness, which fuel the experience of stress and promote depression (114–116). The family of the stroke survivor experiences a similar upheaval. The usual family goals and tasks are now anachronistic. The family needs to reengineer itself and learn how to meet new demands of the disabled stroke victim. Family members need to assist the patient both with daily routine and by coordinating and facilitating (e.g., driving, waiting) physical, occupational, and speech therapies. Family plays a role even when they do not live with the depressed stroke patient (e.g., coordination of caregivers, finances, relocation). The pessimism and resignation of the poststroke depressed patient often contaminates those expected to help and in turn can immobilize them. Without guidance, even the most committed family members may not be able to be of effective help, and may even become a hindrance. Finally, physical, occupational, and speech therapists need to understand the psychosocial context of the poststroke depressed patient and his or her "ecosystem" and coordinate their interventions (e.g., dose, timing, barriers) so that they are not excessively demanding and disorienting to patients and families. These problems must be addressed early after the onset of stroke because there is a time window in which neural repair is most active and in which interventions can be highly effective (117–120).

Treatment

A recent review by Robinson and Spalletta (1) suggested that antidepressant medications are effective in poststroke depression. In addition to reducing depressive symptoms, antidepressants may reduce mortality (121), motor impairment (122), and disability (123). The effect on disability was independent of the effect of antidepressants on depressive symptoms (124). Use of antidepressants early after stroke was associated with gradual improvement of disability over 2 years, whereas late treatment did not prevent gradual deterioration revealed by 12- and 24-month follow-up (125). However, a Cochrane meta-analysis showed an unclear benefit of antidepressants in poststroke depression (126). Likewise, whereas a study showed that escitalopram may even prevent development of poststroke depression (127), a Cochrane review of 10 medication trials showed unclear benefit for prevention of poststroke depression (128). Moreover,

use of antidepressants may itself increase the risk of ischemic and hemorrhagic stroke (129).

Electroconvulsive therapy has been used clinically to treat poststroke depression, although there are no randomized controlled trials (130,131). Transcranial magnetic stimulation (TMS) decreased depression in stroke survivors with treatment-refractory poststroke depression in a preliminary study with sham control (132). Another preliminary study found improved depression scores in stroke survivors given high-frequency TMS compared to those given low-frequency TMS or sham control (133).

Psychosocial interventions for poststroke depression have received much less attention than pharmacotherapy. A 2008 Cochrane review identified only four randomized controlled trials of psychotherapy (126). One employed pragmatic counseling by a social worker (134), another used cognitive behavioral therapy (135), the third used motivational interviewing (136), and the fourth used supportive psychoeducation (137). In three of these studies, the control group was usual care and one (135) used both usual care and attention-control comparison groups.

Although the interventions showed some advantage over the comparison conditions, the effect size was small (126). More recently, a study of a combination of antidepressant (recommendations of sertraline were made, but the patient's own physician chose what to administer) plus a psychosocial/behavioral intervention resulted in higher remission rates than usual care at the end of the intervention and at 12-month follow-up (138). Problem-solving therapy may be more effective than placebo in preventing the development of depression in nondepressed stroke patients, but this effect was not significant in intention-to-treat analysis (127). However, the Cochrane review concluded that there was a significant but small treatment effect for preventing depression based on four psychotherapy interventions (128). Two of the four psychotherapy studies included used problem solving (139,140), one used motivational interviewing (136), and the other involved active management by interventionists of patient psychosocial stressors (141).

A meta-analysis of rehabilitation interventions showed that exercise-based interventions significantly decreased poststroke depression (142). Studies involving cognitive behavioral therapy (143) and family involvement (144) in the treatment of poststroke depression are underway. Other approaches include motivational interviewing, grief resolution, selective optimization with compensation, cognitive deficits adaptations, and executive skills training to augment traditional cognitive behavioral therapy (145).

Alexopoulos and colleagues (95) recently developed an "ecosystem focused therapy" that targets the psychosocial storm originating from the patient's disability, the resulting changes in the patient's needs and family life, and the biological burden involved in this cascade of depressogenic events (Figure 31.1). This individually tailored,

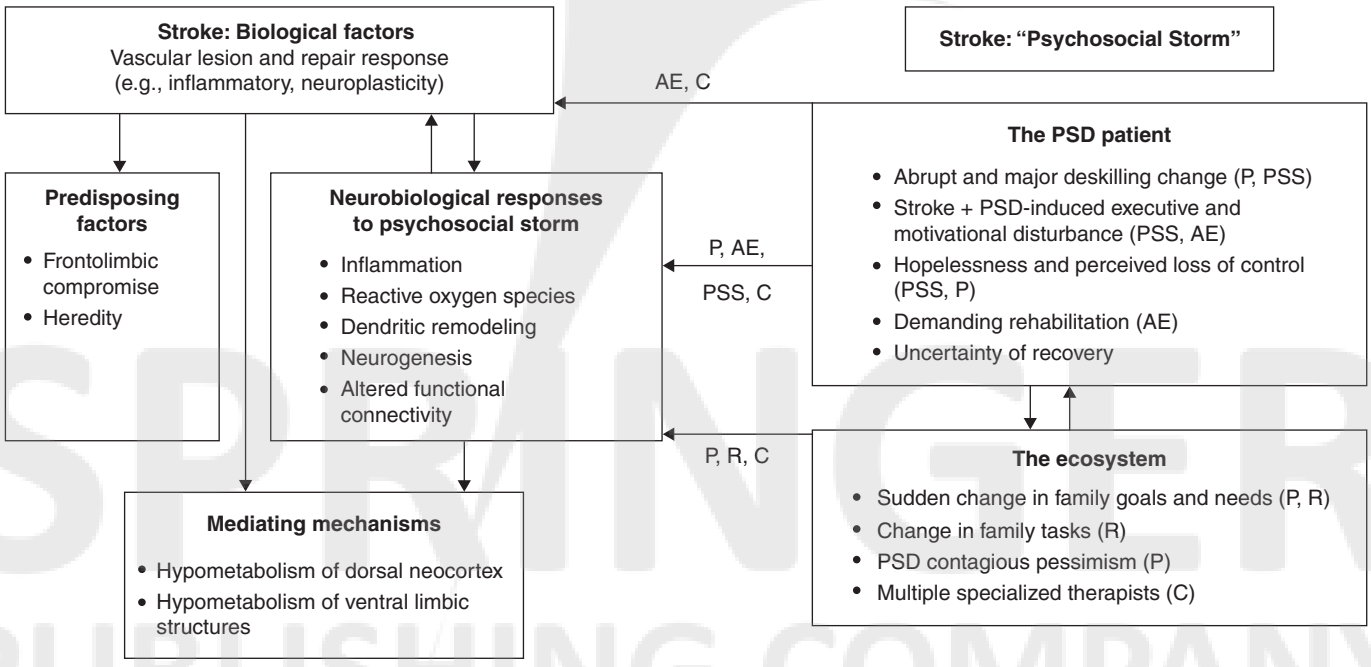

FIGURE 31.1 Integrative model of poststroke depression.

comprehensive psychotherapeutic approach focuses on development of a new and adaptive perspective of functioning; rehabilitation adherence enhancement; problem solving for behavioral activation; adjustment of family goals, involvement, and plans; and coordination of care with specialized therapists (95). A preliminary study of ecosystem-focused therapy yielded encouraging results (95), and a randomized controlled trial is under way.

POSTSTROKE APATHY

Definition and Epidemiology

Apathy has been defined in varied ways over the centuries, beginning with the Greek philosophic understanding of being free from passions or excessive emotions. In modern times, current diagnostic systems do not include apathy as a separate syndrome, nor is it defined (ICD; *DSM*). The major feature of apathy is "loss of motivation not attributable to emotional distress, intellectual impairment, or diminished level of consciousness" (146), which in turn affects emotional, cognitive, and behavioral functions. Accordingly, there is reduction in goal-directed cognition (e.g., reduced interest in learning and experiencing new things, unconcern with personal problems), goal-directed behavior (e.g., reduced effort, energy, and independence in performing daily activities), and related emotion (e.g., reduced responsiveness to desirable or undesirable events) (147). A European task force elaborated upon these criteria and formally proposed their use (148) (Table 31.2). Although apathy is often part of a depressive illness, apathy can be a stand-alone syndrome and, after stroke, may occur either together with depression or independently (149,150). Apathy is also differentiated from abulia, akinesia, akinetic mutism, dementia, delirium, despair, and demoralization (151). Assessment tools used to measure apathy are the Apathy Evaluation Scale (152), six subset items from the Williams Brain Impairment Behavior Scale (153,154), and the apathy subscale of the Neuropsychiatric Inventory (155). The prevalence of poststroke apathy has been estimated to range between 19% and 55% (156) and, when narrow definitions are used, between 20% and 25% (157).

Clinical Outcome and Correlates

Poststroke apathy is associated with advanced age (158–160), medical comorbidity (156), functional dependency (156,158, 161), and cognitive impairment (156,158–160). Poorer performance in attention and speed of information processing tasks is often accompanied by apathy (158). Lesions located in the posterior limb of the internal capsule (160) and bilateral basal ganglia have been associated with apathy (162), but disagreement exists (158,163). One study indicated a trend for right-sided and right fronto-subcortical circuit hyperintensity scores to be elevated (158).

The onset and course of apathy after stroke vary. Stroke patients were 3 times as likely to develop apathy 6 months and 12 months after stroke as they were at 2 months after stroke (163). Apathy and depression, initially independent at 3 months after stroke, became increasingly comorbid at 15-month follow-up (164). This same study found that dementia at initial assessment after stroke was often followed by development of apathy and depression. Poststroke apathy is a predictor of poor recovery from stroke. Patients with higher apathy had less functional improvement after three months of rehabilitation (159). Mayo and colleagues (156) identified five distinct trajectories of apathy in stroke survivors measured at four time points over the course of a

TABLE 31.2 Proposed Diagnostic Criteria for Apathy in Neuropsychiatric Disorders

For a diagnosis of apathy, the patient should meet criteria A, B, C, and D

A: Loss of or diminished motivation in comparison to the patient's previous level of functioning, not consistent with age or culture. These changes in motivation may be reported by the patient or observed by others.

B: Presence of at least one symptom in at least two of the three following domains for a period of at least four weeks and present most of the time:
- **Domain B1:** Loss of, or diminished, goal-directed behavior as evidenced by at least one of the following:
  - –Loss of self-initiated behavior
  - –Loss of environment-stimulated behavior
- **Domain B2:** Loss of, or diminished, goal-directed cognitive activity as evidenced by at least one of the following:
  - –Loss of spontaneous ideas and curiosity for routine and new events
  - –Loss of environment-stimulated ideas and curiosity for routine and new events
- **Domain B3:** Loss of, or diminished, emotion as evidenced by at least one of the following:
  - –Loss of spontaneous emotion, observed or self-reported
  - –Loss of emotional responsiveness to positive or negative stimuli or events

C: These symptoms (A–B) cause clinically significant impairment in personal, social, occupational, or other important areas of functioning.

D: The symptoms (A–B) are not exclusively explained by or the result of physical disabilities, motor disabilities, diminished level of consciousness, or direct physiological effects of a substance.

Source: Adapted from Ref. (148). Robert P, Onyike CU, Leentjens AFG, et al. Proposed diagnostic criteria for apathy in Alzheimer's disease and other neuropsychiatric disorders. *Eur Psychiatry*. 2009;24:98–104.

year. Whereas half of the sample experienced consistently low apathy and 33% experienced consistent minor levels of apathy, 3% suffered from high apathy throughout the study whereas 7% had worsening apathy and an additional 7% had an improving apathy trajectory. Greater apathy, regardless of trajectory, was associated with poorer physical function, physical health, participation in treatment, and health perception (156).

Mechanisms and Treatment

Lesion location influences the comorbidity of apathy and depression after stroke. Patients with right hemisphere stroke had similar levels of apathy and depression, but apathy and depression scores were not correlated. Low apathy and high depression scores were reported in left hemisphere stroke (165). No correlation was found between apathy and depression in a study of patients with five neurodegenerative disorders using the Neuropsychiatric Inventory, whose depression subscale does not include apathy items (166). In stroke and traumatic brain injury, right-sided lesions led to greater apathy than left-sided lesions (167). Overall, an average of 61% of patients with focal frontal lobe lesions had apathy, whereas apathy was identified in 40% of patients with basal ganglia lesions (168–170). Among those with subcortical lesions, damage of the caudate nucleus, globus pallidus, and mediodorsal thalamic nuclei were most frequently associated with apathy. Taken together, these studies suggest that the anterior cingulate cortex, frontal cortex, and ventral striatum are the locations most likely to lead to poststroke apathy.

Few studies have been conducted on the treatment of poststroke apathy unrelated to depression. Anecdotal evidence, primarily case reports, suggests that stimulants (171), amantadine (172), selegiline (173), and methylphenidate (174) may be beneficial. A preliminary study suggested that some cholinesterase inhibitors may help behavioral disability and apathy of stroke patients (175). Nefiracetam, an agent acting on GABAergic, cholinergic, and monoaminergic systems, improved apathy in patients with poststroke depression when used at the high dose of 900 mg/day (157,176).

ANOSOGNOSIA FOR HEMIPLEGIA

Definition

Anosognosia was originally defined by Babinski (177) as lack of awareness of a motoric impairment after stroke. Since then, the definition of anosognosia has expanded, and its current definition encompasses lack of awareness of a variety of functions or dysfunctions. Clinical presentations of anosognosia include inability to recognize one's limb as one's own (asomatognosia), thinking that one's limb belongs to another person (somatoparaphrenia), feeling that the affected limb moves on its own (kinesthetic hallucination), feeling that there is a strange, functional limb (phantom supernumerary limb), giving the limb a name (personification), feeling that the limb is odd (strange feelings), indifference toward the limb (anosoadiaphoria), and negative feelings toward the limb (misoplegia) (178). Anosognosia can be implicit or explicit. For example, patients with implicit anosognosia may be able to verbally acknowledge a deficit but act in a way that does not consider the deficit, such as trying to use an affected arm. In explicit anosognosia, patients may insist that nothing is wrong with their affected side but act in accordance with the paralysis, for example, using a one-handed strategy for tasks typically requiring two hands. The severity of anosognosia ranges from mild to severe and may consist of unawareness of all or part of one's deficits (179). There is some overlap between neglect and anosognosia. *Neglect* refers to inattention to contralesional space, whereas *anosognosia* is unawareness of contralesional paralysis (179). Berti and colleagues (180) suggested that the frequent co-occurrence of neglect and anosognosia is due to involvement of common cortical areas.

Epidemiology and Course

The incidence of anosognosia after stroke varies. A meta-analysis documented that anosognosia occurs in 32.3% of stroke patients (181), whereas other reviews found ranges of 8% to 27% (182) and 7% to 77% (183). The wide range in the incidence of anosognosia has been attributed to differences in the definition of anosognosia across studies. Other causes of the wide range of estimates are differences in patient samples, including difference in time of assessment after stroke, severity of stroke, location of stroke, catchment area, and so on (183). Inclusion of mild anosognosia may lead to inflated estimates. Approximately 60% of patients who did not spontaneously report their hemiparesis readily acknowledged it when asked directly about limb strength (184). Moderate and severe anosognosia had an incidence of 10% (184).

Anosognosia declines over time. One study of right hemisphere stroke patients showed that 32% of patients presented anosognosia during the first 3 days after stroke, 18% after 1 week, and 5% after 6 months (185). However, the decline in anosognosia may have been due in part to practice effects resulting from repeated assessments (186). Other studies also showed that remission of anosognosia occurs in the majority of cases within three months after stroke (178).

Patients with proprioceptive loss, visuospatial neglect, disorientation, and hemianopia during the acute phase of stroke are likely to have anosognosia (187). Chronic anosognosia is usually part of a behavioral syndrome including visuospatial neglect, as well as memory and temporospatial orientation deficits.

It remains unclear whether anosognosia is a predictor of functional outcomes after stroke. One study found no association of anosognosia with rehabilitation outcomes (188), whereas others showed that neglect, rather than anosognosia, contributes to worse outcomes (189,190). Nevertheless, anosognosia for left hemiplegia was correlated with worse motor function (189,191). Early, reversible anosognosia (i.e., within three months after stroke) predicted low functional recovery at one-year follow-up (192).

TABLE 31.3 Common Clinical Interview Measures Used in Diagnosing Anosognosia

Anosognosia Questionnaire (178)	General questions assessing anosognosia itself and 8 anosognosic phenomena
Bisiach Scale (196)	4-point response scale; similar questions to the Anosognosia Questionnaire
Anosognosia for Hemiplegia Questionnaire (197)	10 items; 3-point response scale
Structured Awareness Interview (198)	8 items
Berti et al. assessment (199)	Incorporates both implicit and explicit awareness items (rated on 3-point and 10-point response scale, respectively)
Experimental Bimanual Task (200)	Distinguishes implicit awareness; 8 tasks; patient allowed 3 attempts each; 4-point rating scale of each task

Diagnosis

Traditionally, anosognosia is identified through clinical examination. Various instruments have been developed to capture the heterogeneous nature of anosognosia (Table 31.3). There are other assessments, such as the Visual-Analogue Test for Anosognosia for motor deficit (193) and the Patient Competency Rating Scale (194), that use discrepancy scores between patient self-ratings and caregiver ratings. The Awareness Interview (195) incorporates the discrepancy between patient's self-ratings of abilities with neurological and neuropsychological performance measures.

Mechanisms

Various stroke-induced lesions may result in anosognosia. Right-sided lesions have been implicated, including lesions in the somatosensory cortex, motor and premotor cortices (180), insula (180,201), and frontotemporal cortex (202). A meta-analysis showed that the most common regions associated with anosognosia are in the frontoparietal cortex, basal ganglia, and thalamus of the right hemisphere (181). Chronicity of anosognosia has been correlated with severity of damage to right-sided frontoparietal cortical or subcortical areas (203). Nonetheless, bilateral lesions and left-sided cortical and subcortical lesions also can produce anosognosia (202). However, aphasia resulting from left-sided lesions may interfere with the detection of anosognosia. Damage to the insula (particularly its anterior part) and adjacent subcortical structures was associated with anosognosia for hemiplegia immediately after stroke. Additional lesions in the premotor cortex, cingulate gyrus, parietotemporal junction, hippocampus, and amygdala were associated with the persistence of anosognosia for hemiplegia into the subacute phase (185).

Anosognosia may be caused by disturbances in a variety of complex emotional and cognitive processes (183,187,204). Anosognosia may stem from avoidance of emotional focus toward the physical impairment (205) resulting from damage to brain areas governing affective drive or emotional arousal. This breakdown in arousal prevents the identification of and adjustment to a new impairment (206). Impairment in monitoring systems has been proposed as a mechanism for anosognosia, including disruption of sensory feedback systems involving the motor impairment (207), or inactivation of the monitoring system that coordinates intention to move with actual movement (208). However, not all studies have supported these hypotheses (196,209,210). Others argued that anosognosia results from inability of the right hemisphere to monitor and check confabulations and denial emanating from the left hemisphere (211).

However, this explanation cannot account for anosognosia in those with left-sided lesions. Another theory implicates a disturbance in space-for-action representations that limits the spatial input to the motor monitoring system in stroke patients with damage to the parietal lobe (181). The association of anosognosia with advanced age, greater severity of stroke, and presence of dementia prior to stroke suggests that anosognosia is facilitated by impairment in multiple brain systems (190).

Treatment

There is no definitive treatment for anosognosia (179). Guidelines for the clinical assessment and management of anosognosia have been developed and consist of: (a) assessment of the extent of unawareness, type of coping methods, chronicity, and associated neurological and neuropsychological disturbances; (b) establishment of therapeutic alliance with patient and family; (c) development of an individualized rehabilitation plan; (d) assistance with patient development of interest in their own rehabilitation; and (e) continuation of a training program for as long as improvement is possible (212). Techniques for working with anosognosia patients can include video feedback, mirror therapy, and mental rehearsal, in addition to traditional physical and occupational therapies (179,213). A secondary data analysis showed that antidepressants prevented worsening of anosognosia more effectively than placebo (214).

OTHER NEUROPSYCHIATRIC COMPLICATIONS

Anxiety

Anxiety has been studied considerably less than depression in stroke survivors. Often anxiety and depression are comorbid in the immediate months after stroke, with generalized anxiety disorder (GAD) and depression joint prevalence rates of

TABLE 31.4 Results of Aström Study of Generalized Anxiety Disorder (GAD) Comorbidity in Stroke Survivors

		GAD	
	GAD PRESENT (% OF TOTAL SAMPLE)	COMORBID WITH DEPRESSION (% OF TOTAL SAMPLE)	GAD ALONE (% OF TOTAL SAMPLE)
3 months	31%	21%	10%
1 year	24%	14%	11%
2 years	25%	14%	11%
3 years	19%	15%	4%

15% to 27% (215–218), whereas GAD without depression had a prevalence of 6% to 13% (215,217,218). One study found that 5% of men and 19% of women had an anxiety disorder at four months after stroke, with agoraphobia being most common (4% men, 17% women) and the rest developing GAD (219). Anxiety, once developed, tends to persist long after stroke. Using the Hospital Anxiety and Depression Scale in stroke patients 2 to 5 years after stroke, 19% had anxiety symptoms, 11% had depressive symptoms, and 17% had both (220). Aström (215) followed patients for five years using *DSM* criteria and found significant comorbidity of GAD and depression in stroke survivors (Table 31.4). The presence of anxiety disorder can negatively impact the outcome of co-occurring depression and recovery of function after stroke (215,221). Mortality was significantly greater for those with comorbid anxiety and depression at four months than for those with anxiety alone at one year after stroke (219).

In addition to depression, other correlates of anxiety after stroke are poor psychosocial functioning, anterior circulation lesions, history of migraine, and history of insomnia (216). At multiple follow-up times over three years, stroke survivors with GAD had decreased social networks and increased dependence in ADLs compared to those without GAD (215). In the acute phase, anxiety by itself was related to right hemisphere lesions, whereas anxiety comorbid with depression was associated with left cortical lesions (215,218). GAD in particular was associated with posterior lesions, whereas subthreshhold worry was associated with anterior lesions (218). Three years after stroke, comorbid depression and GAD were correlated with cerebral atrophy, as was GAD with subcortical atrophy, compared to those without GAD (215).

A recent Cochrane review identified only two treatment trials for poststroke anxiety and both targeted anxiety comorbid with depression (222). Both trials involved psychopharmacological treatments and neither used a placebo control. One study measured anxiety with the Hamilton Anxiety Scale (HAS) (223) at baseline and at six-week follow-up among three treatment groups: paroxetine alone, paroxetine plus psychotherapy, and "usual care" (224). Both the paroxetine and paroxetine plus psychotherapy groups had significantly reduced mean HAS scores at follow-up compared with the "usual care" group. The second study compared buspirone hydrochloride with "usual care" and showed a significant reduction in HAS scores for the buspirone group at one month follow-up (225). Clearly, there is need for placebo controlled studies of treatment of poststroke anxiety, with or without depression. Psychotherapy studies are also needed regarding poststroke anxiety. Cognitive behavioral interventions theoretically would be well suited to treat anxiety in the poststroke context, and at least one such study is underway (143).

Involuntary Emotional Expression Disorder

Involuntary emotional expression disorder (IEED) occurs in populations with structural brain damage such as stroke, traumatic brain injury, and dementia. Previously known as pseudobulbar affect, IEED involves uncontrollable and excessive laughing and/or crying (226) that may be inappropriate and incongruent with mood (227). Episodes of emotional expression can be quite brief (a few seconds) or last a few minutes (228). Prevalence estimates in stroke survivors range widely between 4.3% (229) and 52% (230). Scales used to assess IEED include the Affective Lability Scale (231), the Pathological Laughing and Crying Scale (232), and the Center for Neurologic Study—Lability Scale (233); differing scales and cut-off scores have contributed to the variability in prevalence estimates (229). The mechanism of IEED is unclear, although one long-standing hypothesis involves the disinhibition of a fasciorespiratory control center in the brainstem, leading to expression of affect that is desynchronized from emotion (234). Another hypothesis implicates the cerebellum in a disconnection of perceived emotion and displayed emotion (235). Patients with frontal or temporal lesions, regardless of hemisphere, more often had IEED than patients with lesions located elsewhere (236). Bilateral lesions of the pons were also associated with IEED (237).

Tricyclic antidepressants and selective serotonin reuptake inhibitors are commonly used to treat IEED (228). In stroke survivors, citalopram (237), nortriptyline (232), fluoxetine (238), and sertraline (238) were more effective than placebo at treating symptoms of IEED. A treatment for IEED recently approved by the FDA is a combination of dextromethorphan 20 mg and quinidine 10 mg, based on studies of individuals with multiple sclerosis and amyotrophic lateral sclerosis (239–241). Dextromethorphan is the pharmacologically active ingredient that acts on the central nervous system, whereas quinidine sulfate is an inhibitor of CYP2D6-dependent oxidative

metabolism of dextromethorphan used to increase the systemic bioavailability of dextromethorphan. Dextromethorphan inhibits glutamate at the NMDA receptor site by acting as a weak, noncompetitive NMDA receptor antagonist and blocking glutamate-mediated calcium influx through the channel. In addition, dextromethorphan is an agonist of the sigma-1 receptor and may indirectly modulate NMDA-induced neuronal activation and inhibit presynaptic release of glutamate.

Mania

Poststroke mania is uncommon. In a recent review of 50 years of literature on poststroke sequelae, mania was noted in only 74 adult stroke survivors (242). Manic symptoms secondary to stroke were described by Krauthammer and Klerman (243) and are similar to those of primary mania; they include euphoric or elevated mood, pressured speech, racing thoughts, grandiosity, and decreased need for sleep (244–248). The emergence of manic symptoms ranged from immediately after stroke to two years after stroke (249). Poststroke mania was more likely to be found in patients with right hemisphere lesion, in male patients, and in those with at least one vascular risk factor (242). Neither personal nor family history of psychiatric disorder was associated with mania after stroke (242). Genetic vulnerability and subcortical atrophy have also been proposed to contribute to poststroke mania (250,251), but disagreement exists (242). Right hemispheric lesions affecting the ventral limbic circuit, especially the orbitofrontal and basotemporal cortices, dorsomedial thalamic nucleus, and head of the caudate nucleus have also been implicated (245,250,252–254).

There are no randomized controlled treatment studies of poststroke mania. Clinical reports suggest that lithium (245,255), clonidine (256), olanzapine (252), and valproic acid (257) can be helpful. Lithium treatment in secondary mania may be limited by adverse effects, and anticonvulsant medications, such as divalproex sodium, may be better tolerated in this population (258).

Psychosis

Poststroke psychosis with hallucinations and delusions is rare. In a study of 1191 stroke survivors followed for 9 years, only 5 patients had psychotic symptoms (259). Patients with psychotic symptoms were more likely to have right frontoparietal lesions and greater subcortical atrophy compared to patients without psychotic symptoms. Delusions after stroke were most common in nursing home residents with right hemisphere strokes (260). Another study reported on 8 patients with right temporo-parieto-occipital stroke who developed new psychotic symptoms up to 11 years following their strokes (261). The majority of these patients experienced seizures around the time of psychotic symptoms and anticonvulsants ameliorated these symptoms. Epilepsy should be ruled out as a cause of poststroke psychotic symptoms (262). Treatment of psychosis after stroke includes both typical and atypical antipsychotic drugs. The latter may be preferred for their tolerability and better side-effect profile, although they themselves potentially increase risk for stroke (263). As noted earlier, anticonvulsants may also be useful (261).

Aggression

Anger and aggressive behavior are seen frequently in stroke survivors. Milder forms of aggression occur in 17% to 35% of stroke patients (264–267); more intense anger and aggression are less common, with prevalence estimates between 5% and 13% (267,268). Anger and aggressive behavior have been associated with greater cognitive impairment in stroke patients (69,260,265,268) and with left hemisphere lesions (260,268). Aggression has been associated with frontal lesions (265,268), specifically in the fronto-lenticulocapsular-pontine base areas (266). Santos and colleagues proposed four potential contributing factors to poststroke anger and aggression: lesion location, reaction to having to cope with stroke, premorbid personality aggressive traits, and reaction to a perceived hostile environment (267). Comorbidity of aggression with depression and anxiety has been noted (265). Implicated in both aggression and depression is a decreased cerebrospinal fluid (CSF) level of the serotonin metabolite 5-HIAA (269,270). This view has led to the use of antidepressants in the treatment of aggression co-occurring with depression. Aggressive patients who were depressed and were randomized to treatment with either nortriptyline or fluoxetine, and whose depression responded to medication, showed improvement in aggression compared to those on placebo or whose depression did not respond to antidepressants (265). Another study of fluoxetine versus placebo found that poststroke anger was significantly improved in those treated with fluoxetine for three months and that improvement was maintained for an additional three months (271). Effective treatments for aggression are crucial for the stroke survivor's rehabilitation (272,273).

CONCLUSION

Neuropsychiatric syndromes are common after stroke. They complicate behavioral management, impair the quality of life for stroke victims and their families, and interfere with rehabilitation. For this reason, the clinical examination of stroke patients should focus on behavioral abnormalities as well as neurological deficits. Although no definitive syndrome-lesion relationships have been identified, characterizing the presentation of poststroke neuropsychiatric syndromes can guide pharmacotherapy and behavioral interventions. In depression, the most common neuropsychiatric syndrome occurring after stroke, antidepressants may reduce depressive symptoms, motor impairment, disability, and even mortality. Similarly, use of serotonin antidepressants may ameliorate poststroke anxiety syndrome. Behavioral interventions offering support, guidance, and coping mechanisms to stroke patients and their families can be of great value both in alleviating depression and anxiety and in increasing participation in rehabilitation.

Fatigue After Stroke

Kathleen Michael

Though implicated as a major disabling symptom in several chronic neurological conditions (1,2), fatigue remains poorly understood in individuals with stroke (3–6). We know little about the characteristics and mechanisms underlying poststroke fatigue, and even less about the effects of fatigue on activity behaviors, social engagement, and function in everyday life (4). For many individuals with stroke, fatigue ranks among their most distressing and function-limiting symptoms (3,6), yet we have seldom evaluated it, nor have we developed effective evidence-based treatments. The frequency, severity, and significance of poststroke fatigue are strongly evident in current scientific literature, signaling a call to action to develop effective medical and rehabilitation interventions to reduce the impact of fatigue on the function, independence, and quality of life of individuals living with stroke.

In this chapter, we describe what is currently known about fatigue after stroke. We develop a working definition and discuss some theories and identify some potential mechanisms that may account for poststroke fatigue. We characterize physiologic and biochemical dimensions, work performance and behavioral components, and symptom–sensory elements. We identify predisposing factors and outline the assessment of fatigue in individuals with stroke, along with proposed management strategies to reduce symptom distress and promote function and well-being. Finally, we suggest research directions to further develop knowledge about the mechanisms and features of poststroke fatigue that may lead to effective rehabilitation interventions to reduce its impact.

FATIGUE AFTER STROKE

Clinical experience and an emerging body of research point to the high prevalence and negative impact of fatigue in the stroke population. A substantial proportion of individuals with stroke report significant and persistent fatigue affecting their daily lives (3,4,6). There are many issues unique to stroke that might account for the pervasiveness of fatigue in this population. First, there is the direct damage to brain tissue, sometimes implicated in disruption of attention and sleep–wake patterns, as well as inducing feelings of generalized fatigue. Second, fatigue may be linked with other consequences of stroke, such as depression (2,6–8), or with other underlying disease states (3,9). Further, alterations of energy expenditure associated with hemiparetic gait also may contribute to fatigue (10), as may inactivity-induced cardiovascular and metabolic deconditioning (11). The association of sleep-disordered breathing and stroke risk is well established (12–14), and the persistence of sleep disturbances after stroke may further contribute to subjective symptoms of fatigue. Deficits associated with stroke may impose limitations on social function and self-efficacy and may contribute to isolation and the subjective experience of fatigue (10).

However, these physical and psychosocial associations with fatigue are inconsistent (4) and do not fully explain the widespread prevalence of fatigue in this population, nor do they clearly map a course of effective management. Understanding how fatigue relates to underlying pathology and impairment, and how it is manifested in functional and behavioral outcomes, may hold the key to preventive and remedial strategies in stroke rehabilitation.

Prevalence

The actual prevalence of poststroke fatigue is thought to range from 23% to 75%, depending on the definition of fatigue and the characteristics of the patients included (15). The frequency of self-reported fatigue is roughly twice as high in individuals with stroke as in matched controls and is not related to time after stroke, stroke severity, or lesion location (4).

Severity

Fatigue is frequent, often severe, and persists for months and even years after stroke (3). Significant numbers of individuals with stroke report that fatigue is either their worst or one of their worst symptoms (3). Ingles and colleagues (4) found that individuals with stroke attributed more functional limitations to their fatigue than did control subjects with fatigue. In one of the few studies to examine fatigue in

large numbers of individuals with stroke (3), self-reported fatigue was identified as an independent predictor for having to move into an institutional setting after stroke. Fatigue was also an independent predictor for being dependent in primary activities of daily living. This suggests that fatigue may reflect a decline in general health status and that fatigue accompanies reductions in functional independence.

Duration

Fatigue is known to persist over time. Stein and colleagues (16) showed that 76% of individuals at 8 months after stroke complained of fatigue. In the chronic phase of stroke, the number of individuals stating that they are "always" or "often" fatigued is consistently reported in the literature to be approximately 40% (4,10). The observation that fatigue persists over time in individuals with stroke further increases the likelihood that fatigue is an important clinical feature of a progressively disabling pattern of inactivity. Patients who continue to experience subjective feelings of fatigue are less likely to be physically active. In studies of patients with neurological conditions other than stroke, evidence was found for a negative relationship between subjective fatigue severity and physical activity (17,18).

Significance

Combined with the motor deficits, cardiovascular and metabolic deconditioning, sleep disorders, and social isolation that often accompany neurological impairment, poststroke fatigue is associated with disruptions in physical, occupational, and social functions. Fatigue may impede full participation in a rehabilitation program and promote and reinforce sedentary behaviors that contribute to learned patterns of disuse. The functional activity necessary to restore and maintain mobility and independence may be negatively affected by fatigue (10). Even though fatigue has been associated with deterioration of activities of daily living in individuals with stroke, the symptom has received relatively little attention.

What Is Fatigue?

The symptom described as fatigue is common to many medical conditions and is recognized to have serious functional and emotional consequences. To define fatigue, one may try to explain what it feels like, what it is caused by, or what it does. Most current definitions describe fatigue's multidimensionality and frequently include a behavioral or work performance decrement, a physical or biochemical dimension, and a subjective or symptom–sensory aspect (19–21).

One definition by Aaronson and colleagues (22) applies to poststroke fatigue particularly well. Fatigue is depicted as "the awareness of a decreased capacity for physical and/or mental activity resulting from an imbalance in the availability, utilization, and/or restoration of resources needed to perform activity" (p. 46). This definition affirms that fatigue occurs when systems are out of balance, and there are insufficient resources because of either excess demand or deficient supply. The definition also makes it clear that fatigue is not the same thing as tiredness, which is remedied by the restoration of resources when the individual rests. Poststroke fatigue is a new life experience that differs from ordinary tiredness and seems to be a significant problem in the stroke survivor's struggle to regain a new normalcy (23).

Stroke imposes serious restrictions on the ability to activate, use, maintain, and restore physiologic and psychosocial resources, thereby promoting the imbalance that is felt as subjective fatigue. For example, the increased energy expenditure of hemiparetic gait results from the inability to activate normal movement patterns. There is disproportionately large use of cardiovascular and metabolic capacity to produce ambulation (24), often compounded by the existence of deconditioning, underlying disease, and changes associated with aging. Because individuals with hemiparetic stroke have very little margin of unexpended reserves, their ability to restore physiologic resources is diminished. Add to this the sleep disturbances associated with stroke, and the balance of demands and reserves is further threatened.

Fatigue is characterized by distress and decreased functional status related to reduced energy and behavioral adaptations to reduce symptom distress. Persons experiencing fatigue might describe it as a sense of weakness, exhaustion, tiredness, lack of pep and energy, and/or low vitality. Other descriptions of fatigue include feeling drained of energy, more susceptible to pain, experiencing helplessness or loss of control, having difficulty with concentration, and irritability. Individuals may use terms such as tired, weak, exhausted, weary, worn-out, heavy, or slow. In whatever way it is described, fatigue is a multicausal, multidimensional sensation that affects sensory, affective, behavioral, and physiologic realms. Indeed, individuals with stroke clearly describe and differentiate their experience between tiredness as an ordinary life event and fatigue as a poststroke life condition (23).

MECHANISMS OF POSTSTROKE FATIGUE

In defining fatigue, much attention has been paid to describing its origins. Sources of fatigue differ from person to person and from time to time. They may include physical causes, such as pain, disease, anemia, inactivity, and other health problems. Fatigue may be associated with depression, overdoing, or trying to compensate for a disability. Erratic sleep and too much stress may contribute to the development of fatigue as well. Environmental surroundings and accessibility issues, such as noise, air quality, stairs and other architectural barriers, weather, and uncomfortable furnishings, may add to fatigue (25).

Out of these observations came the idea that there are specific types of fatigue and that their mechanisms of

development and actions are distinct. Theories materialized in the attempt to organize and explain the complex and elusive nature of fatigue. One theory distinguished physical and psychological fatigues as two separate types (26,27). Another theory attempted to differentiate the fatigue associated with disease from that associated with exertion (28,29). Piper (19) proposed that there were two types of fatigue, acute and chronic, where acute fatigue occurs as a natural and protective response to a single cause, and chronic fatigue comes from multiple, additive, or unknown causes and is deemed abnormal.

Each of these theories characterized fatigue as falling into two discrete categories. As the body of fatigue-related research expanded over the past decade, multidimensional factors became incorporated into the descriptions and measurement of fatigue. Fatigue could no longer be completely and accurately categorized by types. The contributions of physiologic and psychological functioning as well as social and cultural factors had to be acknowledged (22), as did the outcomes of fatigue (30–32) and the interactions of an assortment of variables (33,34).

Physiologic and Biochemical Mechanisms

There are a number of physiologic and biochemical issues associated with stroke that increase the likelihood that fatigue will develop. A neurophysiologic model explains fatigue in terms of central and peripheral nervous system components (35). Strokes create impairments of the central nervous system because of direct damage. For example, impairment of the central component can lead to decreased transmission of messages from brain and spinal cord and exhaustion of brain cells in the hypothalamic region. One study suggests that individuals with caudate infarcts are more likely to develop fatigue than individuals with damage to other areas (36). Post-polio research about fatigue has explored the effects of viral damage to the neurons of the reticular activating system, which may be pertinent to certain types of stroke with damage to these areas. Damage to the reticular activating structures impairs the ability to maintain attention and leads to experiences of diminished concentration and drowsiness that polio survivors have aptly called "brain fatigue" (25). However, imaging studies have not been able to establish a direct connection between areas of brain damage and the development of poststroke fatigue; instead, these studies tend to find numerous other variables that contribute to fatigue, supporting its multidimensional characteristics (37). Some anticonvulsants and analgesics used to manage stroke-associated sequelae may further exert their effects on the central nervous system and can compound the symptom of fatigue for stroke patients.

Impairment of the peripheral neurological component can alter complex biochemical interactions between nerve and muscle that generate the force and power of movement. In individuals who have experienced strokes, there may be significant damage to the central components, and concomitant effects on peripheral components because of immobility, weakness, or spasticity. The peripheral components are likewise compromised because of lack of innervation and the inability to recruit motor units (38).

Another physiologic model of fatigue explains that changes in concentrations of metabolites interfere with force produced by muscle contractile proteins, leading to reduced muscle function and feelings of fatigue. The accumulation of lactic acid in working muscle is also implicated in the development of fatigue, which signals the body to rest to restore biochemical equilibrium. Other explanations of the organic etiologies of fatigue have included looking at the causal role of physiologic conditions such as decreased pulmonary function, decreased muscle strength and endurance, and increased oxygen consumption demands. Additional fatigue-related factors include the presence of pain (39) or vitamin B_{12} deficiencies, particularly in lacunar strokes (40). High serum levels of glucose and IL-1beta, and low IL1-ra and IL-9 may predict fatigue after ischemic stroke, indicating that the development of poststroke fatigue might be accounted for by a proinflammatory response. These findings support a possible cytokine theory of fatigue after stroke (41,42).

Other important physiologic fatigue-related issues after stroke include sleep–wake disturbances, disruptions in circadian patterns, and sleep-disordered breathing, discussed elsewhere in this text.

A further physiologic model of fatigue that warrants discussion in the context of chronic stroke is that of the stress response and the activation of the corticotrophin-releasing hormone and the sympathetic nervous system. Persons with chronic disease of any kind can be expected to experience a high degree of stress (35), springing from a variety of social, psychological, and physical sources. The stress response triggers the release of hormones (ACTH and corticotrophin) that act upon specific areas of the brain to coordinate behavioral responses. It is thought that in the presence of chronic disease, the sustained stress response may lead to defective releases of corticotrophin, giving rise to behavioral depression and subjective fatigue (35,43). Sources of chronic stress in this patient population might include physical issues such as immobility, gait problems, pain, spasticity, perceptual and communication deficits, and unaccustomed energy expenditures. The stress response might also relate to psychological, social, and role adjustment issues (44).

Work Performance and Behavioral Components of Fatigue

In the many definitions of fatigue, one common observation is its negative effect on work performance. When fatigued, people are less able to engage in physical, mental, or social activity. In the case of hemiparetic stroke, there appears to be a two-way relationship between fatigue and the work performance decrement. Subjective fatigue reduces activity levels, and reduced activity levels contribute to deconditioning and loss of function. Using ambulation as an example, one can discern the multiple triggers for the development

of fatigue. First, there is the increased workload and energy expenditure in hemiparetic gait, stemming from the inability to control the functional and efficient manipulation of body segments through space (45). Adjustment of gait in hemiparesis includes reductions in walking speed, cadence, and step length (46), as well as musculoskeletal adjustments that shift the center of gravity and produce decreased velocity, decreased support time on the affected limb, and decreased weight transfer through the limb, all resulting in increased energy costs (46).

The greater the deficits and movement difficulties, the more body systems are involved in compensation: neurologic, motor control, musculoskeletal, ligamentous, and cardiopulmonary. The increased recruitment of other systems to compensate for missing function leads to increased energy demand and fatigue, which can be seen with ambulation as decreased velocity and increased heart rate (47).

The development of fatigue in the face of mobility impairment and cardiovascular deconditioning is logical when one considers that reduced physical activity can be both an antecedent to and a consequence of fatigue. A reciprocal and perpetuating association may exist between impairments in functional ability and fatigue. For example, neurological deficits that compromise gait and balance increase energy expenditure and cardiovascular and metabolic demand for mobility-related activities of daily living tasks, and cause patients to use a greater proportion of their physiologic fitness reserve to ambulate (48,49). The depletion of energy may result in subjective fatigue, and patients may respond to symptom distress by limiting their activity. Inactivity further disrupts gait and balance through losses of muscle strength, and lowered cardiovascular and metabolic activity tolerance (48). Inactivity may also contribute to social isolation and loss of confidence in the performance of activities of daily living. Thus, a cycle of reduced activity and loss of fitness and mobility is propagated in the presence of fatigue (50,51).

There are also behavioral components of the work performance dimension that perpetuate the fatigue experience in individuals with stroke. Many individuals experience reduced motivation when their functional recoveries are slow or absent. This may contribute to social isolation and a disinclination to participate in household or community activities. The need to navigate architectural barriers may confine individuals to their homes. Fear of falling is also implicated as a behavioral limitation that has effects on the amount of activity in which individuals with stroke engage (52,53). With increasingly sedentary behavior patterns, individuals with stroke are at risk for fatigue associated not only with energy costs of hemiparetic gait but also with cardiovascular and metabolic deconditioning.

Paradoxical, however, is the likelihood that individuals with stroke who experience fatigue actually reduce their physical activity levels to maintain perceived fatigue levels within an acceptable range, in the same way that older adults in general interpret fatigue as a signal to rest (54). This can explain fluctuations in subjective fatigue report or difficulties in evaluating or quantifying fatigue.

Psychosocial Factors

Psychosocial and behavioral factors may be as important as physical health variables in affecting stroke survivors' ability to function normally in their everyday lives. Social support appears to play a significant role in explaining differences in subjective functioning (55). After stroke, high levels of family support, instrumental and emotional, are associated with progressive improvement of functional status (56). Peer influence is powerful: social networks may subtly or directly influence physical activity and simultaneously reinforce a sense of belonging, purpose, and self-worth, thereby promoting mental health that may be reflected in low self-perceived fatigue and positive activity levels (57). Social support may also be influential in reducing the impact of depression and perceived disability (58). For example, in patients experiencing chronic fatigue, lack of social support was identified as a perpetuating factor of fatigue severity and functional impairment (59). In evaluating the relationships of mobility deficit severity, cardiovascular fitness, ambulatory activity and the effects of fatigue, inclusion of social measures adds a valuable dimension.

Symptom–Sensory Dimensions

Several characteristics are common among all symptoms and all patient populations: intensity, timing, level of perceived distress, and quality (60). In the case of fatigue in individuals with stroke, very little is known about the specific dimensions of the symptom. Intensity has been measured using scales that were developed for other populations and may not capture the distinct characteristics of stroke-related fatigue. The timing of fatigue in individuals with stroke is known mainly in terms of its persistence and has not been measured according to situational or temporal fluctuations. We also know little about the course of fatigue development after stroke. Rough estimates of the level of distress have been made based on how much patients report that fatigue affects their function and how often they describe fatigue as their worst or one of their worst symptoms (4). Recently, the development of poststroke fatigue has been linked to attentional and executive impairments, as well as depression and anxiety (61). More work is needed to fully describe the symptom of fatigue in the stroke population.

Behavioral Adaptation

Another way to look at fatigue is in the context of adaptive response. In response to a condition or stimulus, fatigue might actually serve a protective purpose (22). For example, in severely deconditioned patients, the perception of fatigue might curtail activity that would otherwise exceed their physiologic reserves. In individuals with stroke, the loss of cardiovascular and metabolic fitness results in reduction of exercise capacity. Individuals with stroke use a greater proportion of their physiologic reserve to perform everyday activities. This energy expenditure is compounded when

gait and balance deficits increase the workload of functional ambulatory activity. Fatigue may be a warning sign of reaching the limits, causing patients to slow down or stop their actions, thereby protecting their diminished energy reserves and maintaining balance. Recently, attention has been directed toward the phenomenon of *fatigability*, which attempts to identify the point at which individuals report activity-associated changes in perceived fatigue and the performance decrement that occurs in response (54).

SIGNIFICANCE

With the evidence of fatigue's prevalence and persistence in the lives of persons living with stroke and its potential contribution to negative functional outcomes and disability, finding ways to prevent, manage, or respond to fatigue is imperative. The causes of fatigue in the chronic stroke population are many. Attention must be directed toward understanding the link between fatigue and the ability to engage in activities and also toward appreciating fatigue's relationship to specific functional outcomes such as ambulatory activity patterns. By building knowledge about fatigue after stroke, it may be possible to identify strategies for prevention, remediation, and/or compensation, thereby improving and preserving function, independence, and quality of life.

Predictors of Poststroke Fatigue

To anticipate risk for poststroke fatigue and implement proactive preventative strategies, it is important to identify factors that predispose or predict the likelihood that an individual with stroke will experience fatigue. Predisposing factors include advanced age and female gender, along with several physiologic issues such as level of functional disability, the presence of prestroke fatigue, medical comorbidities, medications, continence issues, sleep disturbances, and nutritional problems (15). Psychological and cognitive predictors can include the presence of depression and cognitive dysfunction, and also organic conditions such as damage to particular brain areas with consequent neurochemical alterations, perfusion deficit, and neuroinflammation (15).

Manifestations of Fatigue After Stroke

Numerous features can be observed or measured in a person who is experiencing fatigue. Manifestations of fatigue include perceptual, physiologic, biochemical, and behavioral signs. Contributors to fatigue may include innate host factors such as age or gender. They also may reflect the accumulation of certain metabolites, for example, in muscle fatigue with the rise in lactic acid that follows strenuous work. There may be pattern changes in energy and energy substrates, which can be seen in the mismatch of energy expenditure to reserve in hemiparetic gait. Disturbances in regulation and transmission patterns may result from injury to brain tissue and lead to subjective fatigue. Changes in activity and rest patterns may contribute to the experience of fatigue, as can disruptions in sleep and wake cycles, the presence of disease, or certain treatment effects. We may recognize the outcomes of fatigue in many areas of daily life in individuals with stroke. For example, individuals with poststroke fatigue are more likely to have difficulties with basic and instrumental activities of daily living than those without fatigue (62).

Psychological, social, and life events also have a role in the development of fatigue. Because the physical environment assumes greater importance in the presence of functional impairments, it must not be overlooked as another dimension of fatigue. For individuals with stroke, fatigue-inducing disruptions may occur in many areas and at many levels simultaneously. It has also been demonstrated that poststroke fatigue is an independent risk factor for poor physical health 18 months after stroke (63). As we noted earlier, self-reported fatigue was identified as an independent predictor for having to move into an institutional setting after stroke (3).

Fatigue plays a role in poststroke quality of life as well. Like other distressing symptoms, such as pain or depression, fatigue has a lot to do with how individuals rate their quality of life. Importantly, low health-related quality of life is actually associated with increased mortality (64). For example, in young individuals with ischemic stroke, the presence of fatigue was predictive of early mortality (65).

Assessment of Fatigue

In individuals who have had strokes, the assessment of fatigue is complex. Its presence as a distinct symptom may emerge in the evaluation of other issues, such as weakness or depression. For instance, individuals may experience significant weakness as a result of stroke yet not describe themselves as fatigued. But when individuals are fatigued, their weakness may be more pronounced (3). In individuals with stroke, somatic signs of depression may not always be accompanied by depressed mood and, in fact, may be more indicative of fatigue (7). Even when individuals do not have feelings of depression, the presence of fatigue may have a negative effect on their recovery (4). For individuals with stroke, fatigue should be anticipated, recognized, differentiated, evaluated, monitored, documented, and managed at all stages, from acute event through treatment and rehabilitation to long-term recovery. To do so, we need to have accurate methods to assess and measure fatigue in stroke.

Fatigue may be measured in a variety of ways. To judge the presence and severity of fatigue, or to determine if our interventions have had any effect on that experience, we may use measurement tools in conjunction with patient report, history, and observation of signs. Poststroke fatigue is most frequently measured by self-report, using general fatigue scales such as the Fatigue Severity Scale or a Fatigue Visual Analogue Scale, as no stroke-specific scale has yet been developed to measure fatigue (66). Widely used in

stroke research, most scales were originally developed for use in other patient populations, although similarities have been established between fatigue in stroke and that occurring with Parkinson's disease or multiple sclerosis (67).

Researchers call for a uniform taxonomy in addressing fatigue, which includes standardized ways to quantify it (68). It is very likely that many research questions may be better addressed by using multiple measures to capture the many dimensions of fatigue after stroke.

A promising development in the assessment of fatigue has arisen from studies of fatigability in older adults. *Fatigability* describes the relationship between self-reported fatigue and the level of activity with which the feeling of fatigue is associated (69). It also can be objectively measured by evaluating changes in performance at intervals during a standardized walking test. *Perceived fatigability* can actually be quantified by looking at the difference in pre- and posttest self-ratings of fatigue. *Performance fatigability* is reflected in serial measurements of performance to identify at what point performance changes as a result of fatigue (54). Making the connection between subjective fatigue and other physiologic and functional factors that affect performance may be extremely useful in stroke.

Table 32.1 offers a summary of selected instruments for measuring fatigue and fatigability in individuals with stroke.

Because fatigue is multidimensional, its assessment must also be multidimensional. Patient report of fatigue symptoms is the starting point. A careful history should be gathered to characterize the individual's fatigue experience and to identify contributing factors. Assessments of fatigue in individuals with stroke should include evaluation of:

- *Onset, duration, and intensity of fatigue*: How does the patient describe and interpret the fatigue? How has it impacted desired activities, independence, and function?
- *Aggravating and alleviating factors*
- *Disease process*: Which area of the brain has been affected by the stroke? How long has it been since the event? What has the course of recovery been like? Have there been any complications?
- *Current medications*: In particular, does the patient take anticonvulsants, antispasmodics, or pain medications?
- *Sleep and rest patterns, relaxation habits, rituals, customs*
- *Nutritional status*
- *Effects of fatigue on functional status*, including mobility, activities of daily living, cognitive and social activities, job and role performance. Has the patient had any falls?
- *Presence of depression or other psychiatric condition*
- *Complete physical examination*: Are there other disease processes, such as anemia, inflammatory disease, cardiac or respiratory disease?
- *Adherence to treatment plan*, such as therapy, use of adaptive devices, precautions

TABLE 32.1 Selected Instruments for Measuring Fatigue After Stroke

NAME OF INSTRUMENT	DOMAINS MEASURED	COMMENTS
Fatigue Severity Scale (1)	Physical and psychological function	• Patients select rating from 1–7 to signify agreement with statements • Functional impact of fatigue
Visual Analog Scale (VAS) (86)	Single item	• Simple, real-time measure • Cannot be evaluated by many forms of statistical analysis
Multidimensional Fatigue Inventory (MFI) (87)	General Physical Mental Motivation Activity	• Multidimensional
Piper Fatigue Scale (19)	Severity Temporal Affective Sensory	• Multidimensional • Complicated format • Presumes the presence of fatigue
Profile of Mood States—Fatigue (POMS-F) (88)	Intensity	• Measures only one aspect of fatigue
Fatigue Assessment Instrument	Global severity Triggers Situations that modify fatigue	• 1–7 Likert scale • Measures fatigue in the past 2 weeks
Perceived Fatigability Severity (54)	Self-rating of fatigue before and after a standardized walk test	• Score obtained by dividing total distance walked by change in perceived fatigue
Performance Fatigability Severity (54)	Measures change in performance as an objective indicator of fatigue, and identifies at what point patient performance changes	• Percentage changes in walking speed over distance walked, calculated in 2.5-minute intervals over 10 minutes.

FATIGUE MANAGEMENT STRATEGIES

We need treatments for fatigue because it seems to persist in the long term and has an ongoing effect on health, function, and well-being (63). The initial level of fatigue is thought to be a main determinant of the increase in fatigue over time (70), so targeting fatigue soon after stroke may be important in preventing it from becoming established and difficult to change. The contributions of physiological, cognitive, and affective changes underlying fatigue are variable, and treatment is largely symptomatic and rehabilitative (71). Because the etiology and mechanisms causing and contributing to fatigue are multidimensional and interrelated, it is not surprising to find a considerable range of options for fatigue management. Approaches therefore must be individualized according to the features of fatigue, the impact, and the responses to treatments. Strategies may include cause-specific treatments, nonpharmacologic interventions, pharmacologic interventions, and education and counseling.

Cause-Specific Treatments

The literature suggests that the diagnosis of fatigue is one of exclusion and that, even though it is seen very often in clinical practice, fatigue should not be presumed to be a natural consequence of brain injury. Individuals with stroke who have been ill and inactive for periods of time may have nutritional and metabolic deficits resulting in abnormal blood counts, which in turn can contribute to reduced oxygen-carrying capacity of the blood, and fatigue occurs as an adaptation to loss of energy. Treating anemias and supporting nutrition may make a positive difference for these individuals. Correcting fluid and electrolyte imbalances may dramatically restore feelings of energy.

Because individuals who have strokes are more likely to be in advanced years, they may have comorbidities that contribute to fatigue, such as arthritis, changes in thyroid function, alterations in glucose metabolism, and respiratory or cardiovascular disease. Alleviating acute inflammatory processes and correcting physiologic imbalances also may lessen symptoms of fatigue.

Nonpharmacologic Interventions

The association between regular physical activity and reduced fatigue is well recognized in other patient populations (72,73). Reestablishing activity levels that maximize independence and function is a goal of rehabilitation after stroke. Each patient requires an individualized exercise prescription based on needs and abilities, which supports regular physical activity despite disability. For individuals with stroke, the use of appropriate adaptive devices and equipment may enhance participation in a regular exercise program and yield physical and psychological benefits, including reduced subjective fatigue. Treadmill training, among other treatments, improves fitness reserve and lowers the energy cost of hemiparetic gait, which could be useful in relieving fatigue (49,74).

Restorative activities offer dividends for individuals with stroke. Time spent in natural environments, in contemplation, and in social activities may ameliorate the effects of fatigue. Some complementary therapies may be especially useful in managing stroke-related fatigue, such as biofeedback (75), relaxation techniques, meditation (76), music (77), and pet therapy (78). Such therapies offer multiple benefits through distraction and stress reduction, as well as their inherent therapeutic effects.

The ways in which people think seem also to have an effect on the fatigue experience after stroke. Interventions to increase mindfulness have shown benefits across a range of psychological, physiological, and psychosocial outcomes, including anxiety, depression, mental fatigue, blood pressure, perceived health, and quality of life (79). Some cognitive fatigue-transforming strategies have been identified as being on a mission, settling for less, and stalling (80). Investigators have demonstrated that a cognitive therapy program can alleviate persistent fatigue after stroke, with the most powerful results occurring when cognitive therapy is augmented with graded activity training (81).

Pharmacologic Interventions

When there has been damage to brain tissue, caution is warranted in the use of any medications. For some individuals, however, the use of psychostimulants or antidepressants may afford some relief from fatigue symptoms. Fatigue is so often intermingled with depression that treatment of the latter may yield improvement in the former. However, the research findings about the use of antidepressant medications in reducing fatigue are mixed, but the general consensus is that antidepressants, although helpful in treating depression, seem to have little effect on poststroke fatigue itself (82,83). In any case, when considering medications for the management of fatigue symptoms in the context of stroke, it is important to start with the lowest available dose and titrate carefully according to effect, monitoring for any adverse reactions.

Patient and Family Education

An equally important rehabilitation intervention for the management of stroke-related fatigue is patient and family education and counseling. Providing anticipatory guidance about fatigue may diminish distress and misunderstanding if it occurs and help individuals and families maintain feelings of control. Identifying fatigue-provoking activities, problem-solving to modify these activities, and suggesting individualized environmental changes empowers individuals and families to take concrete actions for symptom management.

Persons with stroke may benefit from learning energy conservation strategies that include prioritizing, pacing,

delegating, or scheduling activities for periods of highest energy. They may also do well with structured daily routines that allow them to attend to one activity at a time, and that support scheduled rest times. Family members play an important part in helping to identify and reinforce successful compensatory strategies. Fatigue management group education is also a feasible model that has been shown to reduce fatigue severity, as well as improve social functioning and reduce anxiety (84).

Future Research Directions

Fatigue has been identified among the top 10 stroke research priorities, along with cognition, aphasia, vision, upper-limb function, and mobility (85). Rehabilitation research activities pertaining to stroke-related fatigue may help to substantiate its roots and remedies, determine its impact on function and independence, and strengthen the case for fatigue prevention and management as a worthy part of stroke rehabilitation. Growing from the knowledge that has been gained in the study of persons with other disease- and disability-related fatigue, fatigue assessments and interventions specific to individuals with stroke might be developed and refined. There is also a need for tools that measure the impact of fatigue on function, such as merging fatigue scales with functional independence measures or further developing our evaluations of performance-related fatigability (54). Instruments that can be used with individuals who have cognitive or communication impairments would also be useful.

SUMMARY

This chapter presented some key information about fatigue after stroke, using a relevant working definition of fatigue, with discussion of theories and mechanisms that may uniquely account for poststroke fatigue. Stroke-specific assessment of fatigue was outlined, along with management strategies to promote function and well-being. Much of what is known about fatigue has come from research in nonstroke populations. Further fatigue-related research is needed specific to stroke, to fully elucidate the symptoms, mechanisms, and unique features of poststroke fatigue. With this knowledge, providers may more effectively design and implement rehabilitation interventions to reduce symptom distress, control risk factors, enhance recovery, and promote function, independence, and quality of life for individuals living with stroke.

Sleep Disturbances and Stroke

Ana Sanchez and Arif A. Kabir

Sleep disorders are common in the general population. Insomnia and obstructive sleep apnea (OSA) syndrome are identified in 15% and 4% of the general population, respectively (1). Patients with stroke have an even higher incidence of certain sleep disorders, and these sleep disturbances may be underdiagnosed. Sleep-disordered breathing, sleep–wake disorders, sleep-related movement disorders, and parasomnias have all been described in patients with stroke. Recognition and treatment of these sleep disorders affects outcome and quality of life.

SLEEP-DISORDERED BREATHING AND STROKE

Types of Sleep-Disordered Breathing in Stroke

Several types of sleep-disordered breathing, including OSA, central sleep apnea (CSA), and Cheyne-Stokes respirations (CSR), are seen in association with stroke. OSA is the most common type of sleep-disordered breathing and is characterized by recurrent episodes of partial or complete upper airway obstruction during sleep. OSA can also lead to nocturnal hypoxemia, arousals, and sleep fragmentation.

Sleep apnea is graded in severity based on the apnea hypopnea index (AHI) (2) (Table 33.1). The AHI is the number of apneas and hypopneas per hour of sleep. An *apnea* is defined as a greater than or equal to 90% diminution in airflow that lasts at least 10 seconds. A *hypopnea* is defined as a greater than or equal to 30% reduction in airflow with an associated oxygen desaturation of at least 3% or an associated arousal from sleep. The definition of hypopnea was revised by the American Academy of Sleep Medicine in 2012. Respiratory effort-related arousals (RERAs) are more subtle disordered-breathing events that do not meet the criteria for an apnea or hypopnea but are associated with a sleep disruption in the form of an arousal. RERAs are not recognized by Medicare as an indication for treatment.

Apneas can be obstructive, central, or mixed. Apneas are categorized as obstructive if there is evidence of persistent respiratory effort against an upper airway obstruction. Apneas are central in the absence of inspiratory effort and are mixed if there is an initial absence of inspiratory effort followed by an effort to breathe. CSR is characterized by a crescendo–decrescendo pattern of respirations with associated CSA and can be seen with bilateral or large hemispheric strokes as well as congestive heart failure (3).

OSA and Risk for Stroke

OSA has been found to be associated with an increased risk of stroke, transient ischemic attack, and death (4), with the highest risk in patients with severe OSA. OSA is now recognized as an independent stroke risk factor (4,5).

Recurrent obstructive apneas acutely cause episodic nocturnal hypoxemia, hypercapnia, cardiac arrhythmias, intrathoracic pressure changes, and postapneic arousals. In the long term, OSA is associated with raised sympathetic activation, endothelial dysfunction, oxidative stress, inflammation, increased platelet aggregation, and metabolic dysfunction (6) (Figure 33.1). Furthermore, OSA may be associated with a reduction in cerebral blood flow (7). These changes negatively influence cardiovascular and cerebrovascular disease.

OSA is associated with many of the modifiable risk factors for stroke, including hypertension, atrial fibrillation (AF), diabetes mellitus, cardiac conditions like coronary artery disease and congestive heart failure, and carotid stenosis.

The association of OSA and hypertension is well established. The Wisconsin Sleep Cohort study showed that the odds ratio of developing new hypertension at 4-year follow-up was 2.03 for mild OSA and 2.89 for moderate to severe OSA compared with 1.42 for patients without OSA (8), and there is a high prevalence of OSA in patients with medically refractory hypertension (9). The most recent Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure cites OSA as an identifiable cause of hypertension and resistant hypertension (10). The enhanced sympathetic activation seen with OSA and the subsequent vasoconstriction may at least in part be responsible for the associated systemic hypertension (6). Patients with OSA have also been shown to demonstrate "nondipping," a phenomenon associated with worse cardiovascular prognosis, where blood pressure fails to normally drop 10% to 20% during sleep (11–13).

TABLE 33.1 Severity of OSA

Normal: AHI <5/hour
Mild OSA: AHI 5–15/hour
Moderate OSA: AHI 15–30/hour
Severe OSA: AHI >30/hour

There is also convincing evidence of a strong association between OSA and AF. Various cardiac arrhythmias are seen in association with OSA, including sinus arrhythmia and bradycardia, and the increased incidence of AF is particularly notable in the stroke population. A nested case control study of more than 100 patients with OSA showed that those with ischemic stroke had a significantly higher rate of AF compared with controls with no history of stroke, even after adjusting for confounding factors, demonstrating the strong association between OSA, AF, and stroke (14). The Sleep Heart Health Study reported a four-fold higher prevalence of AF in patients with OSA (15,16). Moreover, patients with OSA have an increased risk of recurrent AF after cardioversion, and treatment with continuous positive airway pressure (CPAP) results in a lower AF recurrence (17).

The Wisconsin Sleep Cohort study was a large longitudinal study demonstrating the increased prevalence of type II diabetes in patients with moderate to severe OSA (18). However, obesity is a confounding factor, and a causal relationship has not been established. There is also speculation that CPAP may improve glycemic control, but interventional studies have had conflicting results. More study is needed to elucidate if there is a causal relationship between type II diabetes mellitus and OSA, as well as effects of therapeutic intervention.

There is a high prevalence of OSA in patients with coronary artery disease and congestive heart failure (15), and OSA is considered a risk factor for cardiovascular disease. Patients with OSA are most likely to experience sudden cardiac death during sleep (12 midnight–6 a.m.) in contrast to the circadian pattern of the general population or patients without OSA in whom 12 midnight to 6 a.m. is the nadir of sudden cardiac deaths and 6 a.m. to 12 noon is the peak (19). The severity of OSA and its subsequent hypoxemia is also independently associated with increased carotid artery intima-media thickness, which is a marker of systemic atherosclerosis (20). Therefore, sleep apnea may negatively influence cardiovascular and cerebrovascular disease risk.

Prevalence of Sleep-Disordered Breathing in Stroke

OSA is prevalent in the general population. In middle-aged Americans, 24% of men and 9% of women have at least mild OSA (21). The OSA syndrome, defined as an AHI greater than 5 with associated excessive daytime sleepiness, is present in 4% of men and 2% of women (21).

Higher prevalence rates are noted in the stroke population. Sleep-disordered breathing, encompassing OSA, CSA,

TABLE 33.2 Clinical Features Indicating a Higher Risk of OSA

RISK FACTORS FOR OSA	SYMPTOMS OF OSA	ADDITIONAL CONSIDERATIONS IN STROKE PATIENTS
Males, postmenopausal women	Loud snoring	Diabetes
Obesity	Witness apneas	Sleep-related stroke
Hypertension	Gasping/choking	Macroangiopathy
Family history of OSA	Excessive daytime sleepiness	
Large neck circumference (>17" men, >16" women)	Morning headache	
Smoking, EtOH, sedatives	Dry mouth	
Upper airway or craniofacial abnormality	Difficulty concentrating	

and CSR, is present in 44% to 70% of patients with acute stroke (22–25). A meta-analysis of more than 2000 patients with ischemic stroke, hemorrhagic stroke, or TIA showed that 72% had at least mild sleep apnea and 38% had at least moderate sleep apnea (26). The sleep-disordered breathing identified in this population was predominantly OSA, with only 7% of patients with sleep apnea suffering primarily from CSA (26).

There are few studies addressing what risk factors predict the presence of sleep-disordered breathing in the stroke patient population specifically. In the general population, risk factors for OSA include male gender, postmenopausal status in women, obesity, hypertension, family history of OSA, large neck circumference, smoking, excessive use of alcohol or sedatives, and upper-airway or craniofacial anatomical abnormalities (Table 33.2). Generally, patients with OSA may report symptoms including a history of loud snoring, gasping/choking, witnessed apneas, and excessive daytime sleepiness. In the stroke population, neither the location of the stroke nor stroke severity predicts the presence or severity of sleep-disordered breathing (23,24), which may support the theory that OSA often precedes stroke. A prospective study by Bassetti et al. reported that the presence of diabetes, sleep-related stroke, and macroangiopathy may be variables that increase the risk of sleep-disordered breathing in stroke patients (24). Interestingly, in contrast to the general population, patients with stroke and sleep-disordered breathing are not typically symptomatic in terms of subjective sleepiness (27). Therefore, the absence of excessive daytime sleepiness by history does not necessarily lessen the possibility of sleep-disordered breathing in the stroke patient population.

There has been some study regarding the prevalence of sleep-disordered breathing in acute stroke versus the more stable subacute phase to determine if there is improvement of sleep-disordered breathing in line with stroke recovery. Parra et al. prospectively studied about 160 stroke patients admitted to a stroke unit. A portable sleep study was performed within 48 to 72 hours of admission and another follow-up sleep study was performed during the subacute phase at 3 months. The severity of OSA did not significantly change, but central events did improve (23). The authors concluded that this evidence indicates that OSA likely precedes stroke and that CSA as well as CSR occur subsequent to stroke as patients improve in the stable phase. CSA may result from brainstem stroke owing to the damage of central respiratory centers (28), although the Parra study did not show a statistically significant correlation between CSA and this stroke location (23).

OSA and Stroke Outcome

The presence of sleep-disordered breathing in stroke patients has been shown to be associated with a longer duration of hospitalization, worse functional outcomes, and higher mortality after stroke; it may also increase the risk of recurrent stroke (24,29–33). A prospective study by Kaneko et al. of about 60 patients admitted to a stroke rehabilitation unit showed that stroke patients with sleep-disordered breathing spent 2 weeks longer in the rehabilitation unit than patients with similar stroke severity but without sleep-disordered breathing (29). The presence of sleep-disordered breathing in patients with stroke has also been shown to be associated with acute worsening of neurologic status as well as worse short- and long-term outcomes (24,28,30–32,34).

One hypothesis is that the nocturnal hypoxemia, bradyarrhythmias, reduced cardiac output, and reduced cerebral perfusion associated with obstructive apneas may negatively influence the ischemic penumbra acutely (29). The worse outcomes in the short and long term are speculated to relate to the aforementioned factors, as well as to long-term complications of associated hypertension (35), sleep fragmentation, excessive daytime sleepiness, and worsened cognitive ability, which are typically thought to be associated with OSA. This might negatively affect a stroke patient's ability to participate in rehabilitation. However, in the study performed by Kaneko et al., there was no significant difference in sleep fragmentation, Epworth scores (a measure of subjective daytime sleepiness), or worsened cognition in stroke patients with or without sleep-disordered breathing. There have also been contradictory results regarding the presence of sleep-disordered breathing and long-term outcome, with some studies showing worse outcome at three months, six months, and one year (28,29,31), and others showing no association between outcome and OSA (24). The reason for this discrepancy is unclear and merits more study.

Treatment of OSA and Effect on Stroke Outcome

As OSA has been shown to be associated with worse outcomes in the stroke population, it will be important to determine if treatment of OSA improves outcomes. Options for treatment of OSA include weight loss, positional therapy if OSA is worse supine, surgery, oral appliances, and CPAP. Whereas surgery and oral appliances may be considered for patients with mild to moderate OSA, CPAP is the most commonly used therapy and the most effective for all severities of OSA. CPAP works by delivering compressed room air, via a hose, through a mask to prevent upper airway structures from collapsing; it thereby eliminates obstruction of airflow.

Treatment of OSA with CPAP in patients with stroke has been shown to be associated with better functional outcome, improved symptoms of depression, decreased blood pressure, and reduced mortality (27,36–38). Ryan et al. performed a randomized, open label, parallel group trial on stroke patients with OSA who were admitted to an inpatient stroke unit. Patients were randomized to CPAP or standard rehabilitation, and both groups spent the same time in therapy. Patients with neurological deficits, including anosognosia, receptive or global aphasia, were excluded owing to probable difficulty adhering to CPAP. There were no adverse events with CPAP, and compliance was high presumably because of the administration of CPAP in an inpatient setting. A significant improvement in functional and motor impairment as well as depression was demonstrated in the CPAP group compared to the control group, but neurocognitive recovery did not differ significantly. The patients in this study had Epworth sleepiness scale (a subjective assessment of sleepiness) scores that were within normal limits at baseline, but Epworth scores still improved with CPAP treatment. The authors speculate that the improvements seen in the CPAP group were not attributable to improved alertness but instead to increased oxygenation and fewer intrathoracic pressure swings, with subsequent enhanced cerebral blood flow (27).

Improvement of depression in patients with stroke and OSA could enhance rehabilitation and functional outcomes. Depression occurs in about 33% of patients with stroke (39), and treatment of depression may positively influence stroke outcome (40). A study by Sandberg et al. showed that patients with severe stroke and OSA who were treated with CPAP for one month had fewer symptoms of depression (36), and Wessendorf et al. found that patients with stroke and OSA who were compliant with CPAP while in an inpatient rehabilitation facility reported improvement in well-being (41).

Various studies demonstrate that effective treatment of OSA with CPAP lowers blood pressure. CPAP was shown to reduce mean arterial blood pressure by 3 mmHg in patients with moderate to severe OSA (37), and this translates into a reduction in stroke risk by 15% to 20% (35). A prospective study by Wessendorf et al. of about 100 patients with stroke and OSA being treated with CPAP during inpatient rehabilitation also reported improvement in nocturnal blood pressure (41), and CPAP was shown to improve systolic blood pressure in patients with heart failure and OSA (42).

Martinez-Garcia showed that patients with stroke and moderate to severe OSA who were compliant with CPAP had fewer new vascular events than patients who were not compliant with CPAP (43). Then another prospective study by the same group demonstrated that patients with ischemic stroke and moderate to severe OSA had an increased risk of mortality and that those who were compliant with CPAP had a significantly lower risk of mortality at five-year follow-up than patients who were not compliant with CPAP. Compliance with CPAP was defined as usage for more than 4 hours per night for more than 70% of nights. There was no difference in mortality for the groups without OSA, mild OSA, and those compliant with CPAP. A limitation of this study was the low overall compliance with CPAP, which was only 30% (38).

CPAP Compliance in the Stroke Population

Despite CPAP being highly effective at eliminating disordered breathing events, adherence is a significant obstacle to optimizing therapy. In the general population of patients with OSA, less than 60% are compliant with at least four hours of usage on a nightly basis (44); in stroke patients, compliance is thought to be even lower (28). Wessendorf et al. prospectively examined the acceptance of CPAP in a population of 100 or so patients with stroke and OSA in a rehabilitation facility. In this study, 70% accepted treatment with CPAP, which is similar to the rate of compliance in moderate to severe OSA patients in the general population. The primary reasons that 30% of patients did not accept CPAP in this study were mask discomfort and sleep disturbance. The presence of aphasia and severe motor disability was also associated with CPAP noncompliance. The authors hypothesize that difficulty adjusting the mask because of motor and cognitive impairment, mask leak because of facial weakness, trouble understanding the importance of CPAP owing to cognitive difficulties, and lack of the symptom of excessive daytime sleepiness in the stroke population may negatively affect compliance (41). Other studies have shown lower CPAP compliance rates in the stroke population (24,35,38). In the general population, the early acceptance of CPAP is one of the factors that predicts long-term adherence (44). Therefore, if CPAP is initiated during inpatient rehabilitation for stroke, compliance may be established early and improve adherence at home.

Guideline to Screen Stroke Patients for OSA and Considerations for Treatment

Given the high prevalence of sleep-disordered breathing in the stroke population, and given that OSA may increase the risk for recurrent stroke and worsen stroke outcome, an evaluation for sleep-disordered breathing should be considered in all stroke patients. A history of loud snoring, witnessed apneas, obesity/weight gain, large neck circumference, crowded oropharynx, and comorbid hypertension raises suspicion of OSA. In addition, if the patient has comorbid diabetes and a history of sleep-related stroke, that may further

increase the probability of OSA in a stroke patient (24). Stroke patients with OSA differ from the general population in that they may not report excessive daytime sleepiness (27), so this symptom should not be used as a reliable predictor of OSA in this particular patient population.

The evaluation for sleep-disordered breathing requires a sleep study. A *sleep study* is a continuous recording of various bioparameters, including electroencephalography, electro-oculography, electromyography, oral and nasal airflow, oxygen saturation, electrocardiography, and respiratory effort. There are different levels of sleep studies that range from recording a full set of these physiologic variables with a sleep technician attending the patient in a lab setting (Level 1) to recording one or two bioparameters, such as oxygen saturation and airflow, in an unattended portable setting (Level 4). Although an overnight Level 1 full polysomnography in the sleep lab is the gold standard for the diagnosis of sleep-disordered breathing, there are various other portable sleep studies that are adequate for the diagnosis of OSA and are more practical for use at the bedside in the inpatient setting in a rehabilitation facility or at home when travel is difficult. A meta-analysis by Ghegan et al. reported that portable sleep testing provides diagnostic information similar to the Level 1 in-lab sleep studies but may underestimate the severity of sleep apnea (45).

The optimal time to perform a sleep study on a stroke patient is not clear. As CSA may improve in the subacute phase of stroke (23), one might consider waiting until then to perform a sleep study. However, there is also evidence that OSA may worsen acute neurologic status (34), so diagnosis and treatment of OSA early in the course may be beneficial. These areas warrant more study.

TABLE 33.3 Treatment of Stroke-Associated Sleep-Wake Disorders

SLEEP–WAKE DISORDER	TREATMENT
Obstructive sleep apnea	CPAP Weight loss Positional therapy Oral appliance Surgery
Central sleep apnea/Cheyne-Stokes breathing	CPAP/BiPAP Adaptive servoventilation Oxygen
Hypersomnia Excessive daytime sleepiness Fatigue	**Stimulating antidepressants:** ■ Venlafaxine 37.5–150 mg/daily **Wake promoting agents:** ■ Modafinil 100–400 mg daily ■ Armodafinil 150–250 mg daily **Stimulants:** ■ Methylphenidate 5–60 mg daily
Insomnia	Cognitive behavioral therapy for insomnia **Nonbenzodiazepine receptor agonists:** ■ Zolpidem 5–10 mg qhs prn ■ Eszoplicone 1–3 mg qhs prn ■ Zaleplon 5–10 mg qhs prn **Sedative antidepressants:** ■ Amitriptyline 10–100 mg qhs ■ Trazodone 50–200 mg qhs ■ Mirtazapine 15–30 mg qhs Melatonin
Restless legs syndrome Periodic limb movements during sleep	**Dopamine agonists:** ■ Ropinirole 0.25–1 mg qhs ■ Pramipexole 0.125–0.75 mg qhs **Ca channel alpha 2 delta ligands:** ■ Gabapentin 300–1200 mg qhs ■ Pregabalin 50–300 mg qhs ■ Gabapentin encarbil 600–1200 mg qhs
REM sleep behavior disorders	Clonazepam 0.5–4 mg qhs Melatonin 3–12 mg qhs

Abbreviations: BiPAP, biphasic positive airway pressure; CPAP, continuous positive airway pressure.

Source: Adapted from Ref. (35). Hermann DM, Bassetti CL. Sleep-related breathing and sleep-wake disturbances in ischemic stroke. *Neurology*. 2009;73(16):1313–1322.

There are no formal guidelines regarding which patients with stroke and sleep disorders need treatment, although there are some recommendations regarding possible treatment strategies (Table 33.3). Hermann et al. recommend treatment with CPAP to stroke patients with moderate to severe OSA, symptoms of excessive daytime sleepiness, or other comorbid cardiovascular conditions such as hypertension (35). If a stroke patient is found to have CSA or CSR, the central component may improve in the subacute phase of recovery (23), or treatment with a more advanced mode of ventilation, adaptive servo-ventilation, may be considered (46). Further research may delineate which specific stroke patients with what particular type and severity of sleep-disordered breathing may gain the most benefit from treatment with CPAP or other modes of ventilation.

Sleep–Wake Disorders and Stroke

A number of sleep–wake disorders may be seen following a stroke. Patients with stroke may present with insomnia, hypersomnia, or excessive daytime sleepiness. *Insomnia* refers to recurrent difficulty initiating or maintaining sleep, early awakenings, or the inability to attain restorative sleep. *Hypersomnia* signifies excessive sleeping or sleepiness and may be present with the symptom of excessive daytime sleepiness. *Excessive daytime sleepiness* denotes the inability to stay awake or alert, resulting in drowsiness or naps, during the main waking periods of the day.

Insomnia After Stroke

A study of 277 stroke patients showed that 56.7% of patients complained of insomnia after stroke, which was a new complaint in 18.7% of patients (47). There are many reasons for the high incidence of insomnia in this population, including the initial reaction to having a serious medical condition, adjustment to physical and cognitive limitations, poststroke depression, and medication side effects (48). Sometimes insomnia is thought to result directly from the anatomic location of the lesion. Lesions to sleep centers such as the preoptic nucleus of the hypothalamus, brainstem, frontal lobe, basal ganglia, and paramedian thalamus may be associated with insomnia and cause changes to sleep architecture (49–51).

There are various treatments for insomnia, including behavioral approaches and medications. Good sleep hygiene should always be promoted and cognitive behavioral therapy for insomnia may also be utilized. Underlying depression or anxiety should be addressed and treated. In terms of hypnotic medications, one may consider treatment with a nonbenzodiazepine receptor agonist (non-BZRA) such as zolpidem or eszopiclone. The non-BZRA hypnotics will not worsen underlying sleep-disordered breathing. Other medications used to treat insomnia include benzodiazepines and sedating antidepressants in patients with comorbid depression (Table 33.3).

Hypersomnia After Stroke

Hypersomnia may also be seen after stroke (52). This is most commonly noted when strokes are in the distribution of wake-promoting regions such as the hypothalamus, brainstem, and basal forebrain. In addition, there have been reports of hypersomnia directly following ischemic lesions of the pontine tegmental reticular formation and the paramedian nuclei of the thalamus (48). Excluding anatomical lesions, hypersomnia can also be caused by medications used in the poststroke regimen, as well as by OSA or other sleep disorders.

One frequently used measure of excessive somnolence is the Epworth Sleepiness Scale. It is a subjective validated scale asking patients to evaluate the chances of dozing off in eight different scenarios. A score greater than 10 is considered pathologically hypersomnolent. Other more objective standards for assessing hypersomnia include the mean sleep latency test (MSLT) and the maintenance of wakefulness test (MWT).

The most common treatments for poststroke hypersomnia, not otherwise attributable to another condition, are the wake-promoting agents modafinil and armodafinil. Other reported therapies in stroke patients include methylphenidate, levodopa, and bromocriptine (53–55).

The presence of sleep–wake disorders may affect the stroke patient's ability to participate in rehabilitation and thereby negatively affect functional outcome, but there is insufficient evidence to support this hypothesis.

Movement Disorders and Parasomnias in Patients With Stroke

Restless legs syndrome (RLS) is a sleep-related movement disorder, and REM sleep behavior disorder is a parasomnia that can be seen in association with stroke. According to one study, the prevalence of RLS associated with stroke was 12%. RLS symptoms developed within one week of the stroke and were more common with strokes affecting the basal ganglia, corona radiate, and pons. The RLS symptoms were either bilateral or contralateral to the stroke (56). Dopamine agonists are typically first-line therapy to treat symptoms of RLS. There are also rare case reports of REM sleep behavior disorder seen after a pontine stroke that was successfully treated with clonazepam (57).

CONCLUSION

Sleep disturbances are prevalent in patients with stroke and may be underrecognized. Identification and treatment of these sleep disorders could improve functional outcome as well as quality of life and therefore warrant more attention.

Malnutrition After Stroke

Hillel M. Finestone, Norine Foley, and Linda S. Greene-Finestone

Patients who have had a stroke are vulnerable to being malnourished. *Dysphagia*, defined as having difficulty swallowing (owing to central neurological injury in the case of stroke), is an important factor that may lead to eating difficulties. Other physical, cognitive, and perceptual issues often associated with advancing age and stroke may also contribute to malnutrition (Table 34.1). Awareness and proper management of the nutritional issues and problems associated with stroke can contribute to better outcomes. Identification and treatment of declines in nutritional status associated with stroke may counteract their known negative impact on survival and functional recovery (2–4). Malnutrition and hypoalbuminemia have been associated with poorer functional outcomes (2,5), higher complication rates (5), longer lengths of stay (2), and reduced functional improvement rates (2) in acute and rehabilitating stroke patients. In this chapter, the authors address the magnitude of the malnutrition problem, methods of screening and assessing stroke patients' nutritional status, and technical and clinical strategies for improving their food and fluid intake.

PREVALENCE

Malnutrition typically refers to protein–energy malnutrition resulting from a long-standing negative imbalance of both energy and protein, with metabolic requirements exceeding nutritional intake. The reported prevalence of malnutrition following stroke ranges widely, from 6% to 62% (4,6–23). Table 34.2 presents the results from 18 studies that assessed the nutritional status of patients following stroke using primary criteria to identify malnutrition. Many factors may have influenced the precision of the estimate, such as method and timing of nutritional assessment, differences in stroke subtypes (infarction vs. hemorrhagic, large vs. small, and cortical vs. subcortical infarcts), comorbid conditions, and use of medication. Although many of these studies showed declines in nutritional indices and increases in malnutrition in the weeks following stroke, it is unclear whether this represents further declines superimposed on preexisting (prevalent) malnutrition or whether these were incidental cases. Hama et al. (18) and Finestone et al. (9) reported that 57% and 49% of stroke patients, respectively, admitted to a rehabilitation unit were malnourished, which suggests that malnutrition develops as a consequence of stroke. The estimates of malnutrition assessed at admission to acute care hospitals are substantially lower, ranging from 8% to 19% (4,6,8,10,13,15–17,20).

ENERGY REQUIREMENTS FOLLOWING STROKE

Hypermetabolism has been defined as an increase in metabolic rate associated with a diseased state greater than that predicted, using equations accounting for age, sex, height, and weight (24). Metabolic rates 140% to 200% above predicted values have been described for burns, sepsis, and head injury (24), reflecting increased oxygen consumption associated with severe injury. However, it is unclear whether stroke results in similar metabolic perturbations. Several studies have been conducted to measure the resting energy expenditure of patients following stroke. Three studies focusing on patients receiving mechanical ventilation have given disparate findings. Bardutzky et al. (25) reported that in 34 sedated intensive care patients, total energy expenditure was not elevated and could be estimated using the Harris–Benedict equations (regressions using height, weight, age, and sex to estimate basal metabolic rate in noninjured or nondiseased states). Furthermore, energy expenditure was similar between those with ischemic stroke and those with hemorrhagic stroke. In contrast, in 14 patients with intracranial hemorrhage, 79% of whom were sedated, median energy expenditure appeared elevated at 126% of basal energy expenditure (26). Frankenfield et al. (27) reported that critical care patients with hemorrhagic stroke (n = 36, 58% with craniotomy or craniectomy and 11% with coil embolization of an aneurism) had higher metabolic rates than those with ischemic stroke (n = 30, 20% with decompressive craniotomy). When compared to the metabolic rate predicted by the Mifflin equation for healthy individuals (28), hypermetabolism (more than 15% above Mifflin) was observed in 60% and 86% of those with ischemic and hemorrhagic stroke, respectively.

In other studies, energy expenditure was elevated by 10% to 15% above predicted values, which suggests that stroke patients are not at increased risk for malnutrition caused by

TABLE 34.1 Factors Contributing to Eating Difficulties and Nutritional Impairments After Stroke

PRIMARY FACTOR	SECONDARY FACTORS
• Dysphagia	• Factors affecting ability to feed self (e.g., visuospatial perceptual deficits, upper-extremity paralysis or paresis, and apraxia) • Cognitive changes affecting eating behaviors (e.g., attention–concentration deficit or forgetting to eat, combativeness or throwing food, eating too fast or too slowly, forgetting to swallow, and chewing constantly or overchewing food) • Right and left disorientation • Visual neglect or denial of the paralyzed extremity • Disturbance of sensory function • Depression • Agnosia • Dygeusia (109)

the effects of hypermetabolism in the early poststroke period. Weekes and Elia (29) found that patients were not hypermetabolic in the acute recovery period after stroke. Finestone et al. (30) studied 91 normally nourished patients recovering from stroke from hospital admission at 3 weeks and at 90 days. Although much individual variation existed, patients were not noted to be hypermetabolic. Their resting energy expenditure during the study period was, on average, approximately 10% higher than the values obtained using a standard prediction equation developed with the Harris–Benedict formula. In fact, the energy expenditures of subjects with stroke were similar to those of control subjects who had not experienced a stroke. The authors concluded that a "stress factor" specific to stroke was not evident. In a pilot study comparing 10 stable chronically tube-fed stroke survivors, resting energy expenditure was approximately 90% of weight-based predicted levels (31). It was also lower in the stroke survivors than in healthy controls, even after adjustment for lower fat-free mass owing to hemiparesis and/or prolonged bed rest.

Although there is conflicting evidence that stroke patients receiving mechanical ventilation may have increased energy expenditure, it appears that hypermetabolism is not evident in stroke survivors who do not require ventilation. Furthermore, longer-term stroke survivors who are chronically tube-fed may have lower energy needs than predicted levels. Finally, energy requirements will also vary with the stroke survivor's ability to participate in an active rehabilitation program with physical therapy (32). The nutritional state of stroke patients should be evaluated on an individual basis and be based on their estimated energy expenditure. Detrimental patient outcomes may arise from both insufficient and excessive calories.

PROTEIN REQUIREMENTS FOLLOWING STROKE

There has been very little research on protein requirements of stroke survivors. Evidence of increased protein catabolism following acute stroke was noted by Mountokalakis and Dellos (33) when they compared nitrogen loss, expressed as urea:creatinine ratio, in stroke patients and in surgical patients before and after surgery. Though the ratio rose significantly in both groups, it exceeded the upper limit of normal only in the stroke patients. The ratio reached its peak in that group between the 4th and 10th days. Chalela et al. (34) reported that, of 27 severe stroke patients (median National Institutes of Health Stroke Scale of five) receiving goal rates of enteral nutrition because of depressed consciousness or at risk for aspiration or intubation, 44% were in negative balance while receiving 25 to 30 nonprotein Kcal/kg per day and 1.5 to 2.0 g of protein/kg per day. The authors concluded that "critically ill stroke patients are being underfed."

There is evidence of elevated acute-phase reactants following stroke (35–37), and this has been summarized elsewhere (38). The acute-phase response includes a hypermetabolic, hypercatabolic state in which lean body mass and body fat are catabolized for energy. Other factors, such as insufficient energy intake leading to a breakdown of muscle tissue to satisfy the body's need for energy (gluconeogenesis) and muscle atrophy owing to immobilization, can also contribute to negative nitrogen balance in stroke patients. However, though protein requirement can increase during times of metabolic stress or catabolism, the extent to which the requirement associated with stroke increases the need is not yet known. Protein requirements of 0.8 g/kg per day have been previously recommended for healthy adults aged 19 years or older, including elderly people (39), yet it may be insufficient to meet the needs of stroke patients, particularly in the presence of concomitant infections.

SCREENING AND ASSESSMENT OF NUTRITIONAL STATUS

Nutritional Screening

Nutritional screening can be diagnostic, intended to identify individuals who are considered to be malnourished or at nutritional risk and who would benefit from nutritional interventions. It can also be used as a prognostic tool to identify patients who may be at increased risk for

TABLE 34.2 Studies Assessing the Nutritional Status of Patients Following Stroke

AUTHOR/YEAR	PREVALENCE OF MALNUTRITION AND TIMING OF ASSESSMENT	INDICATORS AND CUT-OFF POINTS OR INDICES USED TO ASSESS NUTRITIONAL STATUS	CRITERIA USED TO ESTABLISH MALNUTRITION
Axelsson et al. (1988) (6)	16% at hospital admission, 22% at hospital discharge	Serum albumin < 38 g/L (male) or 37 g/L (female) Prealbumin < 0.18 g/L Transferrin < 1.7 g/L (male) or 1.5 g/L (female) Body weight < 80% relative body weight, tricep skinfold thickness (four levels based on age), and arm muscle circumference (four levels based on age)	Two or more variables below reference limits
DePippo et al. (1994) (7)	6.1% at any point between rehabilitation hospital admission and discharge	Albumin < 25 g/L, sustained ketonuria without glycosuria > 2 weeks	At least one variable below reference limits
Unosson et al. (1994) (8)	8% on admission to hospital	Weight < 80% of reference value Tricep skinfold thickness < 6 mm (male) or 12 mm (female) Arm muscle circumference (four levels based on age and sex) Delayed hypersensitivity skin testing (< 10 mm induration) Serum albumin < 36 g/L Prealbumin < 0.20 g/L (male) or 0.18 g/L (female)	Three or more variables below reference limits, including one of each of the anthropometric, serum protein, and skin test measurements
Finestone et al. (1995) (9)	49% on admission to rehabilitation unit, 34% at 1 month, 22% at 2 month, and 19% at follow-up (2–4 months)	Serum albumin < 35 g/L Transferrin < 2.0 g/L Total lymphocyte count < 1800/mm^3 Body weight < 90% of reference weight or < 95% of usual weight or body mass index < 20 Sum of four skinfold measurements < 5th percentile of reference population Mid-arm muscle circumference < 5th percentile of reference population	Two or more variables below reference limits
Davalos et al. (1996) (10)	16.3% at hospital admission, 26.4% after 1 week, and 35% after 2 weeks	Serum albumin < 35 g/L Tricep skinfold or mid-arm muscle circumference < 10th percentile of reference population	Any single indicator below reference limits
Choi-Kwon et al. (1998) (11)	25% among patients with ischemic stroke, 62% among patients with hemorrhagic stroke assessed in acute period of stroke: 13% among control subjects	Lean body mass Abdominal skinfold thickness Subscapular skinfold thickness Triceps skinfold thickness (all < 80% of reference values) Body mass index < 20 Total lymphocyte count < 1500/mm^3 Hemoglobin < 12 g/dL Serum albumin < 35 g/L	More than one biochemical indicator and two or more anthropometric indicators below reference values
Aquilani et al. (1999) (12)	30% at admission to rehabilitation	Loss of usual weight ≥ 5% or 10% Arm muscle area < 5th percentile Serum albumin < 35 g/L Total lymphocyte count < 1800 n/mm^3	Loss of weight ≥ 10% but with actual weight lower than reference weight or Loss of weight ≥ 5% plus one other abnormal marker

TABLE 34.2 Studies Assessing the Nutritional Status of Patients Following Stroke (*continued*)

AUTHOR/YEAR	PREVALENCE OF MALNUTRITION AND TIMING OF ASSESSMENT	INDICATORS AND CUT-OFF POINTS OR INDICES USED TO ASSESS NUTRITIONAL STATUS	CRITERIA USED TO ESTABLISH MALNUTRITION
Westergren et al. (2001) (13)	8% at admission (acute), 29% at 1 month, 33% at 3 months	Body mass index < 20 or body weight < 80% of reference weight or weight loss < 5% since admission Subnormal triceps skinfold and mid-upper-arm muscle circumference Serum albumin < 36 g/L	One abnormal weight measurement and at least two other abnormal markers
Westergren et al. (2001) (14)	32% within 6 days following hospital admission	Authors' modified version of Subjective Global Assessment (A = well nourished, B = well nourished but at risk of becoming malnourished, C = suspected of being malnourished, D = severely malnourished)	Subjective global class B or C or D = malnourished
Davis et al. (2004) (4)	16% at admission	Subjective Global Assessment	Defined by the instrument
Dennis et al. (FOOD I) (2005) (15)	7.8% at admission	Body mass index < 20 (more comprehensive assessment may also have been carried out in a portion of the patients, although details not provided)	Underweight versus normal versus overweight
Dennis et al. (FOOD II) (2005) (16)	8.6% at admission	Same as FOOD I	Underweight versus normal versus overweight
Martineau et al. (2005) (17)	19.2% at acute admission	Patient-Generated Subjective Global Assessment (PG-SGA)	Defined by the instrument
Hama et al. (2005) (18)	22%–57% at admission to rehabilitation, depending on criteria used	Serum albumin < 40 g/L Body mass index < 19	Either marker below reference value
Brynningsen et al. (2007) (19)	35% at 1 week after stroke 33% at 5 weeks 20% at 3 months 22% at 6 months	Serum albumin < 550 mcmol/L Serum transferrin < 49 mcmol/L Triceps skinfold < 10th percentile Arm muscle circumference < 10th percentile	Two or more abnormal nutritional variables
Yoo et al. (2008) (20)	12.2% within 24 hours of symptom onset 19.8% at 1 week	Weight loss of ≥ 10% for previous 3 months or ≥ 6% during first week of admission Weight index (actual weight in relation to reference weight) < 80% Serum albumin < 30 g/L Serum transferrin < 1.5 g/L Serum prealbumin < 0.1 g/L	Any single indicator below reference limits
Lim and Choue (2010, 2012) (21,22)	74% and 57.5% within 18 days of stroke onset	PG-SGA Mini Nutritional Assessment (MNA)	Malnourished = PG-SGA of B or C Malnourished = MNA < 17
Crary et al. (2012) (23)	32% at admission to hospital 33% at day 7	Serum prealbumin < 15 mg/dL	

TABLE 34.3 Prognostic Nutrition Screening Tools

INDEX/INTERPRETATION	DESCRIPTION/CALCULATION
Prognostic Nutritional Index (42)	15.8–16.6 (albumin)
Low risk: < 40%	0.78 triceps skinfold (mm)
Intermediate risk: 40%–49%	0.2 (serum transferrin)
High risk: > 50%	5.8 (maximum skin reactivity, scored from 0 to 2)
Prognostic Inflammatory Nutrition Index (44) Correlates with death in critically ill patients when > 30	A-acid glycoprotein (mg/L) × C-reactive protein (mg/mL)/ albumin (g/L) × prealbumin (mg/L)
Nutritional Risk Index (41) > 100: no malnutrition 97.5 to 100: mildly malnourished 83.5 to < 97.5: moderately malnourished < 83.5: severely malnourished	(1.519 × albumin [g/L]) + 41.7 (present weight/usual weight)
Instant Nutritional Assessment (43) Four degrees of nutritional state	Serum albumin (SA) and total lymphocyte count (TLC) 1st degree: SA ≥ 35 g/L, TLC ≥ 1500/mm^3 2nd degree: SA ≥ 35 g/L, TLC < 1500/mm^3 3rd degree: SA < 35 g/L, TLC ≥ 1500/mm^3 4th degree: SA < 35 g/L, TLC < 1500/mm^3

complications, longer hospital stay, or mortality (40). The distinction is important, as some nutritional screening tools, such as the Nutritional Risk Index (41), the Prognostic Nutritional Index (42), and the Instant Nutritional Assessment (43), were developed for prediction purposes and include components that may be depressed irrespective of nutritional state (Table 34.3). These tools may better reflect disease severity and inflammation. It is usually of greater clinical interest to identify patients who are malnourished. Routine nutritional screening is now considered to be part of evidence-based practice and is included in many clinical practice guidelines, particularly when a patient is dysphagic. Patients should be screened within 24 to 48 hours of admission by a nurse or dietary assistant using a valid tool. Patients with positive findings (i.e., those who fail the screen) should be referred to a registered dietician for nutritional assessment.

There are several valid nutritional screening tools designed specifically to identify inpatients who are malnourished or who are likely to benefit from nutritional intervention. Some examples include the Malnutrition Screening Tool (45), Nutritional Risk Screening 2002 (46), the Malnutrition Universal Screening Tool (47), and the Short Nutritional Assessment Questionnaire (48). All of these screening tools include a maximum of six items assessing recent weight loss and/or body mass index, appetite, and recent dietary intake; some also include an assessment of disease severity, the use of supplements or tube feeding, and age. Most of these tools were developed for use in a broad range of inpatients, including general medical/surgery, orthopedics, and oncology; none have been validated for use in patients recovering from stroke. Finally, the short-form Mini Nutritional Assessment (MNA-SF) (49) is a six-item subscale of the 18-item MNA, which was developed as a tool to identify geriatric patients at risk for malnutrition.

Nutritional Assessment

Interest in identifying and treating all patients perceived to be in a nutritionally compromised state was aroused during the early 1970s, when iatrogenic malnutrition was believed to be a significant cause of poor outcome and rising health care costs. During that period, a series of nutrition assessment methods, many of which are still in use today, were proposed and adopted. However, regardless of the patient population under study, nutritional assessment has never been fully standardized, and no consensus exists as to which method of assessment is best. Therefore, wide variations occur in clinical practice. The nutritional screening and assessment of patients can range from very elaborate methods relying on a variety of biochemical and anthropometric markers (measures of fat and muscle stores) to simple methods using only a single measurement, such as body weight.

The ideal nutrition assessment method applicable for use in the stroke patient would be sensitive to recent intake, unaffected by disease state, inexpensive, simple, and noninvasive. Unfortunately, no such method exists. This limitation can affect not only the initial determination of nutritional status but also subsequent efforts to evaluate the response to nutritional interventions. In the absence of an acute or chronic underlying disease and/or institutionalization, the identification of malnutrition is less complicated, and the condition is thought to be attributable to negative energy balance, where nutritional intake is lower than required. However, in most diseases, including stroke, other metabolic processes may influence the detection of malnutrition.

TABLE 34.4 Biochemical Markers of Nutritional Status

MEASURE	NORMAL VALUES	LIMITATION(S)
Serum albumin (half-life 14–21 days)	> 3.5–5.0 g/dL	• Large body pool, best used with other indicators • Slow response to nutritional repletion (3–4 weeks) • Poor specificity to nutritional status • Decreased during acute-phase response
Serum transferrin (half-life 8–10 days)	> 200 mg/dL	• Better indicator than albumin owing to shorter half-life, smaller body pool, and quicker response to changes • Not specific to nutritional status • Decreased during acute-phase response
Thyroxin-binding prealbumin (transthyretin: half-life 2 days)	20–50 mg/dL	• Responds to repletion in 2–3 days • Not specific to nutritional status • Decreased during acute-phase response
Retinol-binding protein (half-life 10–12 hours)	3–7 mg/dL	• With short half-life and small body pool, reacts rapidly to repletion of energy and protein • Not specific to nutritional status
Total lymphocyte count	2000–3500/mm^3	• Inexpensive screening tool • Can be used with total leukocyte count when interpreting results • Poor sensitivity and specificity • Not specific to nutritional status

Source: From Ref. (51). Chicago Dietetic Association, The South Suburban Dietetic Association and Dietitians of Canada. *Manual of Clinical Dietetics*. 5th ed. Chicago, IL: American Dietetic Association; 1996:21–22.

This interaction between nutritional status and severity of illness was recognized by the Board of Directors of the American Association of Parenteral and Enteral Nutrition and the Clinical Guidelines Task Force:

> There is an inextricable relationship between nutritional status and the severity of illness. Severely ill patients, no matter what assessment tools are used, will be identified as being malnourished. Whether this assessment in fact truly indicates malnutrition (a state induced by dietary deficiency that may be improved solely by administration of nutrients) or is merely a reflection of the severity of metabolic derangement caused by the underlying illness is arguable. (50)

Although sophisticated measurements, such as bioelectrical impedance analysis of body composition, antigen skin testing, and muscle strength, are available to aid in the assessment of nutritional state, they are often impractical for use in clinical practice. More frequently, a traditional approach is used. This method combines the results of biochemical tests, such as serum albumin and transferrin levels, and measurement of skeletal muscle mass and subcutaneous fat stores, collectively referred to as *anthropometric measures*. Examples of anthropometric measurements include body weight, mid-arm muscle circumference, and skinfold thickness, which can be measured using skinfold calipers and a measuring tape. With a traditional approach, the identification of malnutrition is usually inferred, based on a single value or multiple values falling outside specific population reference ranges or below a given percentile within these ranges. Several examples of this approach to nutrition assessment in the stroke patient are presented in Table 34.2. With a system based on cut-off values, a patient's state can change abruptly from one of being well nourished to one of malnourishment. These designations may be somewhat artificial, and additional information, including that obtained from questionnaires designed to assess premorbid nutritional intake, mood, functional status, or comorbid conditions, may be necessary to identify the truly malnourished patient.

Table 34.4 presents some of the biochemical indicators more commonly used in nutrition assessment, their normal reference ranges, and their limitations. Although declines in the serum levels of these indicators may be associated with the development of malnutrition, many are affected independently by factors associated with stroke or any other acute illness. For example, the hepatic production of albumin, transferrin, and prealbumin is downregulated during periods of acute illness, resulting in depressed serum values (52,53). This effect is likely mediated by cytokines, such as tumor necrosis factor and interleukin-6, which have been reported to be elevated following stroke (35,37,54–57). The presence of concurrent infection or temperature elevation is also associated with depressed serum levels of the same proteins. With respect to albumin in particular, transcapillary escape resulting from systemic inflammation may be manifest as hypoalbuminemia (58,59). Whereas serum albumin levels can fall abruptly, recovery of levels may take time, owing to its relatively long half-life of 14 to 21 days; therefore, response to nutritional interventions can be slow (60). Moreover, several reports failed to demonstrate an association between serum albumin levels and adequacy of protein and energy intake (61–63). Using serum albumin as one of two nutritional indicators, Davalos et al. (10) reported that early, appropriate enteral feeding did not prevent the development of malnutrition during the first week after hospital

admission. Similarly, levels of serum transferrin as an acute-phase protein fall in response to physiological stress. Although serum transferrin's half-life of eight days is shorter than that of albumin, its specificity as a nutritional marker is similar to that of albumin (64). Of all of the visceral proteins used for nutritional assessment, serum prealbumin has the shortest half-life, at two days; therefore, it is more sensitive to changes in both disease severity and nutritional intake than either albumin or transferrin. Prealbumin also correlates with nitrogen balance. A dramatic decrease in serum prealbumin level can occur following three to five days of inadequate protein and energy intake or after significant physiological stress (64). Therefore, the serum concentration of prealbumin will normalize with resolution of the stressful insult if nutritional intake is adequate, but it will remain depressed in the presence of adequate intake if stress or inflammation persists.

There are also limitations associated with anthropometric measurements, which can remain static and may be insensitive to recent change in nutritional intake. Skeletal muscle losses may also occur over prolonged periods as a result of atrophy or secondary to immobility, and they can be difficult to distinguish from those with a nutritional cause (65,66). Specialized equipment, training, and practice are required to ensure that reproducible measurements of body composition are obtained, and appropriate reference population norms must be available to ensure proper interpretation.

Several nutritional assessment tools have been validated and are used in clinical practice. Subjective Global Assessment (SGA) (67) is a technique for assessing nutritional status that relies exclusively on the physical examination and history to determine whether a patient is well nourished, moderately malnourished, or severely malnourished. This technique was originally validated in a population of surgical patients (67). Although it has been adapted for use in other diseases such as kidney and liver disease and cancer, it has never been validated with stroke patients. Some of the components of the evaluation may be less applicable to this population because they were developed to identify malnutrition associated with progressive gastrointestinal conditions before surgical intervention, whereas stroke represents a distinct event. The more general items, such as weight and dietary intake history, are likely to be more useful to the clinician than items such as the presence of ascites or a history of nausea and vomiting, which pertain more specifically to patients with significant gastrointestinal disorders.

A variation of SGA, the scored Patient-Generated Subjective Global Assessment (PG-SGA) (68), was adapted from SGA and has also been validated. This tool was designed specifically for patients with cancer and includes a more detailed history section. Items related to weight change, food intake, functional capacity, and gastrointestinal symptoms can be completed by the patient using check boxes. A physical examination is then performed by a health care professional. Each component of the PG-SGA is scored from 0 to 4 according to the impact of the symptom on nutritional status. The total score is used to identify patients at risk for malnutrition and to triage them for nutritional interventions, based on four categories. A global score based on the SGA classification system (i.e., A, B, or C) is also provided as an overall representation of the patient's nutritional state. Like SGA, the PG-SGA has not been validated for use in stroke survivors.

The MNA includes 18 items related to anthropometrics, dietary assessment, self-perceived health and nutritional state, mobility, medication, depression, and lifestyle (69). Items are scored from 0 to 1, 0 to 2, and 0 to 3. An overall score of less than 17 indicates malnutrition, 17 to 23.5 indicates risk of malnutrition, and 24 to 30 indicates normal nutritional status. Both the MNA-SF and the full MNA may be difficult to complete if the patient has cognitive or language deficits secondary to stroke. Also, as the tool was designed for use in geriatric patients, it may be less appropriate for use in younger patients.

In summary, the nutritional assessment of stroke patients is imperfect, affected by the lack of a gold standard or consensus with respect to the most appropriate method of assessment. There are limitations associated with almost all routinely used indicators of nutritional status, whether used alone or in combination. When evaluating the nutritional state of a patient who has sustained a stroke, the clinician is advised to incorporate the history, physical examination, and body weight, as well as objective and subjective biochemical and anthropometric data. The use of serial assessments is encouraged to monitor the nutritional status of patients over time (see Table 34.2 for examples) and to evaluate the response to nutritional interventions.

NUTRITIONAL INTERVENTION STRATEGIES

The major diet strategies for patients undergoing rehabilitation for stroke are dysphagia diets, enteral feeding, high-energy (-calorie) and high-protein diets, energy-reduced diets, diabetic diets, low-saturated-fat diets, low-sodium diets, and high-fiber diets.

Dysphagia Diets

The word *dysphagia* is derived from the Greek words *dys*, meaning "difficult," and *phagein*, meaning "to eat." If not diagnosed and treated, dysphagia can lead to loss of the basic pleasure of eating, impaired nutritional status, or death caused by aspiration pneumonia (70,71). The diagnosis and treatment of dysphagia in patients who have experienced a stroke are discussed in Chapter 11. This section outlines the various dietary—oral and enteral—options available to the stroke patient with dysphagia.

Prescription and Implementation

The approach to the treatment of dysphagia is often multidisciplinary, with the team including nurses, speech–language pathologists, dieticians, and occupational therapists (72). Signs and symptoms of dysphagia observed during and between meals are given in Table 34.5. Stroke patients should be screened initially for swallowing difficulties by a nurse, and those suspected of being dysphagic should be referred

TABLE 34.5 Signs and Symptoms of Dysphagia During and Between Meals

- Drooling, excessive secretions
- Excessive tongue movement, tongue thrusting, or spitting food out of mouth
- Poor control of tongue
- Facial weakness
- Pocketing of food in cheek, under tongue, or on hard palate
- Slurred speech
- Coughing or choking while eating[a]
- Regurgitation through nose, mouth, or tracheostomy tube
- Wet, gurgly voice after eating or drinking, or frequent clearing of throat
- Hoarse or breathy voice
- Complaints of food getting stuck in throat or chest
- Delay or absence of laryngeal (Adam's apple or thyroid cartilage) elevation with swallowing
- Recurrent pneumonia (owing to aspiration)
- Prolonged chewing or eating time
- Reluctance to consume particular food consistencies or to eat at all
- Poor dentition, poor dental hygiene, or dental caries
- Breathing difficulties while eating
- Multiple swallows with single bite
- Effortful swallowing, gulping
- Unexplained weight loss
- Report of dysphasia

[a]Caveat: Aspiration very commonly occurs without coughing. The presence or absence of the gag reflex does not indicate whether the swallowing reflex is intact.

Source: From Refs. (70,72,73).

to a speech–language pathologist for assessment. Speech–language pathologists have extensive training in swallowing disorders. It is within the scope of practice in some jurisdictions for dieticians who have received advanced training to perform screening and dysphagia assessments as well (74). A bedside clinical assessment is usually performed first if the patient is alert and sufficiently conscious to participate. A videofluoroscopic examination (called a videofluoroscopic swallowing study [VFSS] or modified barium swallow [VFMBSS]) may be performed if there is uncertainty with respect to clinical management. Based on the results of these assessments, diet recommendations are made, which usually include modification of solids and liquids. The clinical dietician helps ensure adequacy of energy, macro- and micronutrients, and fluid, and assesses indicators of nutritional status; he or she may also recommend the type, rate, and route of enteral feeding. Nursing staff may assist or supervise the patient at mealtimes. Where possible, this can be done in a common dining room to enhance the social atmosphere and allow for monitoring of eating difficulties, such as coughing, choking, or food pocketing. The occupational therapist can provide recommendations for feeding techniques, upper-extremity positioning, and adaptive equipment to assist with mechanical aspects of feeding. The physical therapist can help determine any requirements for external support during feeding, such as positioning of the bed and wheelchair, and can aid with implementing swallowing strategies (72).

Types of Dysphagia Diets

Dysphagia diets are characterized by modifications of the texture of food and viscosity of fluids. The goal of the diet is to reduce the risk of aspiration and its possible sequela (pneumonia) by facilitating a safer swallow. Dysphagia diets are individualized according to the degree and site of the oral–pharyngeal impairment. Solids may be puréed, ground/minced, or soft/moist (72,73). The puréed diet includes mashed or blenderized foods that are smooth, dense, and homogeneous, with a pudding-like consistency. The minced (pieces up to ¼") or ground texture diet includes soft foods that are chopped and moist enough to form a bolus (for example, shepherd's pie) but require little chewing. The soft/moist diet includes easy-to-chew "bite-sized" foods such as minced, diced, or tender thin-sliced meats. Adequate chewing and dentition are necessary. Patients with dysphagia at the mild oral and/or pharyngeal phase would benefit from this diet; however, tolerance to mixed textures should be assessed (72,73).

Thin fluids are difficult for the dysphagic patient to control, as they can enter the pharynx prematurely and leak into the airway (72). Thicker fluids can be sensed and controlled more readily. Thickened fluid viscosities generally vary from those of nectar to honey to spoon-thick (73). Commercial prethickened products are available. Thin liquids are most often thickened with commercially prepared starch-based products, although other food ingredients such as skim milk powder, puréed fruit, or infant cereal may be used. It is important that food items maintain their thickness until swallowed. For example, ice cream must be held at a sufficiently cold temperature to maintain its thick consistency.

Dysphagia diets are nutritionally adequate, provided that patients consume sufficient quantities to meet their energy requirements. Regular consultation with a registered dietician is essential. Patient compliance and acceptance of the diet are known to be poor, and many institutions provide thickened, high-calorie, high-protein supplements as a standard component of the dysphagia diet. For this reason, the diet should be as liberal as possible, both for psychological reasons (75) and to enhance palatability. Swallowing status should be reassessed frequently enough to avoid needless dietary restrictions.

Enteral Feeding

In cases where the patient is unable to meet his or her nutritional requirements by mouth for a prolonged period, regardless of diet type, or if the risk of aspiration is high owing to dysphagia, enteral nutrition should be considered. By far, the greatest number of patients receive enteral nutrition because of unsafe swallowing. During the transition from enteral to oral intake, both types of feeding may be provided, with the enteral portion gradually being decreased as the oral portion is increased. Nonoral feeding may be discontinued once the adequacy of oral intake has been established.

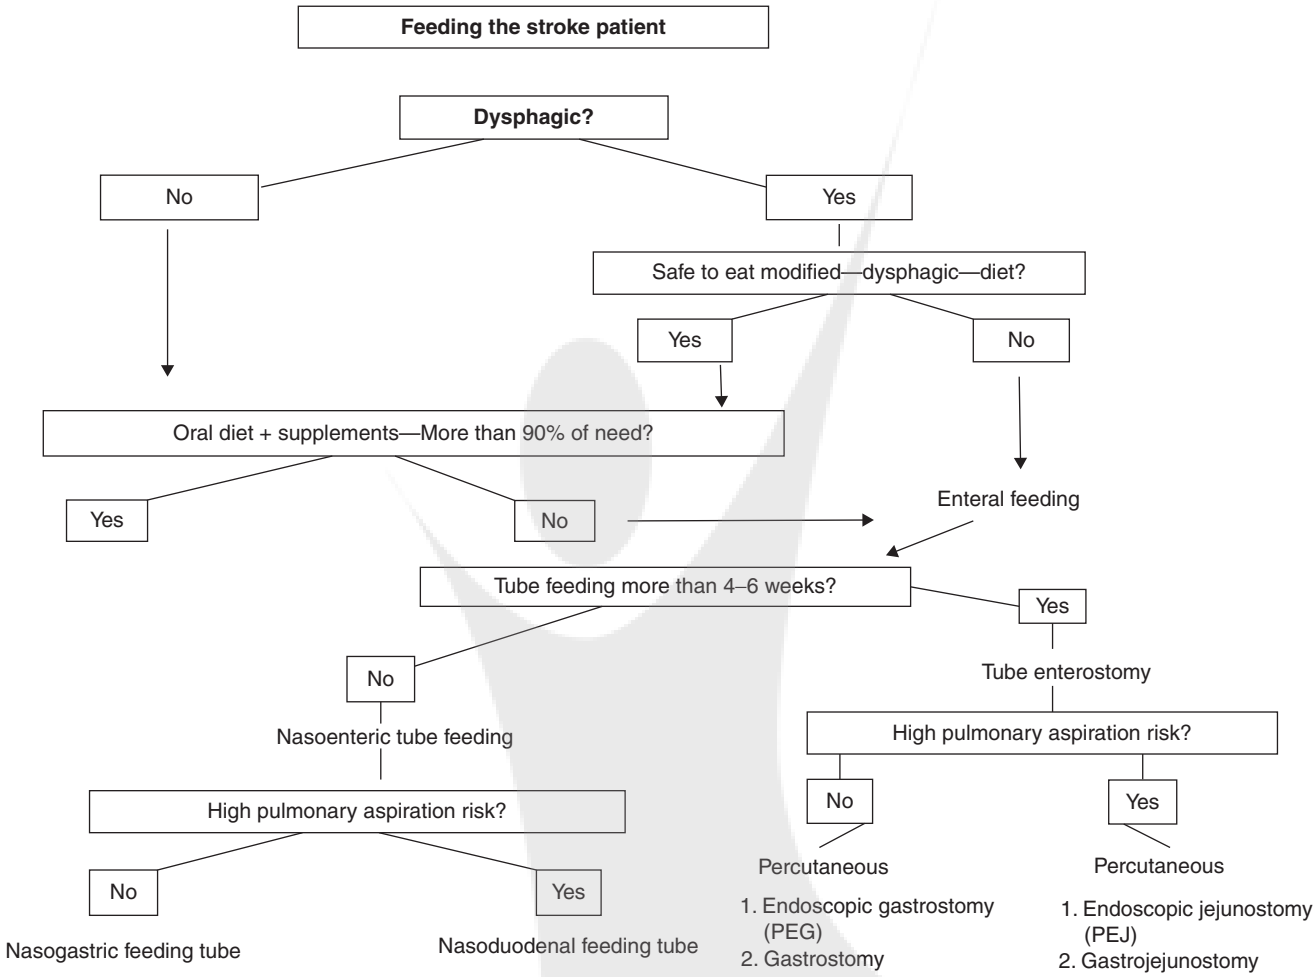

FIGURE 34.1 Algorithm for determining the optimal type of enteral feeding.

Although most patients recovering from stroke are potential candidates for nonoral feeding, it is contraindicated in those without a functional gastrointestinal tract (e.g., because of gastric or intestinal obstruction or paralytic ileus) and those with intractable vomiting or severe diarrhea. The choice of feeding tube and the route of access are dictated by the patient's medical conditions and the expected length of use. An algorithm for determining the optimal type of feeding is given in Figure 34.1. This flowchart takes into account the adequacy of oral intake, anticipated duration of enteral support, and risk of aspiration.

Enteral Formulations

Although enteral formulas vary in their energy density, osmolality, and molecular form of the substrates, most stroke patients do well with a standard polymeric formula (1.0–1.2 Kcal/mL). These nutritionally complete formulas can be titrated to meet patients' energy and protein requirements. Patients with impaired renal function, compromised pulmonary function, or diabetes can be given specialized formulas when required. A clinical dietician should be consulted for advice on the management of patients who are being fed enterally.

Routes of Access

Feeding tube access can be achieved through either nasoenteric or enterostomy routes. Figure 34.2 illustrates the location of these sites. Nasoenteric feeding includes nasogastric (tube from nose to stomach, which is, by far, the most common), nasoduodenal (tube from the nose through the pylorus and into the duodenum), and nasojejunal (tube from the nose through the pylorus and into the jejunum, usually placed radioscopically) feeding. The latter two are seldom used in patients with stroke. Nasogastric tubes were not found to affect swallowing in Japanese or German populations (76,77). Enterostomy tubes can be inserted percutaneously or, less frequently, surgically. Common routes include the prepyloric gastrostomy and postpyloric jejunostomy. A gastrostomy involves tube placement into the stomach. Tube size and techniques vary. Jejunostomy involves the creation of a jejunal stoma that can be catheterized intermittently via needle catheter placement or direct tube placement. This, too, is performed only rarely in the stroke patient. The rationale for wanting to deliver tube feeding to the stomach is that it is more "physiologic." Patients with severe reflux, however, may benefit from postpyloric tube insertion to prevent tube-feeding-related aspiration.

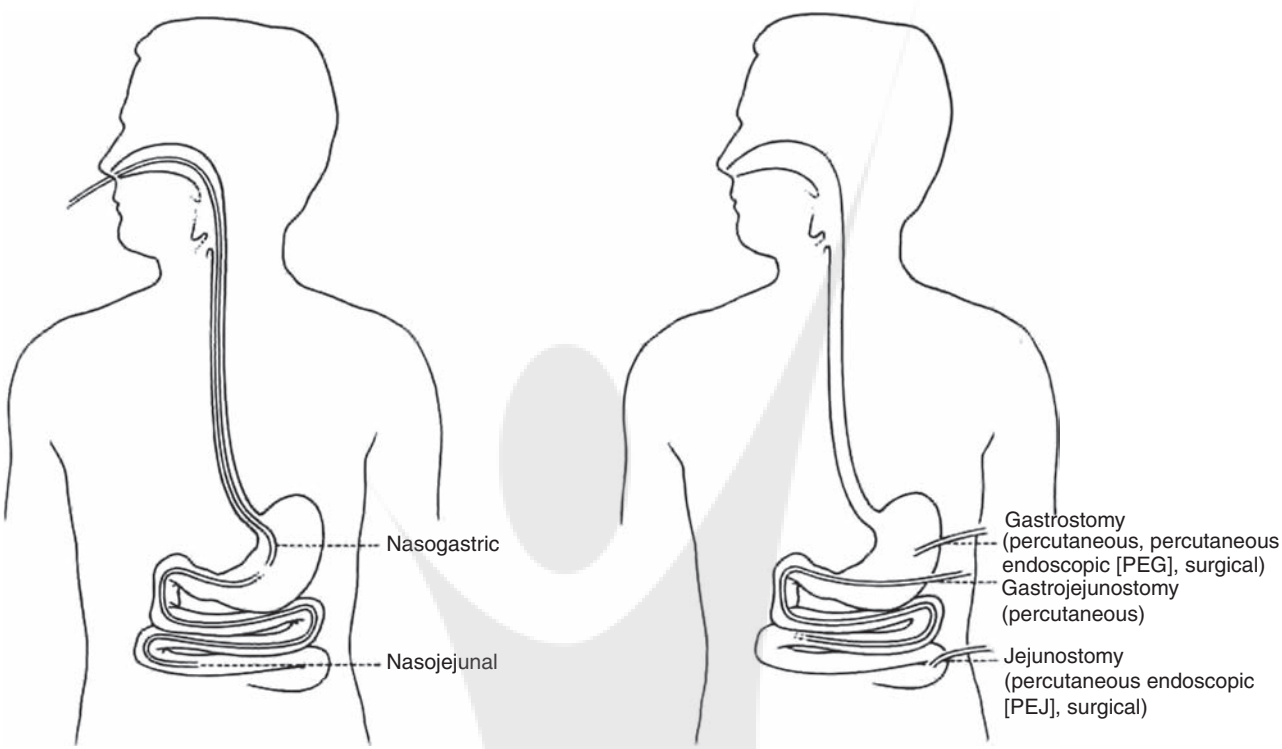

FIGURE 34.2 Common enteral feeding access routes.

Source: Reprinted from *Principles of Neurologic Rehabilitation*, edited by Richard B. Lazar, by permission of The McGraw-Hill Companies.

Percutaneous endoscopic gastrostomy (PEG) and jejunostomy are procedures in which the feeding tube is inserted percutaneously under endoscopic guidance into the stomach or jejunum. The tube is secured by rubber bumpers or an inflated balloon catheter. These procedures are often performed with local anesthesia by a gastroenterologist. Percutaneous gastrojejunostomy involves the percutaneous insertion of a guidewire followed by a feeding catheter into the jejunum via the stomach. This procedure is usually performed by a radiologist under fluoroscopic control, and only local anesthetic is required. Often, local experience and expertise will determine which method of tube insertion is chosen.

Methods of Administration

Feeding formula can be delivered by gravity drip or, for better volume accuracy and tolerance, infusion pump set at a constant rate. Feeding may be provided on a continuous basis, usually over a 24-hour period. This method reduces the possibility of pulmonary aspiration.

Intermittent infusions are equally divided feedings infused at intervals four to six times throughout the day (78). They can be given by gravity drip over 30 to 60 minutes or by infusion pump. This type of feeding frees patients from tube-feeding equipment between feedings, so it is convenient for those undergoing active rehabilitation and those at home. It is also used in patients who are not critically ill. A cyclic method of intermittent infusion may be used wherein the tube feeding is administered at a high infusion rate over 8 to 20 hours. This may be helpful in the transition from tube feeding to oral diet, with tube feeding delivered at night and oral diet ingested by day (78).

Bolus feeding involves the rapid delivery of a feeding into the gastrointestinal tract by syringe or funnel. It is suited to rehabilitating patients who are receiving gastric feeding in a rehabilitation facility or at home. Feeding is completed over a short period, for example, 200–300 mL over 5 to 15 minutes, followed by a flush of 30 mL of water. The advantages are freedom of movement and breaks from feeding. Disadvantages include risk of aspiration, volume intolerance, and delayed gastric emptying (78). Similar volumes of enteral feeding delivered into the jejunum are usually not tolerated by the stroke patient.

Feedings should begin with a full-strength formula, usually at a rate of 25 mL/h and advanced by 25-mL increments every 4 hours to goal rate, as tolerated (78). The residual gastric volume is often monitored every four hours when continuous feeds are administered. Occasional episodes of high-residual volume do not necessarily indicate that there is dysfunction. However, if a high volume (e.g., 200 mL) occurs frequently and is associated with symptoms of cramping, the rate of formula administration should be reduced. Once the problem has resolved, rate increases are then slowly attempted. Diarrhea, a common problem, can be treated by slowing the rate of infusion or adding loperamide or codeine to the formula. In some cases, changing the formula (for example, to a lower fat content) proves effective.

Alternative methods of administering and/or delivering enteral feeding have been proposed. These include transnasal PEG placement without sedation (79); use of a novel nasal loop to better secure a nasogastric tube (80); and feeding intermittently via an oroesophageal tube, whereby enteral fluids, for example, are introduced into the esophagus, with the patient often placing the tube himself or herself (81). Beavan et al. (82) performed a trial of a looped nasogastric tube to improve delivery of feedings and fluids. Key findings were that the nasogastric tube group required fewer tubes and had less minor nasal trauma and fewer electrolyte disturbances than the control group. The authors of this chapter do not have experience with this technique. In general, these studies were small, and, although interesting, there are no apparent standards for the use of the methods described.

Complications

Complications associated with tube feeding can usually be detected and controlled through attentive monitoring. Complications largely fall into three categories: mechanical, gastrointestinal, and metabolic (78). Mechanical complications include tube blockage, local skin infection at the site of tube insertion, and inadvertent insertion in the trachea or lung parenchyma. Nasopharyngeal area erosion with prolonged nasogastric tube feeding can occur, especially if poor taping technique is practiced. PEG tube insertion can lead to burying of the bumper subcutaneously at the abdominal insertion site (buried bumper syndrome), causing local pain and swelling (78). Gastrointestinal complications include peritonitis and free air in the abdomen. Gastrointestinal hemorrhage is also a potential complication of tube feeding (16). Pathophysiological changes of the gastrointestinal tract in ischemic stroke have been reviewed (83). A few studies indicate increased incidence of hemorrhage or decreased transit time, but the area warrants further study. Pruthi et al. (84) recently studied the incidence and independent predictive factors of tube-associated gastrostomy complications including deaths in six Canadian hospitals. Of 418 patients, 102 (24%) had complications, including peristomal cellulitis, tube dislodgement or inadvertent removal, tube blockage, peritonitis, and pressure necrosis at the skin insertion site. In multivariate analysis, complications were more likely to occur in patients with radiological percutaneous tubes and after insertions by physicians with the lowest procedure volume.

Metabolic complications in tube-fed populations are often related to fluid balance, electrolyte deficiencies, and hyperglycemia. Glycemic control in stroke rehabilitation patients being fed enterally can be difficult, especially when the patient requires insulin, and enteral feeding is being provided largely at night to avoid interference with daytime rehabilitation activities. Carbohydrate-reduced formulas may prove useful for diabetic patients. The authors have found that the common practice of providing two-thirds of the subcutaneous insulin in the morning and the remaining one-third in the evening must be reversed. Kerr et al. (85) discussed a structured enteral feeding program for diabetic patients with a specific subcutaneous insulin regimen, which precedes three enteral feedings per day. Dehydration, another metabolic complication, may result if daily fluid requirements are not met. On average, standard polymeric formulas contain 85% free water; therefore, additional water must usually be provided to meet patients' needs. Water may be added directly to the feed or may be provided by way of tube flushes. If fluid losses are excessive because of fever, diarrhea, or vomiting and fluids are not replaced, dehydration may also result. Patients who present with preexisting malnutrition resulting from a prolonged period of poor intake and those who have had food withheld for an extended period of time may be at risk for refeeding syndrome, a potentially life-threatening complication that can occur with rapid introduction of carbohydrate-containing feedings. In this syndrome, acute decreases in serum levels of potassium, magnesium, and phosphorus can appear, owing to intracellular shifts of electrolytes, with possible resultant cardiac, neuromuscular, and other dysfunction (86).

A comprehensive listing of potential adverse reactions to tube feeding, together with potential causes and management, is available from the American Society for Enteral and Parenteral Nutrition (78).

Home Tube Feeding (87)

Several factors should be considered before discharging a patient on a home tube-feeding program. The experience can prove overwhelming for patients and their families. The cognitive and functional ability of the patient or caregiver should be assessed to ensure that all tube-feeding-related tasks can be carried out correctly and safely. The compatibility of tube feeding with the home-life schedule should also be considered. The availability of funding to cover, or partly cover, the cost of formula, infusion pump (if required), and associated supplies also must be explored. Finally, the availability of support personnel and a mechanism for home monitoring, follow-up, and support must be established.

Patient instructions should include the following, with written guidelines provided:

- Proper sanitation techniques for preparation
- Storage and infusion of formula
- Proper sanitation of equipment
- Rate and strength of feedings
- Time of administration
- Body position and length of time to remain in position
- Formula temperature
- Maximum hanging time
- Maximum time to keep open formula
- Amount of fluids to flush between feedings
- How to deal with complications
- Care of the tube and exit site

The reported incidence rates of death, aspiration pneumonia, and complications associated with home enteral nutrition vary among studies but are generally low (88–90). In time, most patients are able to resume a regular diet.

High-Energy (High-Calorie), High-Protein Diets

Patients with preexisting malnutrition and those at nutritional risk owing to poor intake may benefit from a high-energy, high-protein diet. The rationale behind this diet is that the augmented protein intake supplies amino acids required for the building, maintenance, and repair of body tissue. Supplemental calories are needed to spare the protein from being used as a source of energy. At the same time, the energy level is increased to maintain body weight or promote weight gain.

High-energy/high-calorie supplements, which come in many forms (liquids, bars, and puddings) and flavors, may be offered. For dysphagic patients, liquid supplements can be thickened so that they can be consumed safely. Supplements may be given at mealtime along with reduced portions or between meals. The medication pass supplement program (med-pass), which provides a nutrient-dense supplement (60 mL four times daily), has been shown to be efficient (91,92). Most oral supplements contain approximately 250 to 300 Kcal and 8 to 13 g of protein per 250 mL serving. Efforts should be made to provide a pleasant atmosphere for inpatients and to offer appealing food that reflects the patient's food preferences. Six small meals per day, including snacks and nutritional supplements, may augment energy intake (93).

Energy-Reduced Diets

Although some patients may develop malnutrition following stroke, weight gain and obesity are encountered more frequently. *Obesity*, defined as body mass index greater than 30, adversely affects functions such as transfers and ambulation and places extra stress on caregivers. Furthermore, following stroke, patients' mobility and, consequently, energy requirements are often reduced.

Excess weight is treated by a reduction in total energy intake, whereas other nutrient requirements remain age-appropriate (39). Behavior modification, such as serving smaller portions, serving food on a smaller plate, instructing the patient to eat slowly (as it takes approximately 20 minutes to feel a sense of satiety), and increasing activity appropriate to the medical condition, may help the patient reduce energy intake. In addition, strategies to deal with contributing factors such as boredom and depression should be developed. Medications, such as antidepressants and steroids, should also be evaluated, as increased appetite may be a side effect (94). Unfortunately, weight loss can be difficult to achieve following stroke. A collaborative team approach, which may include a psychologist and recreation therapist, may be helpful.

Diabetic Diets

Diabetes is a risk factor for stroke. Many patients enter the rehabilitation program with a diagnosis of diabetes and require special dietary attention. Promoting good glycemic control during the hospital stay will support the patient in his or her daily physical and mental activities. Stroke rehabilitation is also a good time to provide patients with additional diabetic education and to connect them with appropriate community resources.

Low-Saturated-Fat Diets

After a stroke, many patients are prescribed medication to lower their blood lipid levels. In conjunction, a diet low in fat, particularly saturated and trans fats, is introduced to maximize achievement of the blood lipid targets.

Low-Sodium Diets

Following stroke, a therapeutic sodium-restricted diet may be used to manage hypertension. The level of sodium restriction will depend on hypertension severity and treatment; it generally varies between 1500 to 2400 mg per day. For the control of hypertension, a diet high in fruits and vegetables to provide potassium and high in low-fat or fat-free dairy products to provide calcium and potassium is also recommended. Alcohol should be restricted to not more than two drinks per day for men and one drink per day for women. A drink is equal to 150 mL of wine, 355 mL of beer, or 45 mL of liquor. This approach is sometimes called the DASH (Dietary Approaches to Stop Hypertension) diet (95,96).

High-Fiber Diets

Constipation may be associated with stroke. Reduced mobility, lack of dietary fiber, and inadequate fluid intake are the most common reasons. The degree of hydration should be assessed. Fluid intake should be recorded, and urine output and color noted. Fluid intake of at least 1500 mL (six 8-ounce glasses) should be encouraged, provided there is no medical reason for fluid restriction (97). When commercial fiber supplements (for example, psyllium) are used, additional fluid intake is recommended. Dietary sources of insoluble fiber are particularly effective in increasing fecal bulk (98), and the clinical dietician can advise on this. Insoluble fiber is found in many fruits and vegetables, wheat bran, and products such as whole grain breads, pastas, and brown rice. Stool softeners such as docusate sodium, along with judicious use of oral and rectal laxatives, are helpful adjuncts in the treatment of constipation. Exercise opportunities should be provided. Attention to the urge to defecate and the establishment of a routine schedule for toileting should be encouraged. Constipation may be a side effect of certain medications (94), such as antidepressants and narcotic preparations.

DEHYDRATION AND FLUID REQUIREMENTS

Although the fluid requirements of elderly people and those of younger adults are similar, elderly people are particularly vulnerable to dehydration. Therefore, attention to intake and output data is critical in elderly people (99). Besides dysphagia, reasons for underhydration in elderly people include

a blunted thirst mechanism, renal changes, and decreased mobility to reach a fluid source (99,100). In addition, loss of lean body mass with aging contributes to decreased total body water as a proportion of body weight, as lean muscle mass holds 40% of total body water (100).

Dehydration after stroke is associated with poor outcomes (101,102), yet the risk of dehydration in stroke patients is often underdiagnosed, particularly in those with dysphagia who are receiving all their nutrition orally (103,104). For these patients, thin fluids—the most difficult food item to manipulate and control—are often restricted or replaced by those that are thickened. Dislike for the taste or texture of thickened fluids, dependence on others to provide and/or help consume fluids, and fatigue are all factors that increase the risk of dehydration (105).

In a prospective study on inpatients with dysphagia, the greatest contribution to oral fluid intake was from food, not beverages, whether the patient was receiving diet alone or diet with enteral or parenteral fluid support (106). Thus, providing fluid-dense foods rather than thickened beverages may increase the fluid intake of those with dysphagia. Supplemental enteral or parenteral fluid may be necessary to achieve minimum daily fluid requirements (20 to 40 mL/kg of body weight, or 1.0 to 1.5 mL/Kcal of energy expended) (99). For stroke rehabilitation inpatients, physicians should consider ordering overnight intravenous fluid administration or hypodermoclysis.

There is no "gold standard" measure of dehydration. The urea:creatinine ratio is the best indicator of hydration routinely available; however, it is not a specific measure. There are conflicting findings regarding the usefulness of urine specific gravity as an early indicator of hydration status (107,108). Further research is needed to develop a practical tool for the early detection of dehydration in stroke patients.

THE FOOD TRIALS: FEEDING INTERVENTION STUDIES IN PATIENTS WITH STROKE

In 2005, *The Lancet* published the findings of the Feed or Ordinary Diet (FOOD) trials, a long-awaited series of three related large randomized controlled trials (15,16). The investigators attempted to provide definitive answers to three clinically relevant questions regarding the nutritional management of patients in the acute poststroke period:

1. Does routine oral supplementation decrease the number of patients having a poor outcome and patients requiring enteral feeding?
2. Do those who receive early feeding have better outcomes than patients whose feeding is delayed?
3. Do patients with PEG tubes have better outcomes than those with nasogastric tubes?

The trials enrolled 5033 patients, but they were stopped before target numbers were reached owing to lack of funding.

Unfortunately, the trials led to limited new findings of practical use to clinicians. A few highlights include:

1. Routine supplementation does not reduce the odds of a poor outcome for all patients, regardless of nutritional state, but supplementation is still recommended for malnourished patients and those perceived to be at nutritional risk.
2. There is a greater risk of gastrointestinal hemorrhage with placement of any type of feeding tube but particularly with the use of nasogastric tubes. This finding has limited clinical applicability because the long-term use (i.e., more than four to six weeks) of a nasogastric tube for enteral nutrition of stroke patients is not practical; thereafter, a PEG tube would be recommended.

CONCLUSION

The high prevalence of malnutrition in stroke patients on admission to a rehabilitation service (9,12,18) suggests that the decline in nutritional status develops as a consequence of stroke. In turn, malnutrition may adversely affect recovery from stroke. In malnourished stroke patients, poorer functional outcome and prolonged rehabilitation stay have been reported (2–4). Therefore, the clinical goal is to prevent or to identify and treat inadequate nutritional states. Nutritional evaluation methodology, however, is far from a perfect science, and numerous types of evaluations are described. Validation in stroke populations is lacking.

The nutritional care of patients who have sustained a stroke is a relatively new field. Although much research in this area has occurred, there is room for further evaluation of the dietary needs of specific stroke diagnostic groups and of optimal methods of assessment, nutritional delivery, and therapy. Attending to nutritional issues is an important step toward helping stroke patients achieve their full rehabilitation potential.

Bladder and Bowel Management After Stroke

Sylvia A. Duraski, Florence A. Denby, and J. Quentin Clemens

Of all the functional deficits experienced by the survivor of a stroke, incontinence is often an overlooked consequence, despite its huge impact on rehabilitation and recovery. Over the years, health care providers and researchers have concluded that those who experience urinary incontinence (UI) after stroke have a poorer prognosis, decreased functional outcomes, and an increased risk of institutionalization (1–6). This does not include other negative consequences that can result from UI, such as depressed mood, social isolation, increased risk of skin breakdown, infection, and falls with or without injury.

BLADDER MANAGEMENT

Urinary Incontinence

Prevalence

The prevalence of UI after stroke varies depending upon when the survivor is assessed. In the acute-stroke survivor, the prevalence of UI has been documented to range between 32% and 83% (1–6). Brittain et al. (7) specifically looked at nine studies conducted to identify the prevalence of UI after stroke. The studies showed that between 32% and 79% of stroke patients at admission experienced some form of UI. The huge variance in prevalence could be the result of two factors. One is the varying times between the onset of stroke and when the survivor is first assessed for incontinence. Some studies assessed the stroke survivor within days of the onset of the stroke, whereas others assessed the survivor from three months to two years after stroke. Still other studies did not list the time from stroke onset. The second possible factor for the large variance in prevalence of UI after stroke is the lack of information about the presence of prestroke UI. Borrie et al. (8) conducted one of the few studies to identify that 17% of their subjects were incontinent prior to stroke.

The prevalence of UI after stroke is significant even weeks after onset. Ween et al. (9) found that 41% of the poststroke survivors were incontinent on admission to rehabilitation. However, the prevalence of poststroke incontinence decreases over time. In 135 stroke survivors studied over a 6-month period, Brockelhurst and his colleagues (10) showed that 51% of their subjects were incontinent of urine during the first year after stroke. Incontinence resolved 8 weeks after stroke in 55% of the subjects, and by 6 months, 80% of stroke survivors were continent. Borrie and his colleagues (8) similarly demonstrated a downward trend in the number of incontinent survivors over time. In 151 patients with 154 strokes, 55% were incontinent after 1 week, 32% were incontinent after 4 weeks, and 21% were incontinent after 12 weeks. Brittain et al. (11) cited rates of UI in hospitalized stroke patients between 32% and 79% at the time of admission, 25% and 28% at discharge, and 12% and 19% several months after onset. Patel et al. (3) reported that in 235 stroke survivors, 40% were incontinent on initial assessment, 19% at 3-month follow-up, 15% after 1 year, and 10% after 2 years. The method used to manage the incontinence was not identified in any study. Therefore, it is unknown if any particular intervention or if natural recovery led to the decrease in UI.

Prognostic Factors

Numerous studies have reported on UI and its prognostic factors in stroke mortality and recovery. Wade and Hewer (12) showed that incontinence had an overall predictive value of 78% for death. Nakayama and his colleagues (5) looked at 935 acute-stroke patients admitted to the hospital over a 19-month period. Of those with some degree of UI on admission, 68% died before discharged, and 25% died within 6 months of discharge. Brittain and her colleagues (7) concluded that 52% of the patients who experienced UI were dead within 6 months, compared to only 7% who were continent.

UI may affect functional status and recovery in rehabilitation. Jongbloed (13) reviewed 33 studies conducted between 1950 and 1985 to identify factors predictive of improvement in stroke survivors. He concluded that the presence of UI on admission was an adverse prognostic factor for functional outcome (13). Wade and Hewer (12) and Ween (9) also found that UI is an important prognostic factor affecting rehabilitation. In these studies, UI was associated with a more severe stroke, an inability to communicate, an inability to transfer, fecal incontinence (FI), and a greater risk of infection. Other studies confirm that UI is a strong predictor of functional recovery (5,12). In stroke survivors younger than 75 years of age, UI was the best single predictor of disability at 3 months.

Risk Factors

It is unclear whether UI results from time lost from therapeutic treatment; the survivor's advanced age or gender; severity, location, and type of stroke; and/or cognitive, language, or functional impairments (14). In 1987, Reding and his colleagues (14) documented possible comorbid reasons for UI in the stroke survivor. This study concluded that there was an association between UI and the presence of aphasia, or the combination of hemiplegia, visual association, and cognitive impairment and incontinence. Gelber et al. (14) assessed 51 patients with unilateral ischemic hemispheric strokes admitted to a neurorehabilitation unit. They concluded that the presence of aphasia, cognitive impairments, and poorer functional status strongly correlated with incontinence in the stroke survivor (14).

Owen et al. (15) performed a retrospective review of 225 patients admitted to a rehabilitation center in a tertiary medical center during a 14-month period of time. Their findings compared characteristics of incontinent stroke survivors to those of continent stroke survivors. More than 90% of subjects who remained incontinent experienced dysphagia, lower functional independence measure (FIM) scores, and significant impairments in orientation to time, memory, and problem solving. Nakayama et al. (5) found that patients with initial UI were older, female, and had more comorbid conditions. Ween et al. (9) concluded that the incontinent group in his study had significantly lower admission average FIM scores (43 vs. 75) when compared with that of the continent group. In a nonrandom sample of 45 continent and incontinent stroke survivors, Gross (16) found that the group that remained incontinent had significantly lower admission and discharge FIM scores. Although the incontinent group improved in all measures in this study, they still had lower mean FIM scores (16). All of these researchers agreed with previous studies showing that stroke survivors who were incontinent experienced more disabling strokes. Though incontinent stroke survivors do make functional gains, those gains are not as great as in the continent stroke survivor. This not only impacts functional outcomes but also affects the length of hospital and rehabilitation stays, as well as discharge destination.

Discharge Destination

Whether the result of UI alone, or combined with the severity of stroke or other medical comorbidities, numerous studies have documented that discharge destination for stroke survivors is negatively affected. Van Kuijk et al. (17) studied a cohort of 143 stroke survivors admitted for postacute rehabilitation. They showed that in the incontinent group, 8 survivors went home and 6 went to nursing homes, whereas in the continent group, 119 went home and 8 went to nursing homes. They found that the difference in discharge destination was statistically significant, suggesting an association between UI and admission to a long-term nursing facility (17). Ween et al. (9) similarly found that of patients with UI on discharge, 61% went to nursing homes, compared to 18% of patients who were continent (9). Patel et al. (3) found that if stroke survivors remained incontinent over time, institutionalization rates were even higher. In one study that did not find a correlation between incontinence and discharge destination, the majority of patients in both the continent and incontinent group went home after discharge (16).

Neural Control of the Lower Urinary Tract

Components of normal lower urinary tract function include the storage of urine at low pressure without leakage (storage phase), interrupted by the periodic, voluntary expulsion of urine (voiding phase). These processes involve the coordination of the peripheral autonomic, somatic, and central nervous systems (18,19). Sympathetic autonomic activity promotes urine storage, whereas parasympathetic activity promotes voiding.

Preganglionic parasympathetic efferent neurons exit the spinal cord at S2–4 and travel in the pelvic nerve to ganglia located in the bladder wall. These parasympathetic fibers modulate detrusor muscle contraction. Sympathetic efferent fibers exit the spinal cord at T10–L2 and travel in the hypogastric nerve. Alpha sympathetic fibers modulate contraction of the urethral smooth muscle and bladder outlet, and beta sympathetic fibers inhibit parasympathetic activity to the detrusor muscle. Somatic efferent fibers exit from S2–4 and travel in the pudendal nerve to the striated urethral sphincter. These fibers modulate voluntary urethral sphincter contractions. Afferent fibers from the urethra and bladder are distributed throughout the pelvis in the pelvic, hypogastric, and pudendal nerves. Coordination of the bladder and urethral sphincter appears to be accomplished in the pons, as experimental electrical stimulation of the pontine micturition center (PMC) causes detrusor contraction and urethral relaxation (20). The PMC receives input from multiple areas, including the cerebellum, basal ganglia, thalamus, hypothalamus, and cerebral cortex. Signals from these areas provide inhibition of the PMC and allow voluntary expulsion of urine when socially appropriate.

When the bladder fills, stretch receptors in the bladder wall cause afferent signal transmission to the spinal cord. These signals result in increased sympathetic activity (contraction of the urethral sphincter and bladder neck) and decreased parasympathetic activity (detrusor muscle relaxation; Figure 35.1). When voiding is desired, cortical signaling triggers a switch from storage to voiding function. PMC activity then leads to a coordinated relaxation of the urethral sphincter (decreased sympathetic activity) and contraction of the detrusor muscle (increased parasympathetic activity; Figure 35.2). After completion of voiding, the storage phase resumes.

Detrusor muscle contractions are mediated by muscarinic cholinergic receptors in the detrusor muscle cell wall (21). Parasympathetic neurons release acetylcholine, which binds to muscarinic receptors and triggers an increase in intracellular calcium. This in turn triggers downstream intracellular processes that cause muscle contraction.

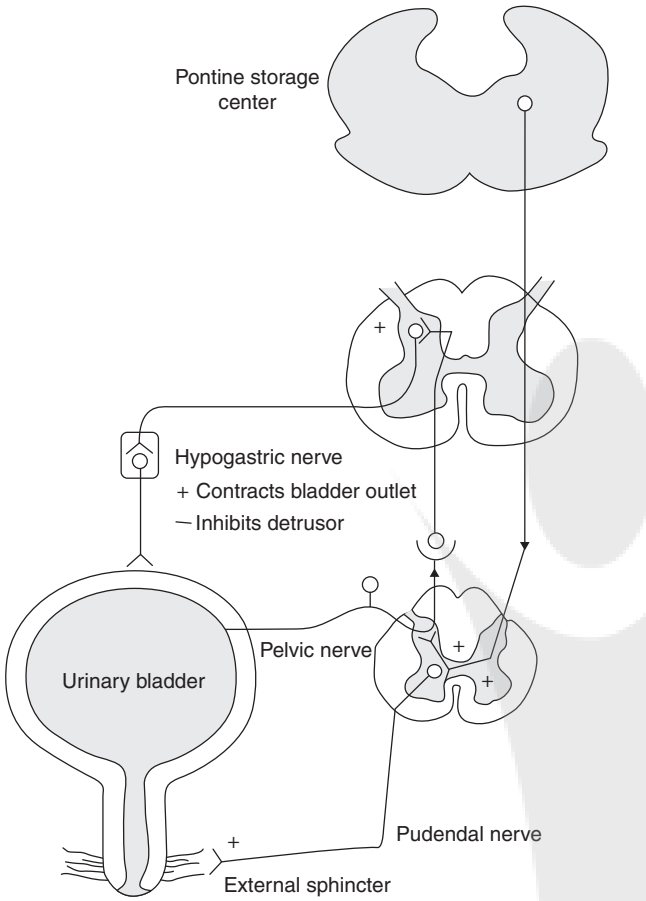

FIGURE 35.1 Storage reflex afferent signals from the bladder wall to the spinal cord result in relaxation of detrusor muscle and contraction of the bladder neck and urethral sphincter.

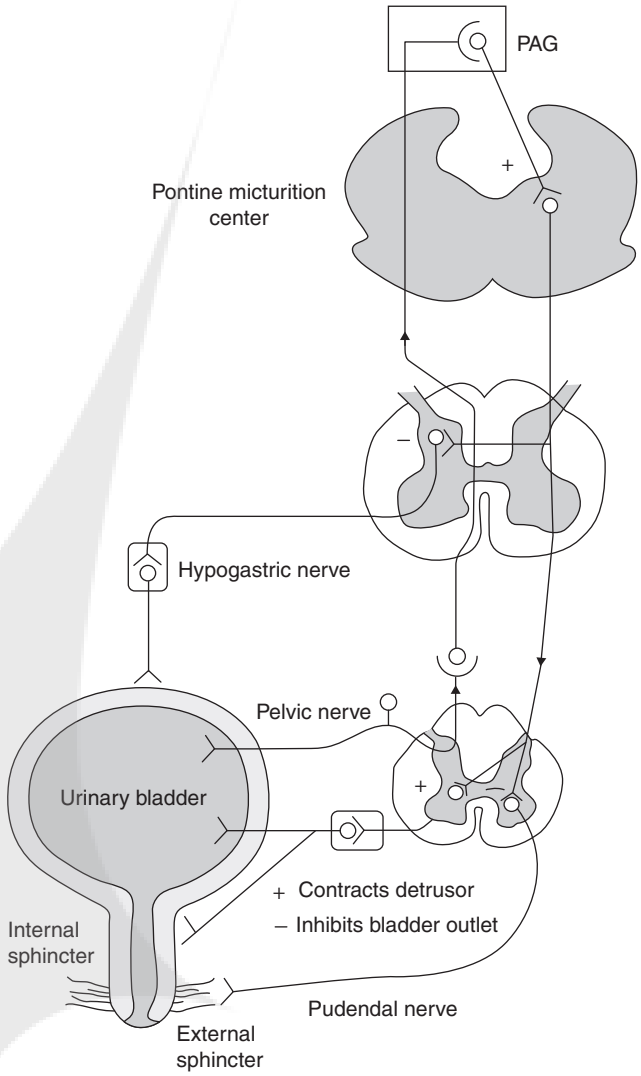

FIGURE 35.2 Voiding reflex cortical signaling leads to relaxation of the urethral sphincter and contraction of the detrusor muscle.

Classification of Voiding Dysfunction After Stroke

Researchers have concluded that the degree of voiding dysfunction after stroke is dependent upon the size, the location, and the time from onset of the stroke.

Early Phase

After the onset of stroke, areflexia has been documented as the most common detrusor dysfunction. Detrusor areflexia presents clinically in the stroke survivor as urinary retention or overflow incontinence, a problem of bladder emptying. Oftentimes referred to as "cerebral shock," this term is used to describe the loss of reflexes below the level of the lesion, much as "spinal shock" is used to describe what is experienced in someone with an acute spinal cord injury. The neurophysiology of cerebral shock is unclear (22). Some speculate that persistent areflexia in the stroke survivor may be the result of a lesion in an area of the brain that is responsible for voiding (23). Others believe that detrusor areflexia is caused by an impaired level of consciousness or a temporary detrusor failure resulting in overdistention (24).

Whatever the cause, many studies of detrusor activity after stroke have concluded that detrusor hyporeflexia immediately after the onset of stroke is common. Reports of the incidence of urinary retention after stroke vary and are estimated as high as 47% when survivors are assessed within 72 hours after the onset of stroke (25). Gelber and his colleagues followed 19 stroke survivors with unilateral ischemic stroke admitted to a neurorehabilitation unit. Urodynamic studies were performed on all of the survivors. Gelber concluded that bladder hyporeflexia occurred in the early phase of acute hemispheric stroke, with a gradual increase in bladder tone as the survivor recovered (14). In 1996, Burney and her colleagues followed 45 men and 15 women between the ages of 32 and 80 years of age 3 days after the onset of stroke. Forty seven percent (47%) of patients who were evaluated presented with retention and overflow incontinence. The cause of retention was reported to be detrusor areflexia (26). This study correlated the increased frequency of detrusor areflexia

with rapid assessment time from onset of stroke. Other studies varied in the amount of time from stroke onset to assessment. Those that assessed more chronic stroke survivors found less detrusor areflexia in cystometric testing.

One study found that a large number of those who experienced detrusor areflexia were diagnosed with lesions of the cerebellum, but no other study has been able to duplicate these results (26). Other potential causes of detrusor areflexia have been assessed. Several studies looked for other causes of urinary retention, such as urinary tract infections, anticholinergic medications, diabetic neuropathy, and benign prostatic hypertrophy. Given the average age of the stroke survivor, other factors may contribute to the retention. It has been estimated that approximately 50% of men by the age of 60 years and 80% of men by the age of 80 years have benign prostatic hypertrophy (BPH) (27). Some of the potential problems that also cause retention, such as BPH, may have existed prior to the stroke, but it is not until the stroke occurs that the individuals exhibit symptoms they can no longer manage. Most studies concluded that true detrusor areflexia with normal smooth sphincter function was common immediately after stroke. Smooth sphincter function is generally unaffected by stroke (22).

Late Phase

Just days to weeks after the onset of stroke, the most common detrusor dysfunction observed is hyperreflexia. The cause for this change is thought to be the result of the release of spinal micturition reflexes secondary to injury to the cerebral inhibitory centers of voiding (23). During this phase, the stroke survivor generally has intact sensation and presents with urgency, frequency, and urge incontinence as a result of the inability to suppress bladder contractions even at low detrusor filling volumes. This is a problem that can be categorized as a failure to store, secondary to bladder overactivity. Some studies demonstrate via cystometric testing that stroke survivors who are incontinent may have symptoms of hyperreflexia, not urgency. Tsuchida et al. performed cystometric studies on 39 stroke survivors. The time of stroke onset ranged from 11 days to 13 years. They concluded that urinary frequency or urge incontinence was the most commonly observed symptom in this population (28). Khan and his colleagues found that the most common cystometric finding in this group was detrusor hyperreflexia (29). Kong et al. studied 27 stroke survivors admitted to a rehabilitation center in a 3-month time period. Cystometric studies demonstrated that 11 patients had detrusor hyperreflexia, one patient had detrusor areflexia, and 15 patients had normal results (1). Of interest, the one patient who had detrusor areflexia was identified with the condition only 12 days after stroke.

Though it is still not completely understood what part of the brain controls voiding, lesions of the cerebral cortex, particularly the frontal lobe, have been identified as impairing the stroke survivor's ability to suppress detrusor contractions. Several studies concluded that cerebral hemispheric lesions most commonly cause detrusor hyperreflexia (14,26,29). Sakakibara et al. followed the urinary history and cystometric test results of 72 acute hemispheric stroke patients. They concluded that voiding dysfunction is common in frontal lesions and infarctions of the anterior cerebral artery territory (30). Burney et al., Khan et al., and Tsuchida et al. concluded that stroke lesions in the cerebral cortex, internal capsule, and basal ganglia resulted in detrusor hyperreflexia (26,28,29). Other researchers also concluded that there was no difference between voiding dysfunction and dominant and nondominant hemisphere lesions.

Incontinence has also been documented in stroke survivors with normal cystometric testing of the detrusor muscle. As there is no true voiding dysfunction in these stroke survivors, how is incontinence in this group explained? Health care professionals have concluded that neurologic deficits of the stroke contribute to incontinence (25). For example, motor deficits prevent the stroke survivor from getting to the bathroom for toileting. Sensory deficits interfere with the awareness of the need to void. Cognitive deficits interfere with remembering what to do to stay dry. Communication deficits interfere with the survivor asking for assistance with toileting.

Management

Initial management consists of supportive care and management of life-threatening sequelae of the stroke. It is common for an indwelling urethral catheter to be placed at this time. When the patient is medically stable, the catheter is removed and a voiding trial is begun. If the patient is able to void, postvoid residual volumes should be obtained. If the residual volumes are less than 100 mL after 2 to 3 voids, no additional measurements are needed. In a patient with an unsuccessful voiding trial, a urine culture should be obtained, and any bacteriuria should be treated with 3 to 7 days of appropriate antibiotics.

Cerebral Shock Phase (Failure to Empty)

During the cerebral shock phase (6–12 weeks), it is common for patients to fail decatheterization trials. When the catheter is removed, these patients may be unable to void, or they may void but only partially empty the bladder. Management of these patients consists of supportive care, medications, and catheterization.

Supportive Care

Intensive stroke rehabilitation is paramount, as immobility, polypharmacy, delirium, and pain may contribute to voiding dysfunction. As performance status improves, the ability to void also improves. Therefore, the timing of catheter removal must be individualized, as it may not be appropriate to remove an indwelling catheter in patients who remain severely disabled (e.g., cannot get out of bed).

Medications

Medications to decrease bladder outlet resistance and increase bladder contractility may be prescribed (Table 35.1). These

TABLE 35.1 Medications Used to Treat Lower Urinary Tract Symptoms

GENERIC NAME	TRADE NAME	DOSE	INDICATION
Bethanechol	Urecholine	5, 10, or 25 mg po TID to QID	Increase bladder contractility
Tamsulosin	Flomax	0.4 mg po qD	Reduce bladder outlet resistance
Alfuzosin	Uroxatral	10 mg po qD	Reduce bladder outlet resistance
Doxazosin	Cardura	1, 2, 4, or 8 mg po qD (must be titrated)	Reduce bladder outlet resistance
Terazosin	Hytrin	1, 2, 5, or 10 mg po qD (must be titrated)	Reduce bladder outlet resistance
Tolterodine	Tolterodine Detrol	2 mg po bid	Decrease urgency, frequency, and urge incontinence
Tolterodine	Detrol LA	4 mg po qD	Decrease urgency, frequency, and urge incontinence
Oxybutynin	Ditropan	5–10 mg po tid	Decrease urgency, frequency, and urge incontinence
Oxybutynin	Ditropan XL	5, 10, or 15 mg po qD	Decrease urgency, frequency, and urge incontinence
Oxybutynin	Oxytrol patch	3.9 mg—change twice weekly	Decrease urgency, frequency, and urge incontinence
Solifenacin	Vesicare	5 or 10 mg po qD	Decrease urgency, frequency, and urge incontinence
Darifenacin	Enablex	7.5 or 15 mg po qD	Decrease urgency, frequency, and urge incontinence
Trospium	Sanctura	20 mg po BID	Decrease urgency, frequency, and urge incontinence
Mirabegron	Myrbetriq	25 or 50 mg po qD	Decrease urgency, frequency, and urge incontinence

may help to decrease the duration of urinary retention. Reduction of bladder outlet resistance may be instituted with alpha-adrenergic blockers such as tamsulosin (Fomax), alfuzosin (Uroxatral), doxazosin (Cardura), and terazosin (Hytrin). These agents are used to treat bladder outlet obstruction caused by BPH and are commonly used as initial therapy in men with urinary retention. As alpha-adrenergic receptors are located in the bladder neck as well as the prostate, these agents could theoretically be used in both men and women, although very limited data exist regarding the efficacy on the latter.

After reducing bladder outlet resistance, bethanechol (Urecholine), an oral cholinergic agonist, theoretically may improve bladder contractility by stimulating cholinergic receptors in the bladder wall. However, data to support its clinical efficacy are very limited. Potential side effects include diarrhea, nausea, and bronchospasm.

Catheterization

Intermittent or continuous bladder catheterization must be used in patients who are unable to empty their bladders spontaneously. The choice of which method to use must be individualized based on the patient. Intermittent catheterization (IC) is often preferred, as it allows the clinician and patient to document voiding efficiency in an ongoing manner, and it appears to be associated with fewer infectious complications than those of indwelling catheterization (31). In the inpatient setting, nurses can perform IC, and the patient can attempt to void prior to each catheterization so that postvoid residual volumes can be assessed. Continuation of IC in the outpatient setting may not be possible, as the patient or caretaker may not be able or willing to perform the catheterization. If the patient is discharged with an indwelling catheter, arrangements must be made for follow-up visits for decatheterization trials.

Late Phase

Typically, urinary retention associated with cerebral shock is replaced by urgency, urge incontinence, and complete bladder emptying. This is felt to be caused by the loss of cortical inhibition of the voiding reflex (32). Therefore, the problem changes from a "failure to empty" to a "failure to store." Symptoms may be exacerbated by the loss of mobility that often occurs with a stroke, as more time may be required to get to the toilet. A moderate degree of urgency that is manageable for a healthy person may be quite troublesome for someone who requires more time to get to the toilet. Management of this problem is the same as for other patients with urgency and urge incontinence, although these treatments may be less effective following a stroke owing to the more severe nature of the symptoms.

Behavioral Therapy

Simple measures (use of a bedside commode, timed/prompted voiding, and avoidance of bladder irritants such as caffeine) may be used on virtually all patients. In studies using timed/prompted voiding, researchers have documented a decrease in UI from 80% to 20%. Unfortunately, those who use this therapy should know that one management method alone is not always sufficient or effective. This means that behavioral therapy for the management of UI may be very labor intensive and may require a great deal of time on the part of the caregiver to be effective or successful. A voiding diary completed by either the patient or caregiver also could identify the cause of incontinence. It is important that health care providers correctly identify the issue leading to UI because management techniques may differ based upon the cause (33). Other therapies, such as pelvic floor physical therapy, biofeedback, and electrical stimulation,

require a level of motivation and muscle control that may not be present in all patients. However, these measures may be quite effective in properly chosen patients (34).

Antimuscarinic Medications

These oral medications block the binding of acetylcholine to the muscarinic receptor, and result in decreased detrusor muscle contractile activity (35). Clinically, this receptor blockage causes a reduction in urinary urgency, frequency, and urgency incontinence. Examples of these medications include tolterodine (Detrol), oxybutynin (Ditropan, Oxytrol), solifenacin (Vesicare), darifenacin (Enablex), and trospium (Sanctura; Table 35.1). Side effects (e.g., dry mouth, constipation, dry eyes) are common, and clinical response is variable and unpredictable. The outcome appears to be better if these medications are combined with behavioral therapy (36).

Additional Diagnostic Tests

At times, patients may demonstrate incomplete bladder emptying or urinary retention that persists longer than would be expected after the initial cerebral shock phase. This may be because of a preexisting voiding dysfunction that was present prior to the stroke. In such patients, further evaluation with urodynamic testing and cystoscopy can be useful to determine if there is evidence of underlying bladder outlet obstruction (27). If obstruction is present, treatment with prostate resection can allow resumption of voiding, but these patients should be counseled that they may experience urge incontinence postoperatively.

Research Frontiers

The urgency and urge incontinence that often occur following a stroke can be more severe and difficult to treat than similar symptoms that occur in the absence of neurologic pathology. Two relatively new treatments that may be applied to these patients include sacral neuromodulation and detrusor injections of botulinum toxin.

Sacral Neuromodulation

Sacral neuromodulation was approved by the U.S. FDA in 1997 for the treatment of refractory urinary urgency and urge incontinence. Although the exact mechanism of action is not clear, the therapy appears to activate latent inhibitory reflexes to the bladder through stimulation of somatic afferent nerve fibers (37). The outpatient procedure is performed using sedation and local anesthesia, with the patient in the prone position. Under fluoroscopic guidance, a lead is placed percutaneously into one of the S3 sacral foramena. The lead is initially attached to an external battery, which is worn for a two- to three-week test period. If the stimulation results in a greater than 50% improvement in incontinence episodes, a second outpatient procedure is performed in which the external portion of the lead is removed, and a permanent subcutaneous battery is placed in the upper buttock. Multiple initial series demonstrated 70% to 80% success rates for the treatment of urgency and urge incontinence, although none of these focused exclusively on patients with these symptoms following a stroke (38). Potential complications include lead migration, pain at the stimulator site, and wound infection. No major neurologic complications have been reported to date. As with any metal implant, magnetic resonance imaging cannot be performed following the procedure. Most recently, in a series of 12 patients with refractory urge incontinence following stroke, Kuo found improvements in the grade of incontinence in 50% of patients after detrusor injections of 200 units botulinum toxin type A (39).

Injection of Botulinum Toxin

The use of botulinum toxin for medical purposes is well established in physiatry, but its use for urologic applications has been a very recent development. In 2000, Schurch and colleagues first described the cystoscopic injection of botulinum toxin type A into the detrusor for the treatment of neurogenic detrusor overactivity in individuals with traumatic spinal cord injury (40). Since then, multiple other investigators have reported excellent results for the treatment of both idiopathic and neurogenic urge incontinence (41,42). Significant improvements in incontinence episodes, pad use, and quality of life have been consistently demonstrated. Typical doses have been from 200 to 300 units injected at a random location into the bladder wall in 10-unit increments. To date, there have been no reports of de novo urinary retention. In those who respond to the treatment, the effects have been reported to last from 4 to 14 months. Botox® (onabotulinumtoxin A) was approved by the U.S. FDA for overactive bladder on January 18, 2013.

BOWEL MANAGEMENT

Introduction

Equally, if not more, distressing to the stroke survivor is FI. Those with FI have problems similar to those with UI, with poor prognosis, decreased functional outcomes, and the possible need for institutionalization.

Fecal Incontinence

There is a natural relationship between urinary and bowel continence. In a survey of 18,000 Wisconsin nursing home residents, UI was the greatest risk factor for developing FI, and FI was the greatest risk factor for developing UI. Decreased ability to perform activities of daily living, immobility, dementia, and specific diseases such as stroke and diabetes are also related to FI (43).

Bowel disturbances occur when the central nervous system is impaired. Uninhibited neurogenic bowel occurs when there is injury to the upper motor neurons located in the cerebral cortex, internal capsule, brainstem, or spinal cord. If cerebral control is interrupted, then the awareness of urge and ability to inhibit defecation are lost, resulting in FI. Sensory impulses travel through the sacral reflex arc to the

brain, but the brain is unable to read the impulses, resulting in a decreased awareness of the need to defecate and a decrease in voluntary control of the anal sphincter. Involuntary elimination occurs when the sacral defecation reflex is activated, but if sensation is not impaired, incontinence is coupled with a sense of urgency. In the uninhibited neurogenic bowel, the pattern of incontinence is characterized by a poor awareness of the need to defecate (44). In the general population, FI is the involuntary loss of anal sphincter control leading to the release of stool at any inconvenient or inappropriate time. There are three subtypes of incontinence: passive (the involuntary discharge of stool or gas without knowing); urge (the failed attempt to hold bowel contents); and fecal seepage (stool seeping out after a normal bowel movement) (45). FI increases the vulnerability for poor hygiene, skin breakdown, infection, depression, and social isolation. The etiology of FI may be the result of neuro–sensory–motor dysfunction of anal sphincter or pelvic floor; abnormal colonic transit; loose or liquid stool consistency; or decreased intestinal capacity with overflow. Multiple factors, including impaired consciousness and/or physical disability, influence bowel control after stroke (46,47).

Prevalence

In a U.S. householder survey of functional gastrointestinal disorders, 7.1% of the population reported fecal leakage, whereas 0.7% of the population experience fecal straining for more than 1 month. In the practice guidelines for diagnosis and management of FI, Rao summarizes its prevalence as ranging between 1% and 7.4% in the well population, and up to 25% in the institutionalized (45).

The prevalence of FI in community-dwelling individuals is reported between 1.4% and 15% in the adult population, and between 3.1 and 16.9% in individuals over the age of 60. The Chicago Health and Aging Project (CHAP) study of older biracial, geographically defined residents described the prevalence of FI by race, age, sex, the presence of stroke and diabetes, and the use of certain psychoactive medications. FI was significantly higher among persons with a reported history of stroke (21.5%) than in those with no stroke (8.3%, $P < .0001$). FI has a high association with stroke and diabetes. In a study using multivariate logistic regression analyses adjusted for age, sex, and race, the odds of FI was 2.8 times greater for persons who reported stroke (95% CI: 2.2–3.5) compared to people without stroke. Users of anticonvulsant, antipsychotic, hypnotic, antidepressant, and anti-Parkinsonian medications were two to three times more likely to have FI (48).

According to the Copenhagen Stroke Study, 40% of 935 stroke patients had FI at the time of admission, 18% at time of discharge, and 9% at 6-month follow up. Secondary to multiple risk factors, 62% of stroke survivors became incontinent during the 9 months after the 3-month acute phase (5). FI affects 56% of acute stroke survivors, 11% at 3 months after stroke, and less than 22% at 12 months (10,49). In a descriptive study of the natural history and independent associations of new onset FI in patients 3 months after stroke, the prevalence of poststroke FI was 30% at 7 to 10 days, 11% at 3 months, 11% at 1 year, and 15% at 3 years. One-third of the patients with FI at three months were continent at one year. Sixty-five percent of those who had been continent at three months were incontinent at one year (50).

Prognosis

In patients who were incontinent of feces at the time of admission, 53% died by the time of discharge, 27% had full FI, 6% had occasional incontinence, and 82% had no FI. At a 6-month follow-up, 5% of the responders had full FI, 4% had partial incontinence, and 91% had no FI (5).

Stroke patients who suffered total anterior circulation infarcts were more likely to be incontinent of feces at three months than those with partial anterior circulation infarct or posterior circulation or lacunar circulation infarct. No association was noted between FI and cerebral or subarachnoid hemorrhage versus infarct. Even though they are coexisting maladies, FI is less prevalent than UI. The strongest association with UI occurs at 3 months, with only 8% of stroke survivors having double incontinence. Identification of FI as a public health problem will continue to increase as the oldest age groups continue to grow. FI is associated with the presence of certain conditions: stroke, diabetes, aging, and the use of certain medications. Therefore, new-onset FI, common for stroke survivors, may be transient and treated. Drugs that cause constipation, fecal impaction or incontinence, decreased mobility, impaired proprioception, neglect, and inability to perform toileting activities are treatable risk factors (50).

Discharge Destination

In the Copenhagen Stroke Study, of patients with complete FI, 53% died prior to discharge as compared to 24% with partial FI, and only 3% of those with no fecal incontinence (5). Thirty-six percent of patients with new-onset FI died at 3 months after stroke, as compared to only 4% of continent patients. Of stroke survivors in nursing homes, 20% of incontinent patients died within 1 year, compared with only 8% of continent patients (50). Regarding discharge destination, FI at 3 months increased the risk of long-term placement, 28% versus 6%. FI is one of the most common reasons for nursing home placement in the United States, even more than dementia. Often caregivers are unable to manage the challenges of toileting, changing, and cleaning a dependent stroke survivor in the home setting (45,47). FI is directly related to functional disability after stroke and is more a result of poor functional recovery than a risk factor for death or institutionalization at six months (49,51). The more dependent the stroke survivor is on caregivers, the greater the loss of function, and the higher the rate of institutionalization or death.

For those patients returning home with FI, family training regarding bowel program management must be incorporated into the rehabilitation plan. The incontinent patient requires expensive disposable supplies, such as diapers, pads for bedding, and protective barrier creams.

Normal Bowel Function

Physiology of the Bowel

The gastrointestinal (GI) system consists of several organs, each with specialized anatomical functions, divided by autonomic muscular sphincters that compartmentalize each organ yet link together into one functioning system. Other body systems, such as the neural, lymphatic, endocrine, and vascular, work with the gut in serving the needs of the human body (52,53). The GI system transports food starting at the stomach and ending at the anus. Digestion of food occurs in the stomach, duodenum, jejunum, and ileum. Secretory glands positioned throughout the GI tract produce digestive enzymes and electrolytes that stimulate and contribute to digestion (44). The upper GI tract processes food by mixing it with pepsin and acid and breaking it down into smaller particles. The proximal stomach serves a storage function by relaxing to accommodate a meal. The distal stomach contracts and propels solid food remnants against the pylorus, where it is repeatedly propelled proximally for further mixing before it empties into the duodenum. The stomach also secretes intrinsic factor vitamin B_{12} for absorption. The middle of the GI tract extends from the duodenal papilla to the midtransverse colon, where digestion is completed. Absorption occurs in the small intestine and the proximal half of the colon. The colon is shorter in length and larger in diameter than the small intestine (44,52,54).

The large intestine anatomically is composed of the cecum; the ascending, transverse, descending, and sigmoid colon; the rectum; and the anal canal. The colon absorbs water and electrolytes from food matter and stores fecal matter until expulsion is convenient. The colon is bounded by the ileocecal sphincter at its proximal end, and by the anal sphincter at the perineum (54,55). Colonic mucosa prepares feces for evacuation by absorbing fluid from the stool, decreasing the daily fecal volumes from 1,000 to 1,500 mL delivered from the ileum to the 100 to 200 mL expelled from the rectum (52).

There are several layers in the wall of the colon (Figure 35.3). The inner layer of the mucosa is gut epithelium with subepithelial connective tissue. The mucosal musculature senses the stretch of the lumen wall. The submucosa layer is the submucosal plexus with stretch receptors between the mucosa and the middle layer. The middle layer consists of circular musculature, which contracts the lumen, causing mixing. The myenteric plexus is between the middle circular and the outer layers. The outer layer consists of longitudinal muscle layers and the serosa, which encapsulates and facilitates sliding (54) (Figure 35.4).

The Central Nervous System and Defecation

The colon's nervous system has two components: intrinsic and extrinsic. The colonic wall contains intrinsic elements that include the Auerbach's plexus and Meissner's plexus. Auerbach's plexus, also known as the *intramuscular myenteric plexus*, is located between the outer and middle muscle layers and controls GI motility. Meissner's plexus, located in the submucosa, is referred to as *submucosa plexus* and controls GI secretion (56). The intrinsic component is actually the enteric nervous system, providing the basic control for propulsion and fluid regulation. It coordinates the colonic wall, mixing and advancing stool

through the colon. The extrinsic neural input occurs through the autonomic nervous system's sympathetic and parasympathetic pathway, which provides volitional or involuntary control specific for each gut region (52,54,57).

Intestinal activity works with circular and segmental movements of the different sections of the intestinal tract. There are two types of movement in the colon. The propulsion of food matter, caused by a distended colonic segment forming a contractile ring around the colon to propel forward any material in front of it, is called *peristalsis*. The speed of peristalsis is greatest in the duodenum and jejunum and slowest in the ileum. To be effective, peristalsis requires an intact myenteric plexus. If peristalsis is weak, it may be that the myenteric plexus has been disturbed by disease or anticholinergic medication (54,57).

The second type of colonic movement, known as *haustrations,* is a mixing motion consisting of circular contractions digging into and rolling over the fecal material in the colon. Colonic movement depends on haustral contractions and mass movements. The gastroileal reflex stimulates the ileum to move semifluid contents into the cecum and gradually fill the ascending and transverse colon. Propulsion in the cecum and ascending colon is caused by the slow, haustral contractions. Movement of chyme from the ileocecal valve through the transverse colon requires 8 to 15 hours. Chyme evolves into a fecal, semisolid state as fluid is absorbed. This slows down the process for long intervals until a powerful mass movement of the transverse colon propels the contents into the lower colon. All of these processes remain involuntary (52,54,55).

Mass movements replace propulsion at the transverse colon and through the sigmoid colon. Gastrocolic and duodenocolic reflexes expedite mass movements that are strongest for about 15 minutes in the first hour after breakfast. In response to distention, usually in the transverse colon, a constrictive ring forms and mass movements begin. Twenty centimeters or more of colon distal to the constrictive ring lose the haustral contractions and move as a mass or unit. In response, fecal material in that colonic segment is forced down the colon to the rectum. Mass movements last for 10 to 30 minutes but may return in 12 or 24 hours. As feces move into the rectum, the need to defecate is felt (54).

Neurologic Control (Reflexes)

The GI tract is unique among other organ systems, as its function is influenced and altered mostly by the outside environment, not by direct control of the brain. Intrinsic nerves control most basic gut activities, whereas extrinsic nerves modulate visceral activity through sympathetic and parasympathetic functions (53). GI reflexes are mediated by extrinsic vagus or splanchnic nerve pathways. The brain–gut axis alters function in regions not under voluntary regulation. Stress caused by external forces can alter GI motility as well as the gut's immune function (56).

The enteric nervous system and its relationship with the sympathetic and parasympathetic systems support three types of GI reflexes essential for bowel control and defecation. The first group of reflexes occurs within the enteric nervous system and controls GI secretion, peristalsis, and mixing contractions. The second group of reflexes travels from the gut to the prevertebral sympathetic ganglia and back to the GI tract. Gastrocolic reflexes transmit signals from the stomach to cause evacuation of the colon. Enterogastric reflexes from the colon and small intestine inhibit stomach motility and secretion. Colonoileal reflexes prevent the emptying of ileal contents into the colon. The third group of reflexes travels from the gut to the brainstem and then back to the GI tract. These include reflexes in the stomach and duodenum that control gastric motor and secretory activity. Pain reflexes can cause general inhibition of the entire GI tract. Defecation reflexes produce colonic, rectal, and abdominal contractions needed for defecation (57).

Intrinsic neural control is altered by signals from the brain to the autonomic nervous system that innervates the GI tract. The enteric nervous system controls the automatic motor and secretory functions and allows the gut to continue to function in isolation from its extrinsic nerve supply. Intestinal activity relies on the coordinated action of various parts of the nervous system, including the intramural plexus in the bowel wall, the autonomic nervous system, and the voluntary nervous system. The human brain can inhibit the sacral spinal center to decrease peristaltic activity by voluntarily increasing anal sphincter tone and relaxing the colon, causing the urge to defecate to disappear (54).

Defecation requires the integration of the somatic nervous system (voluntary) and the autonomic nervous system (involuntary). Any interruption in the process can impair bowel function. The defecation reflex begins when mass movements propel fecal material forward, caused principally by the duodenocolic reflex that is initiated while the duodenum is filled. Feces enter the sigmoid colon and are kept there until right before defecation. The adult rectum is about four to six inches long and is usually empty of feces until defecation. Fecal bolus is propelled into the rectum by mass movement, causing distention and initiating the defecation reflex. The puborectalis muscle forms a sling around the rectoanal junction. To maintain continence, the puborectalis muscle must be contracted. The rectum contains vertical and transverse folds of tissue that help retain the feces. Each vertical fold contains an artery and vein. During defecation, sacral parasympathetic nerves relax this muscle and straighten the rectoangle. Rectal distention initiates temporary relaxation of the internal anal sphincter through intrinsic and reflex sympathetic innervation. The anal canal, which is about 1.5 inches long, contains an internal and external sphincter. Continual dribbling of fecal matter through the anus is prevented by tonic constriction of the internal sphincter, consisting of thick smooth muscle inside the anus. The external anal sphincter is composed of striated voluntary muscle that surrounds and extends distal to the internal sphincter. The external sphincter is controlled by nerve fibers in the pudendal nerve, which is part of the somatic (voluntary) nervous system (44,53,57). Reflexes to defecate are transmitted through the intramural nerve plexus and intensified by parasympathetic system signals or overdistention of the colon. Feces enter the

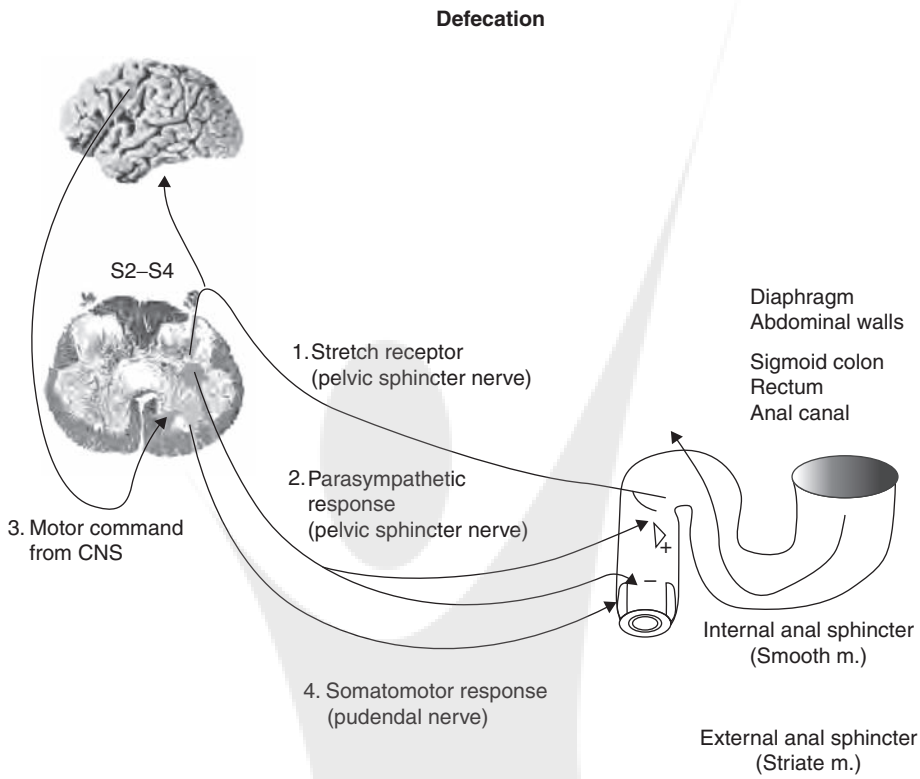

FIGURE 35.5 Colonic spinal afferents contribute to defecation. The sympathetic nerve supply to the internal (involuntary) anal sphincter is excitatory; the parasympathetic is inhibitory. The pudendal nerve supplies the external anal sphincter, which is maintained in a state of tonic contraction.

rectum, causing distention of the rectal wall and initiating afferent signals that spread through the myenteric plexus to start peristaltic waves in the descending colon, sigmoid, and rectum, forcing feces toward the anus. As the peristaltic wave moves toward the anus, the internal anal sphincter is relaxed by inhibitory signals from the myenteric plexus. As sigmoid and rectal contractions increase the pressure within the rectum, the rectosigmoid angle opens by more than 15 degrees. The external sphincter relaxes voluntarily and permits fecal defecation. Voluntary increases in intra-abdominal pressure (i.e., valsalva maneuver) can assist in defecation. If the intrinsic defecation reflex itself is too weak to be effective, it has to be supported by a parasympathetic defecation reflex that involves the sacral segments of the spinal cord. Parasympathetic nerve fibers in the pelvic nerves intensify the peristaltic waves, relax the internal anal sphincter, and convert the intrinsic defecation reflex from a weak movement into a strong defecation process (Figure 35.5). In the continent person, relaxation of the internal sphincter and forward movement of feces toward the anus initiate an instantaneous contraction of the external sphincter, temporarily preventing defecation until an appropriate time (52,57,58).

The GI tract has dual innervation. The small intestine is rich with sensory fibers. Vagal and spinal afferent nerves to the CNS carry information from activated sensory receptors. The extrinsic supply is divided into efferent and afferent branches. Information is transported in parasympathetic and sympathetic nerve tracts, provided by the vagus and spinal nerves. Most efferent parasympathetic and sympathetic fibers terminate in the myenteric plexus and form connections in enteric ganglia. Some sympathetic axons terminate directly on sphincteric smooth muscles. GI activities are carried out independent of external neural control. Cell bodies of these efferent nerves reside predominantly in the brainstem. The vagus nerve contains three groups of efferent fibers: parasympathetic cholinergic, cholinergic, and sympathetic (56). Stimulation of efferent vagal cholinergic neurons principally activates nicotinergic receptors within enteric ganglia, exciting motor activity. The vagus nerve informs the brainstem about activities of the gut. In humans, the enteric nervous system contains up to 100 million neurons, compared to only 2,000 efferent fibers in the vagus. This suggests that the intrinsic nerves direct reflexes and control activities, and extrinsic nerves serve to modulate function (59,60).

Effect of Stroke on Fecal Elimination

To improve the quality of life of patients with stroke, rehabilitation specialists need to have an understanding of how stroke may alter bowel function resulting in FI, diarrhea, and/or constipation. In addition to affecting speech and mobility, stroke can injure the cerebral areas responsible for

bowel control. Ischemic stroke can result in secondary functional changes in the peripheral organs that communicate with the affected vascular areas of the brain (60).

Incontinence

People with stroke who experience UI often have problems with bowel irregularity including constipation, diarrhea, bowel impaction, and FI. Both UI and FI after stroke are frequently the result of immobility, decreased consciousness, and/or functional dependency rather than the impairment of neural pathways. FI in stroke is often temporary and may resolve if the stroke survivor's recovery includes improved cognitive awareness and mobility (10).

Bowel problems in stroke survivors often result from multiple issues rather than a single factor. Needing help to use the toilet is one of the strongest predictors of FI after stroke. Poor mobility, impaired dexterity, changes in vision, decreased sensation, and communication can influence continence (61). Mobility and dexterity can be improved with physical and occupational therapy. The use of anticholinergic medications, including antipsychotics, tricyclic antidepressants, oxybutynin, or antiemetics, increases the risk of FI in stroke survivors by reducing contractility of smooth muscle of the gut by an antimuscarinic effect at acetylcholine receptor sites. In some cases, long-term use may induce chronic colonic dysmotility. As a comorbidity, stroke does not independently affect bowel continence in longer-term stroke survivors, but rather influences continence through associations with other clinical and functional factors. FI is not only a financial burden to caregivers and society but may also cause the stroke survivor the additional cost of social isolation and dependence. The degree of disability is the most important factor causing FI in stroke, but using constipating drugs and functional difficulties with toileting strongly influence FI at three months after stroke (50).

If incontinence is caused by external factors such as medications or mobility, it can be managed through education and therapy. A randomized controlled trial of constipation and FI management showed that one year after a nursing intervention, subjects were more likely to alter their diet and fluid intake to control their bowels and to receive different prescribed patterns of bowel agents. A single-encounter nurse-led intervention in stroke patients significantly improved measures of bowel dysfunction and changed bowel-modifying lifestyle behavior. Findings promoted structured management of bowel problems in stroke patients and encouraged health education (49). In summary, FI is the involuntary evacuation of rectal contents and is most often caused by neuromuscular disorders or structural anorectal problems. FI may be aggravated by diarrhea or urgency, but the causes of those issues must be identified separately (52).

Diarrhea

Diarrhea is the passage of atypical liquid or unformed stool at the rate of 3 or more bowel movements in 24 hours. Acute diarrhea lasts less than 2 weeks, persistent diarrhea lasts for longer than 2 weeks, and chronic diarrhea persists for more than 4 weeks. When diarrhea occurs, it is harder for the anal sphincter to hold liquid stool, as compared to stool in the semisolid state (62). Every 24 hours, the small intestine converts about 10 liters of fluid and digested food into 1.5 to 2 liters of ileal content. This volume is then converted into approximately 200 grams of solid stool by fluid absorption in the colon. When the balance between the absorptive capacity in the intestine and its secretory function is disrupted, diarrhea occurs (63). Malnutrition, tube feedings, and debility put the stroke patient at risk for diarrhea.

Infectious agents cause more than 90% of acute diarrhea. The other 10% is caused by medications, toxic ingestions, and other conditions. Infections are transmitted through fecal–oral direct personal contact, or ingestion of food or water contaminated with pathogens. Diarrhea is one of the most common sources of nosocomial infections in hospitals and long-term care facilities. There are many microorganisms in the hospital setting. Currently, the most persistent microorganism is *Clostridium difficile*. Hospitalization predisposes stroke patients to nosocomial infections. Common outbreaks usually occur through foodborne epidemics, sharing toilets, or rooming with patients with infective diarrhea. Impaired cognition, decreased mobility, and functional disabilities contribute to decreased personal hygiene. Antibiotics disrupt the gut's normal flora and break down the colon's immunity. Side effects from drug therapy are the most common noninfectious cause of acute diarrhea and can be easily determined by connecting the onset of symptoms with drug start date. In the stroke population, the most frequent diarrhea-causing drugs are antibiotics, cardiac antidysrhythmics, antihypertensives, nonsteroidal anti-inflammatories, antidepressants, antacids, and laxatives (63).

Constipation

According to the practice guidelines for the management of constipation published by the Rehabilitation Nursing Foundation, a proposed definition of *constipation* is "the passage of small amounts of hard, dry stool fewer than three times per week or a significant change in one's usual routine, accompanied by straining, and feelings of being bloated, or having abdominal fullness. Persistence of these symptoms for 3 months or longer is defined as chronic constipation" (54).

In the general population, the prevalence of constipation in North America is estimated to be between 2% and 27%. Approximately 42 million people in the United States meet the defined criteria for functional constipation (54). Twice as many women as men complain of symptoms of constipation. It is more prevalent in the elderly (older than 65 years), nonwhites, and individuals from lower socioeconomic or less educated groups. It is a serious problem in clinical practice, affecting up to 60% of those in stroke rehabilitation units (50,63). Chronic constipation is associated with GI motility and sensory disorders including functional dyspepsia, heartburn, and gastroesophageal

reflux disease (GERD). Twenty-nine percent of GERD patients also report functional constipation. Approximately 63 million people in North America meet the Rome II Criteria for constipation (64).

Constipation is linked to impairments of the central nervous system. In stroke, depending on the location of the lesion, weakness of the abdominal and pelvic muscles and hypomotility of the large bowel may occur (63). The rectum is bilaterally innervated on the motor cortex with asymmetric representation and unilateral dominance. It is uncertain if asymmetry accounts for difficulties in defecation after brain injury or if unilateral pudendal nerve injury causes a disturbance of pelvic floor function (56). Lesions affecting the pontine defacatory center disrupt the sequencing of sympathetic and parasympathetic components of defecation and impair the coordination of the peristaltic wave and relaxation of the pelvic floor and external sphincter. Drugs that contribute to constipation are diuretics, iron, antihypertensives, antipsychotics, anticholinergics, anticonvulsants, opioids, and ganglionic blockers (53,63). Tricyclic antidepressants can cause constipation induced by blocking the reuptake of norepinephrine or serotonin. Antidepressants such as amitriptyline, as well as the selective serotonin reuptake inhibitors, affect visceral sensitivity and motility (48). Ninety-five percent of the patients on opioids are constipated. Verapamil, a calcium channel blocker, causes constipation by delaying GI transit time. Antacids that contain aluminum cause constipation owing to the constricting agent. Diuretics causing fluid loss can constipate (53,63).

In patients with ischemic stroke, colorectal dysfunction is caused by a combination of lesions of the central or peripheral nervous system, immobility, or altered dietary habits. Constipation in patients with stroke has been suggested to be disruption of the neuronal modulation of colonic motility. Colonic transit time is prolonged, especially in the right colon. The mechanism of intestinal pseudo-obstruction in stroke may be defective enteric neurons, smooth muscles, or both. The exact cause of constipation after stroke requires further study. Disruption to the modulation of colonic motility must also be assessed. Because stroke is common in elderly patients, the aging effects of the GI tract have to be considered. GI changes with aging are very subtle (59,60). In conclusion, ischemic stroke may disrupt neural control of GI motility by interrupting or altering the flow of information between the cortex and the GI system. Future research utilizing positron emission test scans and magnetic resonance imaging may be able to demonstrate a relationship between bowel dysfunction and stroke (60).

History

The first component of bowel function assessment is to obtain a history from the stroke survivor. Unfortunately, this may not always be possible, because of cognitive or communication deficits. In these instances, the interviewer will need to rely on the family for information. In cases where the family is not present or unable to provide the necessary information, the nursing staff will have to be questioned.

Previous Bowel Habits

The assessment starts by obtaining information about the stroke survivor's previous bowel habits. Questions about previous bowel habits include: past problems with abdominal pain, bloating, and discomfort; hemorrhoids; episodes of constipation, diarrhea, or incontinence; frequency of occurrence; and use of medications for management. When asking questions about constipation or diarrhea, the interviewer should be specific. Often, misconceptions regarding normal bowel habits can interfere with obtaining accurate information. A scale developed at the University of Bristol, the Stool Form Scale, can be used to help improve communication. The scale provides pictures and descriptions of different stool consistencies so that the interviewer and stroke survivor are using the same terminology when discussing bowel habits. An incontinence problem that existed prior to the onset of stroke may make achieving continence more challenging.

Current Bowel Habits

Information regarding current bowel habits helps to contrast that of past bowel habits. Questions about current bowel habits include: the onset of FI; the number of incontinent and continent bowel movements; the consistency and size of the stool; the activity immediately preceding the incontinence; the ability to distinguish between passing of stool and gas; the presence of urgency, pain, or other symptoms; and the presence of blood in the stool. Changes in bowel habits may be because of stroke-related deficits, prolonged hospitalization, changes in diet, medications, or the development of a new medical problem.

Past Medical History

The health care practitioner should obtain information about a previous history of small bowel obstruction, inflammatory bowel disease, malabsorption syndromes and treatment, GI surgery, trauma to the abdominal area, neurologic diseases that affect the central or peripheral nervous systems, diabetes that can affect gastric motility, antibiotic therapy, and urology problems. With male stroke survivors, the interviewer should ask about the presence of sexual dysfunction that may suggest impairment of pelvic floor innervation (65). With female stroke survivors, the interviewer should ask about the obstetrical history. In multiparous women, stretch injuries or lacerations of the pelvic floor are common causes of anorectal denervation and sphincter damage (65). All of these could likely contribute to FI after stroke.

Fluid and Dietary Intake

The examiner should determine the amounts, types, and timing of fluids consumed. Decreased fluid intake, or the intake of diuretic fluids, can increase the risk of constipation. Fluid intake should be spaced throughout the day to ensure that 2 liters or 8 to 10 glasses of fluid are consumed. Stroke survivors drinking thickened liquids need to be encouraged to increase their fluid intake to prevent constipation. Inquiries about dietary intake should focus on the amount of dietary fiber consumed, potential dietary irritants, and food allergies.

Fluid and oral caloric intake must be monitored closely in stroke survivors on modified consistency diets or enteric feedings secondary to dysphagia. These individuals will have the same incontinence problems but present a bigger challenge because of their swallowing impairment.

Medication Review

With a hospitalized stroke survivor, it is much easier to monitor the medications he or she is taking, as rarely does one take anything other than that prescribed by the physician or administered by the nursing staff. With a stroke survivor who is at home, it is important to find out not only what prescription medications the person is taking, but also any over-the-counter medications, vitamins, and herbal supplements being taken. Not only can certain medications affect stool consistency and GI motility, but medications can also affect a person's level of alertness, balance, or coordination, which can contribute to incontinence.

Functional Status

Functional assessments performed by the rehabilitation team in all areas of mobility and activities of daily living are a necessary part of the bowel function assessment. Knowledge of the stroke survivor's cognitive status determines whether the person can identify the need to have a bowel movement and act upon it. It is important to know about the survivor's communication status. Aphasia or dysarthria may make it difficult for the survivor to communicate his or her needs for toileting. Sensory perceptual deficits may make it difficult to identify the bathroom, or to know what to do or where to go once in the bathroom. Visual deficits may make finding the bathroom difficult. Mobility or balance deficits will make it difficult to get to the bathroom, manage clothing, transfer to the toilet, and manage hygiene. If the environment is not wheelchair accessible, or if appropriate equipment is not available, establishing an effective program will be more difficult. For those stroke survivors who are home, it will be necessary to assess the environment and equipment available to assist with toileting.

Bowel Diary

In cases where the stroke survivor is unable to provide information to the interviewer about current or previous bowel habits, it may be necessary to keep a bowel diary. The diary is a document that will provide the interviewer with information about current bowel function. Any rehabilitation treatment team member can develop a form to obtain the necessary information. The team or family member completing the diary should record fluid intake and timing, continent and incontinent bowel movements and timing, and consistency of stools. The diary can also assist the rehabilitation professional with documentation once a program has been put into effect.

Physical Examination

The next component of the assessment is the physical examination. The examiner should always explain to the stroke survivor what is to occur throughout the assessment. The first part of the physical examination begins with a visual inspection of the abdomen. The examiner should observe for surgical scars that might indicate past GI surgery, or an enlarged, protuberant abdomen that may suggest gas, tumor, pregnancy, or fluid collection. The examiner then auscultates for bowel sounds. Hypoactive bowel sounds could be a sign of constipation, impaction, obstruction, paralytic ileus, or peritonitis. Hyperactive bowel sounds could be a sign of diarrhea or intestinal obstruction. The examiner then palpates the abdomen, assessing for tenderness, masses, and enlarged organs.

After examination of the abdomen, the stroke survivor should be asked or assisted to turn to his or her left side. The next portion of the physical examination is assessment of the anus and rectum. Using two hands, the examiner gently spreads the buttocks, looking for the presence of stool, hemorrhoids, fissures, skin breakdown, bulging, or gaping of the anal opening. These findings are suggestive of sphincter weakness and could help identify the potential cause of incontinence (45). Using a cotton-tip applicator, the examiner gently strokes the perianal area on either side of the anus. This should elicit a contraction of the external sphincter called the *anal wink*. The cotton-tip applicator can also be used to assess perianal sensation. The examiner then asks the stroke survivor to bear down gently, while looking for a bulging of the anus. A small amount of bulging is normal, but a large bulge, loss of stool, or organ prolapse is not. The examiner is now ready to perform a digital rectal examination. Using a lubricated, gloved index finger, the examiner gently checks the rectal vault for the presence of stool. At the same time, the examiner assesses anal tone. The examiner asks the stroke survivor to tighten the external sphincter around the gloved finger assessing for tone. The sphincter should tighten evenly around the gloved finger. Loss of rectal tone suggests that a significant neurologic problem is present.

Diagnostic Tests

There will be instances when some stroke survivors will require diagnostic testing. Diagnostic testing can provide additional information that will assist the health care practitioner determine the potential cause of FI. In stroke survivors with hypoactive bowel sounds, abdominal distention, or oozing of liquid stool upon examination, or when the exact date of the last bowel movement is unknown, a simple abdominal radiograph can identify the presence of stool or impaction in the GI tract. In the stroke survivor with hyperactive bowel sounds, abdominal discomfort, and large amounts of liquid stool, a stool culture can be obtained to rule out infection. Checking stool for occult blood also can help to rule out GI bleeding as a cause of incontinence or diarrhea.

Other diagnostic tests are available, but these are not performed frequently as part of an assessment. When there is a history of previous GI problems, neurologic complications, or the assessment does not help identify a problem, the stroke survivor should be referred to a gastroenterologist

for further testing. Additional testing may include upper or lower GI tract endoscopy, balloon expulsion testing, anorectal manometry, colonic transit testing, endoanal ultrasound and magnetic resonance imaging, and defecography (66).

Treatment

The management of FI after stroke is often easier to address than UI. Depending upon the problem, the stool may have to be softened for easier passage, or bulked up to increase sensory input. A regular toileting schedule may have to be devised. A combination of methods may be implemented. It is important to be realistic when establishing goals for the stroke survivor. It may take several months to achieve 100% continence. Initially, the goal may be to decrease the frequency of incontinence or simply to regulate the individual with a program.

Nonpharmacologic Treatment: Diet

Increasing the fiber content in a diet can add bulk to stool to help increase size and improve rectal sensation. Fiber taken appropriately can also prevent constipation. Fibrous foods are poorly digested and remain in the lumen of the GI tract. They help form viscous, gel-like substances (54). The American Dietetics Association recommends 20 to 35 grams of fiber per day to maintain normal bowel function (67). This amount should be built up slowly in those who do not normally consume this amount of fiber, to prevent abdominal cramping. In those individuals who cannot ingest that amount of fiber in their diet, supplemental fiber can be used. Various supplements and recipes of bran, prune juice, and applesauce can help to increase dietary fiber intake (68). Bran, psyllium, guar gum, and fiber concentrates can also be purchased to increase fiber intakes.

Fluids

The intake of fluid is very closely related to dietary intake. Although increased fiber intake is effective in managing constipation, diarrhea, and FI in stroke survivors, an insufficient intake of fluids (especially with increased fiber intake) can actually be more harmful than beneficial. The American Dietetic Association recommends that the average person take in 2 liters of liquid or 10 to 12 glasses of fluids per day. The type of fluid should also be carefully monitored. The stroke survivor should avoid caffeinated and alcoholic fluids. These fluids are diuretics and can worsen dehydration. In situations when the stroke survivor has an elevated temperature, diarrhea, and vomiting, fluid intake should be increased. Hot or warmed fluids help promote peristalsis and can be used to assist in achieving continence.

Activity/Exercise

Although research has been inconclusive regarding the effects of exercise and activity on bowel function, many health care practitioners will agree that remaining active helps improve appetite, shortens food transit time through the GI tract, and improves bowel function (54,68). In those who have just suffered a stroke, activity and mobility are severely impaired. Participation in a rehabilitation program will help improve activity. Any activity that helps with reestablishing muscle tone can help return bowel function (44). Walking, leg lifts, stationary bicycling, turning in bed, hip lifts, or a home program are just some examples of exercises that have been tested, but none has been found to be more effective than another (54).

Positioning is also an important part of bowel function. As soon as the stroke survivor can tolerate it, sitting at 90 degrees will help gravity empty the rectal vault and decrease the risk of incontinence. The use of raised toilet seats or bedside commode chairs helps to improve compliance. Bedpans should be avoided whenever possible because gravity will not assist in emptying and because of the increased risk of skin breakdown. In those with poor muscle tone, the use of a stepstool under the stroke survivor's feet can help promote emptying. A squat position with the knees slightly higher than the hips improves the passage of stool by increasing abdominal pressure (44). If the person has sufficient trunk control, bending at the waist also can help increase abdominal pressure. Abdominal massage from right to left can also assist with emptying (68). The valsalva maneuver or bearing down should be avoided in any stroke survivor with an unstable cardiac history.

Timing/Privacy

A regular toileting schedule should be established to help decrease FI in the stroke survivor. When setting up a program in the hospital or for the home, the stroke survivor's schedule should be considered. Toileting after meals can help use the gastrocolic reflex to the survivor's advantage. Initially, the stroke survivor may need toileting after every meal, but morning toileting programs have been found to be more effective (69). The stroke survivor should also be provided with plenty of time and privacy for appropriate evacuation. If the person is rushed while having a bowel movement, inadequate emptying may occur. Over time, this can lead to constipation and impaction. Privacy should also be provided to avoid embarrassing odors or sounds. If the stroke survivor anticipates embarrassment from odors or sounds that could be made during toileting, the defecation reflex may be extinguished, which can lead to or worsen constipation or FI over time.

Education

For a program to remain effective, it is necessary that methods implemented be carried over by the stroke survivor. The individual should be taught the importance of maintaining nonpharmacologic treatment methods to prevent constipation, diarrhea, or FI. Misconceptions regarding bowel habits should also be corrected. The stroke survivor should be educated on how to make changes to his or her program when ill or as bowel habits change over time. Rehabilitation staff

should be educated on how to explain the purpose of programs to stroke survivors and their families. Often stroke survivors and families do not understand the purpose of rectal medications and toileting programs to regulate the frequency of incontinent bowel movements. Education will help improve compliance and encourage family assistance. When the date of the last bowel movement is unknown, it will be difficult to establish if the stroke survivor is truly incontinent or simply impacted. It will be necessary to give a rectal or oral laxative to "clean out" the stool before establishing a program. Stroke survivors and families should be made aware of this to prevent misunderstanding on the use of laxatives. The treatment team should be educated on the need to work together to ease the burden of care in a program. Physical therapists can help train staff and families to ease the effort needed for toilet transfers. Equipment that will ease toileting should be issued to the stroke survivor. Occupational therapists can help families or staff identify appropriate clothing to make management and hygiene less difficult. Speech–language pathologists can work with staff and families on developing a communication system that will notify them when the stroke survivor feels the need to use the bathroom. Nursing staff can ensure that a program is in place and monitor the need for changes based on results.

Pharmacologic Treatment

There will be cases when nonpharmacologic treatment alone is not effective in achieving continence. In these instances, it will be necessary to combine nonpharmacologic and pharmacologic treatment to improve continence. When selecting a medication for the stroke survivor, careful attention should be paid to medical history, ease of administration, and availability of a caregiver. Those stroke survivors who use pharmacologic treatment should be monitored closely by a health care practitioner to ensure that the individual does not develop long-term problems.

Bulk-Forming/Hydrophilic Laxatives

This category of medications softens stool by increasing water content. This increases the frequency of stools. The site of action is the small and large intestine. As mentioned earlier, the stroke survivor should drink at least one 8-ounce glass of water with each dose of medication. The onset of action can be as little as 12 hours, or up to 3 days. The most common side effect is abdominal bloating. Bulk-forming agents should be avoided in those individuals with esophageal narrowing, intestinal adhesions, ulcers, or bowel stenosis (70). Several studies have used bulk-forming agents to manage constipation or decrease FI in stroke survivors (49,71). Examples include psyllium, methylcellulose, and calcium polycarbophil.

Stool Softeners/Lubricant Laxatives

This category of medications decreases the surface tension of the stool by adding water and fatty substances. This medication does not induce defecation; it simply softens stool, making it easier to pass. The site of action is the small and large intestine. The onset of action is as little as 6 to 8 hours, though it can take up to 3 days (70). The most common side effect is loose stool that ceases when the medication is discontinued. Examples include docusate sodium, docusate calcium, and mineral oil. Tramonte et al. cited multiple studies that used stool softeners and found them to be very effective in increasing the frequency of stools (71).

Stimulant Laxatives

This category of medication alters water and electrolyte balance, thereby stimulating intestinal motor function. The site of action is the mesenteric plexus. This category of medications includes rectal and oral forms. The onset of action in the rectal forms is 15 to 60 minutes. The onset of action in the oral forms is 6 to 12 hours. The most common side effect is abdominal cramping. This category of medication is not recommended for long-term use (53). Examples include senna, bisacodyl, and cascara.

Hyperosmotic Laxatives

This category of medication increases intraluminal pressure by increasing water content, thereby stimulating peristalsis. The site of action is the small and large intestine. This category of medications can be found in oral or rectal forms. The onset of action of the oral form is 1 to 2 days. The onset of action of the rectal form is 30 to 60 minutes. There are minimal side effects with the rectal preparations, but the oral preparations can cause abdominal cramps, diarrhea, and electrolyte imbalances. Examples include sorbitol, lactulose, sodium biphosphonate, and polyethylene glycol. Tramonte et al. reviewed three studies that found an increase in bowel movement frequency and improvement in stool consistency when lactulose is used in long-term care and outpatient settings (71).

Research Frontiers

Future research should focus specifically on the management of FI. A great deal of work has been done on the management of constipation, but little on its management specifically after stroke. Although many textbooks outline how to set up a bowel program, only Venn et al. (1992) (69) and Harari et al. (2004) (49) analyzed the use of nonpharmacologic and pharmacologic management and the effectiveness of bowel training. Even these authors recommended larger and longer longitudinal studies of patients who have effective bowel habits after discharge from rehabilitation. Traditionally, rehabilitation hospitals utilize rectal suppositories for the regulation of incontinent bowel movements, but this can be very distressing for the survivor and difficult for the family to understand. Research should also address the effectiveness of suppositories versus toileting programs, and whether stroke survivors achieve continence sooner with either or a combination of both interventions.

Orthotic Management in Stroke

Stefania Fatone and Bryan Malas

The word "orthosis" is derived from the Greek word *orthos*, meaning "to make straight." The International Standards Organization (ISO 8549-1, 1989) defines an *orthosis* or *orthotic device* as "an externally applied device used to modify the structural or functional characteristics of the neuromusculo-skeletal system." The standardized nomenclature for orthoses is based on the principal joint or joints that the orthosis encompasses. For example, an ankle–foot orthosis (AFO) physically encompasses the ankle and foot and provides control principally at the ankle, whereas a wrist–hand orthosis (WHO) encompasses the wrist and hand and provides control principally at the wrist. Often, orthoses are further described based on the control exerted on the joints they encompass; for example, a plantar flexion stop AFO or dorsiflexion assist AFO. Orthoses may allow free motion, resist or assist motion, stop motion, or provide an adjustable hold or lock (1). The basic functional goals of orthoses are to provide support, correct deformity, or modify motion occurring at a joint, either assisting motion where it is insufficient or substituting motion where it is absent. Overall, it is generally intended that orthoses aid function.

Generally, orthoses are designed based on biomechanical principles, working primarily through the application of force systems to relieve unwanted forces or moments from the body. However, the amount of force applied by orthoses is limited by tissue tolerances so as not to cause tissue injury (1). Orthoses affect normal movements by applying selective forces in relatively limited directions (1). Control of joint motion is generally achieved through the application of one or more three-point for6ce systems, consisting of two counter (stabilizing) forces and one active (corrective) force applied proximally and distally to a joint to produce angular change in a specific plane (Figure 36.1). Generally, the more complex the impairment, the more three-point force systems are incorporated into the orthosis design. Orthoses may act directly or indirectly: an orthosis acts *directly* if it surrounds the segment or joint that it is attempting to influence, and *indirectly* if it attempts to modify the external forces acting on a joint beyond its physical boundaries (2). For example, during the stance phase of gait, an AFO acts directly on the ankle but indirectly on the knee by influencing the moments acting at the knee (Figure 36.2). Indirect action of the AFO at the knee is predicated on the closed kinetic chain occurring during stance phase and hence is not applicable during swing phase.

With respect to neurologic conditions such as stroke, orthoses may also incorporate design modifications based on neurophysiologic principles. These principles are derived from neurodevelopmental therapies such as those developed by Bobath (3) and used in inhibitive casting. Orthoses designed using neurophysiologic principles attempt to use sensory feedback (e.g., inhibition of reflexes, pressure over muscle insertions, active and static prolonged stretch, and orthokinetics—the physical effect of materials placed over muscle bellies) to decrease tone and improve isolated motor control, in particular facilitating movement patterns associated with decreased tone, while inhibiting movement patterns associated with increased tone (1,4). Tone-reducing modifications are commonly found in the footplate of lower-limb orthoses or the palmar area of upper-limb orthoses. Although there is some evidence to support the biomechanical effects of orthoses on joint motion and alignment (5,6), there is little evidence to support the neurophysiologic effects of orthoses on tone and spasticity (4,7,8).

Orthotic management of the lower limb in stroke is intended to facilitate function, primarily the ability to stand and walk as safely and efficiently as possible. In the upper limb, orthotic management is intended mainly to avoid the development of orthopedic complications because of muscle weakness and abnormal tone (9), although the use of orthoses to facilitate functional improvements is emerging (10,11).

The use of orthoses should be considered as part of an overall management plan during both the acute and chronic stages of stroke rehabilitation (12,13). Furthermore, as stroke recovery is a dynamic process, the use of orthoses should be intermittently reassessed to keep pace with the individual's changing abilities. Generally, the primary goal of orthoses during the acute phase is to maintain range of motion and prevent joint contractures that may interfere with eventual functional outcome (although this may change with increased understanding of the therapeutic benefits of functional electrical stimulation [FES] (14)). Prefabricated orthoses may be used initially during the acute phase as an interim measure while changes are occurring and a definitive

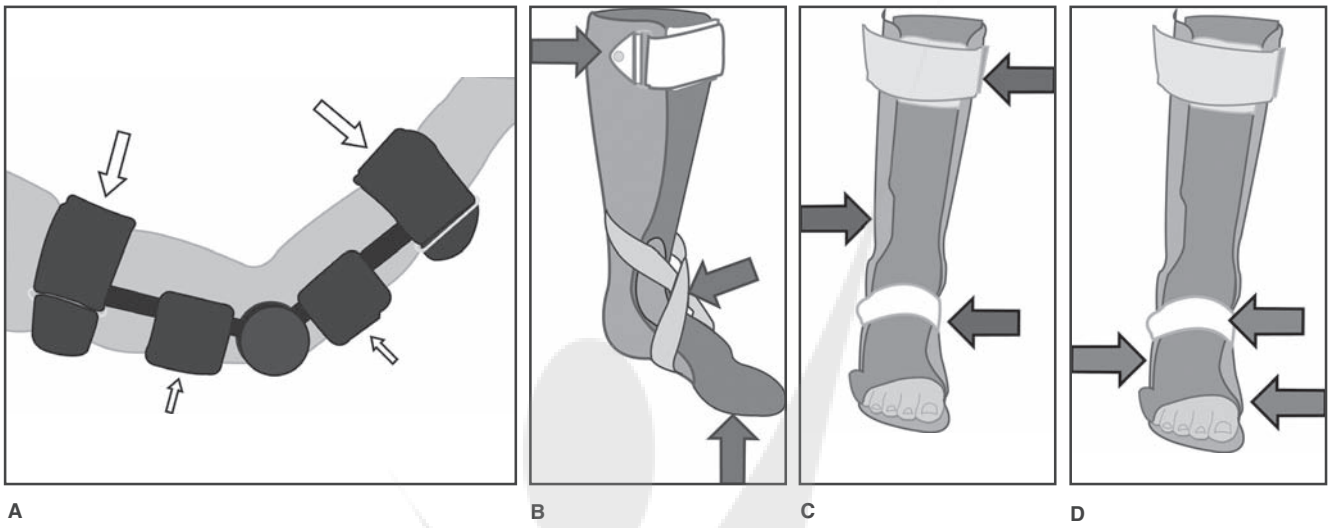

FIGURE 36.1 Examples of three-point force systems used in orthoses for the hemiplegic limb: (A) static progressive contracture management of an elbow flexion contracture with stabilizing forces at each end of the orthosis and the net corrective force acting immediately proximal and distal to the posterior elbow; (B) control of ankle dorsiflexion/plantar flexion using an AFO with stabilizing forces acting on the limb proximally at the posterior calf shell and distally under the plantar surface of the foot with a counterforce over the anterior aspect of the ankle, often through an ankle strap; (C) control of ankle inversion in spastic hemiparesis using an AFO with stabilizing forces acting on the medial arch and medial proximal calf, and the corrective force acting through a flange on the lateral distal tibia; and (D) control of forefoot adduction using an AFO with stabilizing forces acting on the medial aspect of the heel and along the first metatarsal shaft, with a counterforce on the lateral midfoot. Arrows indicate the application of forces.

prescription is unclear, or until a definitive, custom orthosis is ready (12). Adjustable orthoses are often preferred during the acute phase, because they can keep pace with the changes occurring such as with improvements in function. Individuals who demonstrate long-term need for orthotic treatment should receive custom orthoses to provide the necessary degrees of control, correction, and comfort, and the highest degree of compliance in use (13). Currently, no experimental evidence is available regarding optimum timing of orthotic management (12). Hence, we do not know yet whether early orthotic management is superior to waiting until most natural recovery has occurred before making a decision about orthotic management (1). As a result, clinically there appears to be a trend to providing individuals with articulated AFOs that are "uncut" and initially function as solid AFOs. As the person gains function, the same AFO can be cut and articulated to coincide with functional gains. These trends are not surprising and are consistent with recovery statistics for stroke showng that 50% to 70% of stroke survivors regain functional independence, whereas 15% to 30% are permanently disabled (15).

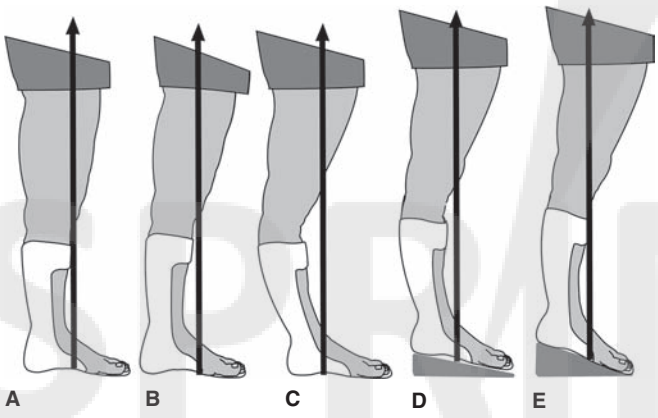

FIGURE 36.2 Indirect action of a nonarticulated, rigid ankle–foot orthosis on the knee during single limb stance: (A) AFO set at 90 degrees; (B) AFO set in dorsiflexion; (C) AFO set in plantar flexion; (D) AFO set in plantar flexion and supported by a small wedge; and (E) AFO set in plantar flexion and supported by a bigger wedge. Note the position of the vertical ground reaction force vector (arrow) with respect to the knee joint, which is indicative of the external knee moment.

For orthoses to be successfully used in the management of stroke, they must be safe, and there must be realistic outcome expectations and appropriate follow-up to ensure proper fit and function. There must be adequate strength and stability of the orthosis to ensure that anatomical joints are protected from unnecessary damage. Orthoses must also minimize the pressure and friction applied to skin and bony prominences by careful fitting and padding. Furthermore, the axes of mechanical joints must be aligned with those of anatomic joints to avoid undesirable torques and motion between the orthosis and the body (16,17). It is also important to realize that most individuals require a period of adjustment or training when receiving an orthosis to achieve maximum benefit (1).

The objective of this chapter is to provide an overview of current practice in the orthotic management of stroke for both upper and lower limbs, describing different orthotic treatments, when and why they are provided, and how they work.

ORTHOTIC MANAGEMENT OF THE UPPER LIMB

Orthoses play a role in preventing or correcting upper-extremity deformities in stroke that result from limited range of motion (18). After stroke, range of motion may be limited by, among other things, immobilization, paresis, increased muscle tone or spasticity, and myostatic contracture (18). Development of contracture is common in the hemiplegic limb, owing to the presence of spasticity and abnormal muscle tone that is inherently resistant to passive stretch (19). Most commonly, the presence of spasticity after the onset of stroke prevents adequate range of motion and, if left untreated, leads to deformity. Although orthoses can be used to prevent deformity, it is often important to treat the underlying spasticity when it is severe to enable safe use of an orthotic device to effectively position the limb. Such treatments may include pharmacologic intervention, serial casting, and surgery, either in isolation or combination. If spasticity is not controlled, the forces required within the cast or orthosis to position the limb may be so great as to cause tissue breakdown. Where spasticity remains, orthoses may have to completely encompass the limb to adequately control position while minimizing the risk of skin breakdown (18).

Paresis following stroke can also contribute to the development of various abnormalities and deformities, especially when coupled with spasticity. Subluxation of the glenohumeral joint is common after stroke, with a reported incidence of 81% to 85% in individuals with spasticity following stroke, and may result in pain and decreased function (20,21). Although shoulder pain is also very common in the hemiplegic upper limb, with a reported incidence of 38% to 84% of individuals with stroke, studies have been unable to establish a direct cause-and-effect relationship between shoulder pain and glenohumeral subluxation (20–25). Despite a lack of evidence regarding whether shoulder subluxation is the primary cause of pain in individuals with stroke (9,19), devices such as slings and wheelchair attachments may be prescribed to prevent subluxation and pain. Unfortunately, some of these devices also markedly restrict shoulder motion, which may diminish function and compromise hygiene. Though there is insufficient evidence to decide whether devices such as slings and wheelchair attachments prevent subluxation, decrease pain, increase function, or adversely increase contracture in the shoulder after stroke (26), a recent study suggests that wearing a vertical humeral cuff sling (similar to that shown in Figure 36.3B) may reduce the laxity of the inferior glenohumeral joint under external loading (27).

Paresis, disuse, and poor positioning of the upper limb may also result in painful edema of the hand. Where possible, the arm is elevated at or above heart level to assist with venous return. A person who is limited to a bed or wheelchair may benefit from pillows or foam wedges placed on a lap board to elevate the arm. In ambulatory individuals, compression gloves may be used to control edema of the hand and wrist. A sling may also be used to support the arm in a position that limits development of edema. However, slings also immobilize the arm and, depending on design, increase flexor tone (9) (Figure 36.3).

At the elbow, flexor spasticity and contracture are common and often severe. Flexion contractures are painful and can lead to breakdown of the antecubital skin and place traction or pressure on the ulnar nerve in the cubital tunnel (18). Similarly, at the wrist, spastic forearm flexors typically cause wrist and finger flexion deformities. Carpal tunnel syndrome is a common orthopedic problem in the hemiplegic arm (28). Orthotic treatment is primarily aimed at preventing wrist flexion so as to alleviate pressure on the median nerve.

Generally, upper-limb assistive devices, including plaster casts, slings, wheelchair attachments, and orthoses, are used following stroke to prevent or correct contracture, maintain limb position, and improve or assist function. Upper-limb orthotic devices are regarded as either static or

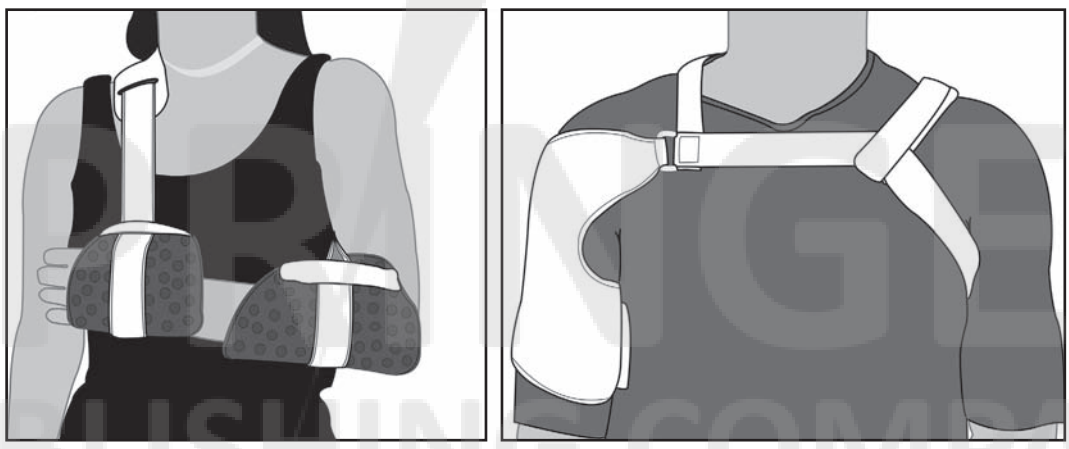

FIGURE 36.3 Examples of two slings: (A) the hemiplegic arm sling and (B) the vertical humeral cuff sling. Both slings attempt to reduce pain caused by shoulder subluxation by supporting the weight of the arm and reducing shoulder subluxation. However, they differ in the position in which the arm is held, with the hemi-sling encouraging a flexed posture.

dynamic. Static orthoses hold the joints in optimum positions to reduce painful motions, prevent or correct deformity, and facilitate function. Dynamic orthoses provide mechanical assistance to joint motion where muscles are weak or paralyzed or where muscle imbalance across joints is present (29). However, orthotic prescription for the upper limb remains primarily empirical, as few upper-limb orthotic devices have been subjected to controlled analysis (9). Furthermore, compliance with use of orthoses is often poor in individuals with hemiplegia, owing to the overall neglect of the involved limb and difficulty with donning and doffing of the orthosis. Many individuals simply use the uninvolved side for activities of daily living.

Contracture Management

Contracture management is important for both the upper and lower limb, as more than 50% of individuals develop contractures following stroke (30). Immobilization, muscle weakness or paralysis, and spasticity are the three main factors leading to the development of contractures that variously affect the joint, contractile tissue, and connective tissue (31). Along with other treatments, such as surgery, passive stretching, and botulinum toxin, casts and orthoses may be used to prevent and correct contractures. There are three main types of orthoses for contracture management: custom orthoses that hold the limb at the limit of range of motion but must be replaced when range of motion is gained; static progressive orthoses, which operate under the same principle as serial casting; and dynamic orthoses.

Casts

Three goals of casting for spasticity have been identified in the literature: increasing or preventing loss of passive range of motion by maintaining muscle fiber length, reducing hypertonicity by decreasing sensory input, and improving function. However, available evidence only supports the use of casts to improve passive range of motion (32). Traditionally, different types of short-term plaster casts (or casts made from other materials such as fiberglass) have been used, sometimes in conjunction with other spasticity management, to prevent or correct contracture. Circular casts applied while an individual is immobile prevent contracture formation, whereas serial casts applied and reapplied at frequent intervals (static progressive stretching) correct contractures. Types of casts include long-arm casts, typically for elbow flexion contracture; short-arm casts, typically for wrist flexion contracture; thumb spica casts for thumb-in-palm deformity (Figure 36.4A); and finger casts for flexion contractures of the interphalangeal joints. By holding the muscle in a lengthened position, both types of casts increase sarcomeres (31). However, the limb is also immobilized, which may allow the antagonists to atrophy and shorten, or lead to fibrous adhesions within the joint space and connective tissue inextensibility (31). Therefore, the challenge is to apply the correct amount of load and use it for the correct period of time to remodel connective tissue without causing further immobility.

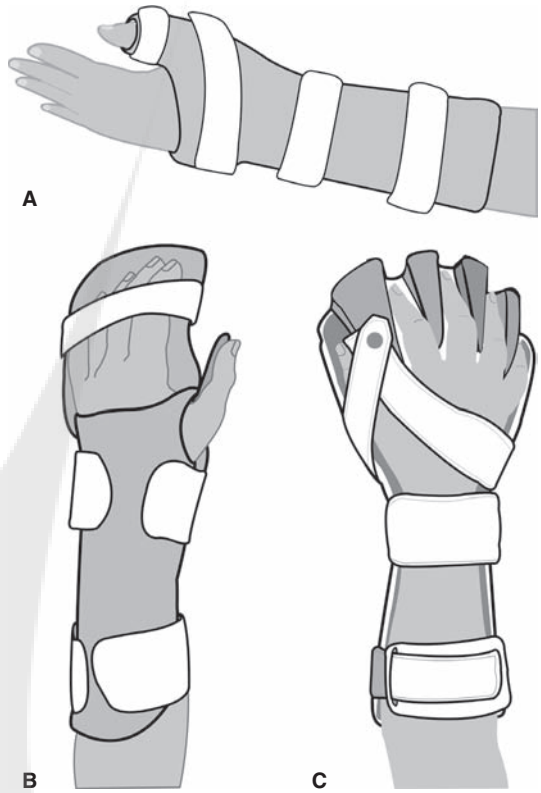

FIGURE 36.4 Examples of static wrist–hand orthoses (WHO): (A) thumb spica orthosis, (B) dorsal WHO, and (C) rigid volar WHO.

Dropout casts may be used when complete immobilization is unnecessary, as they allow movement into the desired range of motion but limit the progression of deformity by preventing motion in the opposite direction (18,31). Bivalved or clamshell designs allow casts to be removed for limb inspection, hygiene, or therapy, but should not be used in the presence of severe spasticity, as they do not provide sufficient immobilization of the limb to protect the skin from shearing and breakdown, nor should they be used where the limb is insensate or when cognition is impaired (18).

Static Progressive Orthoses

Orthoses can also be used to apply a static progressive stretch to joints with limited range of motion owing to contracture (e.g., Joint Active System [JAS], Thera Tech Equipment, Inc.™, Bloomingdale, IL; Air Cast, Vista, CA; turnbuckle orthoses) (33–35). Similar to serial casting, static progressive orthoses allow for incremental changes in joint position, which are then held constant for a prescribed period of time. However, static progressive orthoses also allow patient-directed therapy, as the stretch or force applied is typically increased by the patient to increase range of motion during the period of orthosis use. Static progressive stretch applied to contracted muscles is intended to restore the lost range of motion through the biomechanical principle of stress–relaxation (31); soft tissues respond to mechanical loads in

the same manner as a viscoelastic material, such that when stretched and then held at a constant length, the tendency to rebound gradually declines, leading to permanent plastic deformation rather than an elastic response (36). Static progressive orthoses are typically used for 30 minutes, two to three times per day, although it is possible for them to be applied for considerably longer periods (e.g., up to 6 to 12 hours). Unfortunately, there is scant evidence in the literature as to the most efficacious protocol for management of contracture in individuals with stroke. Joints that allow smoother incremental adjustment of joint position have replaced the use of ratcheting joints in static progressive orthoses, so that current orthotic technology allows the same degree of customization of joint position as casting.

Compared to serial casting, static progressive orthoses can be easily removed at regular intervals to allow inspection of the limb and maintenance of hygiene. Orthoses also reduce some of the risks of immobilization by allowing intermittent stretching of the antagonists, thus maintaining sarcomeres and some normal activity that helps reduce connective tissue accumulation (31). However, despite maximizing lever arms and pressure distribution wherever possible, individuals with both contractures and spasticity are particularly at risk for skin breakdown and may not tolerate a prolonged amount of time in a static progressive orthosis (19).

Dynamic Orthoses

Any technique that holds the joint in a fixed position, like static progressive stretching, will lose its stretching effect after a short period of time owing to relaxation of the connective tissue. Hence, dynamic orthoses were developed that apply a continuous stretch to contracted tissue and are commonly used for 6 to 12 hours (37). Dynamic orthoses attempt to stimulate continuous lengthening by operating under a different biomechanical principle than static progressive orthoses: that of creep rather than stress–relaxation. *Creep* is a loading condition where a force or load is held constant over a long period of time, whereas the displacement is allowed to vary (36).

Dynamic orthoses use a spring to generate torque at the contracted joint. There are three main types of springs used in dynamic orthoses, each with its own advantages and disadvantages: coil springs (e.g., Dynasplint®, Dynasplint Systems, Inc., Severna Park, MD), gas springs (e.g., ORLAU Contracture Correction Device, ORLAU, Oswestry, Shropshire, UK), and clockwork or flat springs (e.g., Advance Dynamic ROM®, Empi, St Paul, MN; Ultraflex Systems Inc., Pottstown, PA). Coil springs produce a linear force that is proportional to the change in length of the spring; in gas springs, the force produced depends on the gas pressure; and in clockwork springs, the torque produced is almost constant throughout the functional range (38). Because not all springs are capable of maintaining a constant torque throughout the joint range, they will need adjustment when range of motion improves if torque level is to be maintained (38). The advantages of spring mechanisms are that they provide an immediate dynamic response to activity by applying a controlled level of torque, and the spring tension can be set so that the user can overcome the stretching effect in the event of something like a spasm but will return to the stretched position (38). For the applied forces to be tolerable, dynamic orthoses should incorporate large interface areas located as far distally as possible from the joint undergoing stretch, to maximize the lever arm (38). It is important to be aware that the application of a mechanically generated load to a joint will generate relatively static compressive forces across the joint surface compared to normal physiological activity, which is more dynamic and results in periodic unloading of pressure from the joint surface (39). Hence, the prolonged use of orthoses should be undertaken with caution to limit compressive loading and its effect on cartilage (39). Although it has been reported that low-load prolonged stretch produces more increase in tendon length than a high-load stretch applied for a short time (40), the evidence is not definitively in favor of one protocol or the other (41).

To prevent contracture or maintain correction following resolution of contracture, static or fixed-position orthoses that hold the joint at the limit of its range of motion may be used (38). Such orthoses may be made from low- or high-temperature thermoplastics, depending on the expected life span of the orthosis (see the "Management of Limb Position" and "Management of the Hemiplegic Wrist and Hand" sections).

Management of Limb Position

Various devices can be used to improve or assist function by positioning the limb adequately for use. At the shoulder, proper positioning and support of the weakened or subluxed upper extremity may help to decrease pain, prevent inferior subluxation, and avoid the development of secondary problems. Individuals with paresis or spasticity of the shoulder, who are restricted to bed, tend to develop adduction and internal rotation contractures. In such cases, a foam abduction pillow can be used to position the shoulder in slight abduction and neutral rotation, preventing contracture and facilitating care and hygiene.

For nonambulatory individuals, the arm may be supported by a lap board placed over the arms of a wheelchair or by wheelchair-mounted slings and arm supports. Slings are the simplest and most common devices used with ambulatory individuals who require support of a flail arm to prevent inferior subluxation of the shoulder. Slings are inexpensive, lightweight, portable, and generally accepted by individuals. Examples include the hemi sling, figure-of-eight clavicular sling, the Bobath sling with axillary roll, the vertical humeral cuff sling, and the distal support sling that engages the thumb and wrist (Figure 36.3) (9). Although there are many different types of slings, no one type of shoulder support appears to be superior in reducing glenohumeral subluxation (9). The disadvantages of slings are that they immobilize the arm, have a tendency to increase flexor tone, and transfer a load that may adversely affect the neck and contralateral shoulder.

Management of the Hemiplegic Wrist and Hand

Upper-extremity orthoses have most commonly been used distally in individuals with stroke (1). The main goals of orthotic management of the hemiplegic hand are to reduce flexor tone at the wrist and fingers; avoid flexion contractures and deformities (e.g., thumb-in-palm and Boutonniere deformities of the fingers—where the proximal interphalangeal joint [PIP] is flexed and the distal interphalangeal joint [DIP] is hyperextended); maintain the hand and wrist in a comfortable, anatomically neutral position; and avoid carpal tunnel syndrome and hand edema (9,19). Avoidance of wrist and hand contractures not only serves a cosmetic purpose, it also allows adequate hygiene and skin care of the hand to be performed (9). Generally, rigid or static resting WHOs are used to position the hand in a "functional position," with 20 to 30 degrees of wrist extension, 35 to 45 degrees of metacarpophalangeal (MCP) joint flexion, 20 to 45 degrees of PIP joint flexion, 10 to 20 degrees of DIP joint flexion, and the thumb carpometacarpal joint partially abducted and opposed (42–44). Although such orthoses provide support for weak wrists and hands, they limit the range of motion and hence function. They are also constructed with rigid materials that are very unforgiving in the event of spasm or increased tone, especially if correction of the deformity is overly aggressive; moreover, it has been suggested recently that they often contribute to deformity rather than prevent it (42). Hence, it has been proposed that use of more flexible materials that provide support but "give" a little in the event of increased flexor tone, as well as positioning of the MCP, PIP, and DIP joints in neutral to stretch flexor muscles, and better strap placement to more positively secure the fingers (e.g., SaeboStretch, Saebo Inc., Charlotte, NC), would result in less deformity and greater compliance with orthotic management (42). Unfortunately, research as to the relative benefits between particular WHOs in the management of individuals with stroke has not been extensively performed.

Dorsal and volar WHOs are lightweight thermoplastic devices that utilize three-point force systems to maintain the wrist, thumb, and fingers in a functional position. The dorsal WHO primarily contacts the posterior surface of the forearm, providing a platform for finger support (Figure 36.4B). The volar WHO primarily contacts the anterior surface of the forearm, maintaining the wrist, thumb, and fingers in a slightly extended position (Figure 36.4C). Volar wrist orthoses are most commonly indicated after surgical lengthening of spastic extrinsic finger flexor muscles in a hand with modest volitional motion and are usually worn at night to maintain the hand in a corrected position (18). They should not be used in the presence of excessive spasticity, as they do not adequately control position and, if rigid, may cause skin breakdown or Boutonniere deformities of the fingers (18). Whether a dorsal or volar WHO design is selected, it is important to avoid forcing wrist/hand alignment that does not exist or is difficult to attain. If alignment is forced, the likely result is discomfort, possible skin breakdown, or discontinued use altogether. As the hemiplegic hand typically exhibits flexor tone, finger slings attached to the orthosis by springs (e.g., elastic bands or coiled wires) may be used within a dorsal WHO to create extension bias and a more dynamic device (9), where active contraction of the flexor muscles deforms the orthosis, and the orthosis returns the joints to a predetermined resting (static equilibrium) position when muscles relax (Figure 36.5). WHOs may also incorporate neurophysiologic principles to inhibit flexor tone, such as abduction of the fingers and avoidance of palm contact, to eliminate facilitation of the grasp reflex.

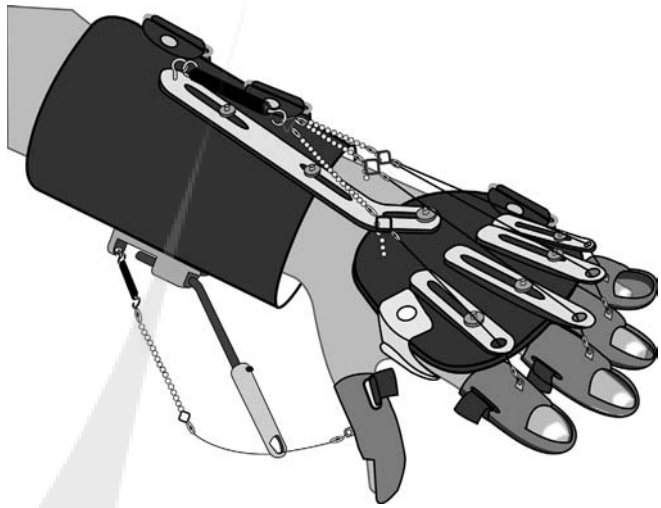

FIGURE 36.5 A dynamic finger extension WHO, the Saebo-flex (Saebo Inc., Charlotte, NC), for functional retraining of the hemiplegic hand. Springs on the dorsum provide resistance to finger flexion.

Dynamic finger orthoses or spring splints are used to correct flexion contractures of the interphalangeal joints but should not be used where flexor spasticity is present. The thumb abduction orthosis or thumb spica (Figure 36.4A) is a lightweight device that holds the thumb metacarpal in an abducted and slightly opposed position. It is used to avoid thumb-in-palm deformity and to improve thumb function, especially pinch. However, it has been proposed that the traditional "C" position of the thumb may actually encourage deformity. A less opposed position, though less functional, would lengthen the thumb flexor and adductor muscles rather than shortening them.

Recently, orthoses have been developed to aid in the retraining of function in the hemiplegic upper limb and hand (10,45,46). The SaeboFlex (Saebo Inc., Charlotte, NC) device uses springs to assist in hand opening for individuals with flexor hypertonicity and/or weak wrist and finger extensors. Use of the device is predicated on the functional task approach (47,48), wherein intensive, repetitive task-oriented training is used to improve function of the hand and upper limb by inducing long-term plasticity in the motor cortex (49–51). It has been suggested that this device potentially reduces tonicity/spasticity and improves range

of motion and motor control through functional tone management, a process whereby spastic muscle activation followed by relaxation teaches individuals how to modulate forces or "turn off" spastic flexors and lengthen them eccentrically (45). Similarly, electromyographic (EMG) signals have been used to trigger robot-assisted exercises and to control powered exoskeletal devices to provide assistance with movement (52). The Myomo device (Myomo Inc., Cambridge, MA) is an exoskeletal elbow orthosis that uses surface EMG signals to control a powered elbow to assist with movement of the paretic limb during therapy. In general, there is good evidence for the positive effect of repetitive function and strength training for the hand and upper limb (8), with mixed evidence as to whether orthoses provide an advantage for this type of therapy (10,45,53–55).

ORTHOTIC MANAGEMENT OF THE LOWER LIMB

Orthotic management of the lower limb is an important adjunct to the management and treatment of individuals with stroke during both the acute and the chronic stages of rehabilitation (12). During the acute phase, the primary goals are similar to orthotic management of the upper limb: that is, to maintain range of motion and prevent joint contractures. Adjustable AFOs may be used at night to prevent or correct contracture of the plantar flexors, whereas knee orthoses, which may or may not include the ankle, are often used to prevent or correct flexion contracture of the hamstrings. Contracture management of the lower limb is based on the same principles as described for the upper limb (see "Contracture Management" section). During both the acute and chronic phases, lower-limb orthotic intervention is linked closely to the functional requirements of ambulation. Generally, lower-limb orthotic devices provide lower-extremity stability and safety by controlling limb alignment and eliminating excessive joint motion; enhance motion when muscle activity is not adequate in strength, timing, or coordination; and inhibit or decrease abnormal muscle tone or cutaneous and postural reflexes either by controlling range of motion or by incorporating neurophysiologic modifications.

Lower-limb orthoses are ideally prescribed based on an assessment of walking to determine changes in limb alignment, motor control, and range of motion resulting from stroke that detrimentally affect function. The degree of sensation present (e.g., proprioception and touch) following recovery from stroke partly determines the ability to ambulate, as sensory deficits impair feedback with respect to limb position and placement (9). Therefore, decisions regarding orthotic prescription should also include assessment of sensation and cognitive status. Impaired balance, loss of trunk stability, proprioceptive loss, and/or loss of motor control may require the use of additional supports for walking, such as a walker or quad cane. Individuals who are unlikely to ambulate may nevertheless require lower-limb orthoses to prevent contractures that impede transfers or the ability to wear shoes.

Although the use of an orthosis may provide overall improvement in one functional task, it almost invariably also limits or resists other desirable movements, thereby hindering other tasks. Stroke affects not only the lower limb but half of the entire body, resulting in problems with proximal control and alignment of the trunk and pelvis. Proximal alignment affects distal function of the lower limb, and there are currently no lower-limb orthoses that can substantially influence alignment and function of the trunk and pelvis directly (56).

Lower-Limb Biomechanics and Function

Normal human walking is characterized by smooth, rhythmic patterns of motion that require relatively little effort by the individual. The functional requirements of able-bodied walking include gait initiation and termination, balance and upright posture, stance phase stability, shock absorption, execution of the stepping motion, forward progression/propulsion, and energy conservation (57,58). These requirements are variably disrupted by stroke.

Although common gait patterns exist, there is great variability among individuals with hemiplegia. Generally, hemiplegic gait is asymmetrical, slow, and uncoordinated owing to poor selective motor control of muscles on the affected side (9,59). Voluntary movement is often characterized by synergistic patterns corresponding to primitive extensor and flexor reflexes. Fortunately, these synergies are somewhat functional: by alternating synergy patterns, a hemiplegic person can walk, as the stance phase predominantly requires extension to create stability and the swing phase predominantly requires flexion to functionally shorten the limb for ground clearance. Unfortunately, following stroke, most individuals present with a predominant extensor synergy pattern in both swing and stance phases, leading to issues with limb clearance during swing and the adoption of compensatory gait patterns.

Compensatory gait patterns are commonly observed in individuals with hemiplegia. Inadequate knee flexion and dorsiflexion may require circumduction of the limb to prevent toe drag in swing (9). Circumduction, excessive posterior trunk bending, pelvic rotation, and hip hiking on the involved side and vaulting on the sound side may be used to assist in swinging the involved leg (59). Disruption in normal motion and alignment, along with compensatory maneuvers and increased muscle activity, lead to greater than normal energy expenditure during walking and fatigue over short distances (60,61).

Hemiplegic gait is generally characterized by shorter than normal step lengths bilaterally (with the uninvolved step length shorter than the involved), longer stance phase duration, and shorter swing phase duration during swing phase on the involved side (9,59). Weight bearing on the involved limb is often decreased because of weakness, fear, perceptual or sensory impairments, and disorientation to midline. Persistent equinovarus of the ankle and foot during stance on the involved limb decreases the base of support,

increasing instability. People with hemiplegia tend to walk with a retracted hemi pelvis, primarily because of perceptual and sensory deficits and secondarily because of altered muscle tone and weakness in the hip abductors, trunk, and abdominal muscles (59). Weak internal rotators and an inability to dissociate hip motion from a retracted pelvis lead to excessive external rotation of the hip during swing phase and excessive toe-out distally. Pelvic retraction can also lead to hyperextension at the knee. Equinus of the ankle–foot may lead to initial contact with the forefoot or a foot-flat position. Inability to achieve initial contact with the heel may result in an external extensor moment at the knee during early stance, leading to hyperextension. Forward flexion of the trunk is common, owing to tight hip flexors or weak hip extensors, and will also contribute to an increased external extensor moment at the knee during stance. Forward flexion of the trunk may also be a compensation for the lack of tibial advancement during stance resulting from tight plantar flexors. Weak knee extensors commonly result in knee instability and buckling, whereas weak dorsiflexors result in insufficient dorsiflexion and drop foot during swing (59).

Types of Lower Limb Orthoses

Shoe Modifications

Following stroke, shoe modifications may be used, alone or (more likely) in conjunction with lower-limb orthoses, to improve ankle–foot function (Figure 36.6). Velcro closures or elastic laces are commonly used to facilitate donning and doffing of shoes with one hand, as individuals with hemiplegia typically lack bilateral upper-limb function. Extra-depth footwear may be necessary to accommodate orthotic devices such as AFOs. When the stroke results in mild varus or valgus angulations of the ankle–foot complex, a high-top shoe may provide some control. Shoe modifications such as a cushion or beveled heel can be used to decrease loading rate of the limb at initial contact and during loading response. A cushion heel involves sandwiching a compressible material within the heel of a shoe, whereas a beveled heel involves beveling the posterior aspect of the existing heel (Figure 36.6A,B). Both modifications alter the point of application of the ground reaction force and serve to facilitate forward progression of the center of pressure, reducing the demand on the quadriceps by decreasing the external flexor moment acting at the knee during loading response. However, cushion and beveled heels are contraindicated in the presence of knee hyperextension unless a rigid, nonarticulated AFO or an articulated AFO with plantar flexion stop is used to provide control at the knee (see the following section on AFOs). Sole and heel wedges placed medially or laterally (Figure 36.6C,D) may be used to counteract undesirable coronal plane moments at the ankle and knee. Addition of a lateral border flare to the sole of the shoe increases the base of support and decreases the tendency for the foot to roll out laterally into varus during stance. Traditional metal AFOs often incorporate T-straps to control varus deformity at the

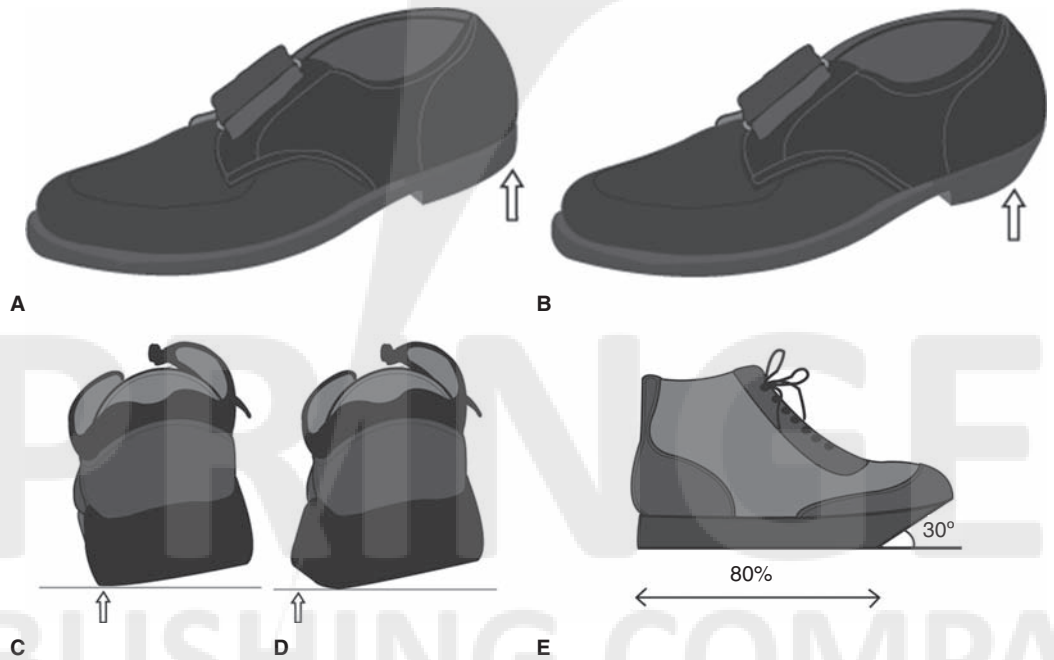

FIGURE 36.6 Examples of three shoe modifications: (A,B) side view of the beveled heel used to alter moments about the ankle in the sagittal plane, (C,D) posterior view of the lateral border flare used to alter moments at the subtalar joint in the coronal plane, and (E) side view of point-loading rocker (dimensions taken from Owen (62)). Arrows indicate point of application of the ground reaction force at initial contact in the unmodified shoes (A,C) and the modified shoes (B,D).

ankle. It should be noted that if initial contact occurs with the forefoot or with the foot flat, shoe modifications used in isolation, without other orthoses, are unlikely to be helpful.

Shoe modifications are also important when tuning segmental kinematics to improve standing balance and gait. A specific example, the AFO-Footwear Combination (AFO-FC) approach consists of a rigid, nonarticulated AFO in which modified footwear in the form of heel and toe rockers is used in addition to heel wedges under the AFO to adjust the shank-to-floor angle, that is, the position of the lower leg relative to the ground when standing (62–64). Subsequent "tuning" of the AFO-FC involves iteratively adjusting the intrinsic wedges and shoe modifications to manipulate the relationship between the ground reaction force and knee and hip joints, thus improving gait performance (65,66). In conjunction with a rigid, appropriately aligned AFO, stiff soles with point-loading (toe) rockers (Figure 36.6E) are used to facilitate terminal stance by allowing the heel to lift off the ground when the point of application of the ground reaction force reaches the point-loading rocker (62). The appropriate position of the point-loading rocker along the length of the foot and the toe spring angle must be determined for each individual. Although this orthotic approach is being advocated for use in stroke (67), only limited evidence exists regarding effectiveness in this population (65,66,68). Footwear modifications effectively increase the length of the affected leg, so some compensation for leg length in the form of a raise on the opposite limb may be required. Custom shoe modifications, though important, are often difficult to get covered by third-party payors in current practice. Where this is an issue, it is important for the medical team to be aware of alternate options, such as commercially available shoes that incorporate some of these design features to some extent.

Foot Orthoses

Foot orthoses (FO) encompass all or part of the foot but terminate distal to the ankle joint. They may extend the length of the foot or terminate at the toe sulcus or proximal to the metatarsal heads. FOs may be used to provide protection for insensate feet or corrective positioning (69). A rigid thermoplastic University of California Biomechanics Laboratory (UCBL) foot orthosis with neurophysiologic modifications may be used in the presence of stable subtalar and ankle joints to manage mild hypertonic foot reflex activity and toe clawing (Figure 36.7) (70). Since an FO such as the UCBL does not cross the ankle joint, it will not correct an equinovarus ankle-foot posture.

Ankle–Foot Orthoses

Equinovarus positioning of the ankle–foot complex is the most common deformity observed in the lower limb following stroke (71); hence, AFOs are the most commonly prescribed orthoses for management of gait abnormalities following stroke. AFOs may be made from a variety of materials, such as metals, thermoplastics, thermosets, or a hybrid of metal and plastic, depending on their particular application. Plastic orthoses are popular because they provide improved cosmesis and circumferential control compared with metal, although metal orthoses are indicated where fluctuating edema cannot be controlled by compression garments or medication (Figure 36.8). Plastic AFOs are generally comprised of an intimate fitting, posterior shell typically made from homopolymer polypropylene or a polypropylene/polyethylene copolymer (1). Polyethylene homopolymer is more flexible than polypropylene and typically is used for circumferential or nonweight-bearing orthoses such as upper-limb orthoses. Fiber-reinforced thermoset laminations, such as those incorporating carbon graphite, are appropriate when transverse rotational forces must be restricted. Despite resulting in stronger, stiffer, and lighter orthoses compared to polymers, thermosets are not used as widely because of their higher cost and more difficult fabrication process, although easier fabrication techniques using "prepreg composites" (i.e., fibrous material preimpregnated with resin, partially cured and ready for molding) are emerging that allow custom thermoset orthoses of varying flexibility and rigidity to be fabricated without the need for specialized facilities (72).

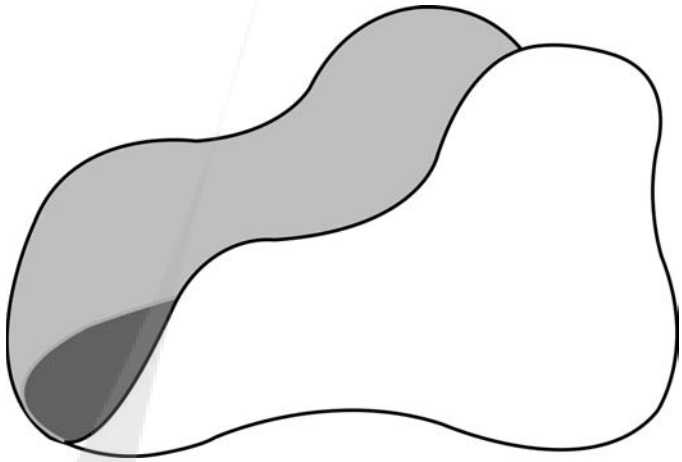

FIGURE 36.7 UCBL (University of California Biomechanics Laboratory) foot orthosis, side view with posterior aspect to the right.

AFOs act directly at the ankle and indirectly at the knee and hip, although there is less evidence for the effect at the hip than at the knee (12,73–76). The basic AFO design includes a proximal trimline that terminates 20 mm distal to the neck of the fibula, providing the longest possible lever arm for ankle motion control, which is particularly important if spasticity of the triceps surae muscle is present (29). AFOs differ substantially from ankle orthoses (AO). AOs are prefabricated orthoses intended to provide mediolateral stability at the ankle joint in the presence of ligamentous insufficiency. AOs provide only minimal support to prevent varus of the hind foot, but may be used transiently in mild cases until gait improves completely (9). Generally, AOs are inappropriate

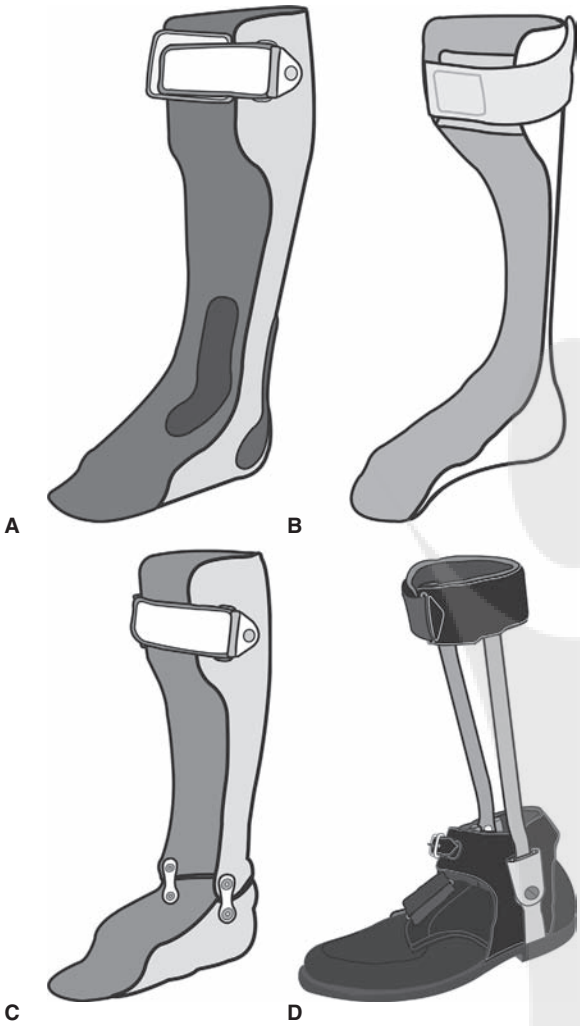

FIGURE 36.8 Four main types of AFO: (A) rigid nonarticulated, (B) posterior leaf spring, (C) polymer articulated, and (D) metal articulated. The articulated polymer AFO incorporates a plantar flexion stop, whereas the metal-articulated AFO has double-action ankle joints that use combinations of pins and springs anterior and posterior to the joint to provide a plantar flexion stop (pin in posterior channel), dorsiflexion stop (pin in anterior channel), dorsiflexion assist (spring in posterior channel), and plantar flexion assist (spring in anterior channel).

for individuals with stroke, as they lack sufficient lever arm in the presence of hypertonicity to adequately control ankle motion. However, when worn, AOs may have greater compliance than AFOs, as they are relatively inconspicuous and fit easily into regular footwear.

AFOs fall into two main categories: articulated and nonarticulated (Figure 36.8). As the name implies, articulated AFOs incorporate mechanical joints at the ankle that allow control of sagittal plane motion. Articulated AFOs may be used to control joint range of motion (e.g., using adjustable joints), provide assistance to motion (e.g., with a dorsiflexion assist joint), or limit motion (e.g., with plantar flexion or dorsiflexion stops). Although nonarticulated AFOs do not incorporate joints, they may or may not allow motion at the ankle in the sagittal plane, depending on their flexibility. In a nonarticulated polymer AFO, motion is determined by the rigidity of the orthosis about the ankle joint, which is usually a product of plastic thickness and geometry. Adding reinforcements about the ankle or an anterior shell may increase rigidity of the AFO. A nonarticulated AFO is generally rigid if the trimlines about the ankle are anterior to the malleoli, sometimes referred to as a *solid* or *rigid AFO*. The more posterior the trimlines are to the malleoli, the more flexible the orthosis becomes, such as in a polymer posterior leaf-spring AFO (PLS-AFO). In a PLS-AFO, motion occurs because of buckling or deformation of the plastic when a moment is applied. A PLS-AFO allows some plantar flexion at initial contact and dorsiflexion during mid-stance. It returns the ankle to neutral during swing phase when the only load acting on the orthosis is the weight of the foot. Hence, the PLS-AFO is contraindicated where there is spasticity, hypertonicity, or clonus of the plantar flexors, as the control of ankle position in swing is diminished if a plantar flexor moment is applied to the orthosis at that time (12).

AFOs may be either prefabricated or custom-made. Prefabricated or off-the-shelf AFOs are convenient, inexpensive, and adequate for some individuals. Although they may be used for training/evaluation or as interim devices, they are rarely recommended for long-term use owing to their generic fit (12), which also makes them unable to accommodate misalignment and deformity of the foot and ankle. Prefabricated PLS-AFOs are common because their limited biomechanical control easily accommodates a more generic shape; however, they are contraindicated where there is significant tone or spasticity, mediolateral subtalar joint instability, or problems at the knee or hip that have to be addressed (71). A fundamental requirement of all orthoses is that they contour well to the body segment(s) they encompass. Custom-made AFOs provide better biomechanical control than prefabricated orthoses because a more precise fit can be achieved, especially in the presence of complex deformities.

The primary indications for AFO use in stroke are inadequate dorsiflexion in mid to terminal swing, resulting in foot clearance problems and compromising the ability to achieve initial contact with the heel; mediolateral ankle–foot instability in stance and swing; and insufficient tibial control in stance. Table 36.1 summarizes indications for the three basic types of AFOs (rigid nonarticulated, articulated, and flexible nonarticulated) as applied to individuals with stroke (12).

It is not uncommon for a person with stroke to require greater stability during the initial acute phase but less stability as recovery occurs. In such cases, a progressive AFO, with biomechanical controls that can be altered as the individual's condition changes, may be useful. This can be a polymer AFO fabricated to include ankle joints but that has yet to be "cut" to allow articulation. Similarly, a knee–ankle–foot orthosis (KAFO) can be converted to an AFO as the individual's needs change (77). An AFO with adjustable ankle joints may also be useful during the acute phase, as

TABLE 36.1 Summary of Indications for AFOs

Nonarticulated AFOs (excluding leaf-spring AFOs) are indicated as follows:
- poor balance, instability in stance
- inability to transfer weight onto the affected limb in stance
- moderate to severe foot abnormality; equinus, valgus or varus, or a combination
- moderate to severe hypertonicity
- as above, but with mild recurvatum or instability of the knee
- to improve walking speed and cadence

Articulated AFOs are indicated as follows:
- dorsiflexor weakness only
- where passive or active range of dorsiflexion is present
- where dorsiflexion is needed for sit-to-stand or stair climbing
- to control knee flexion instability only; articulated AFO with dorsiflexion stop
- to control recurvatum only; articulated AFO with plantar flexion stop
- to improve walking speed and cadence

Posterior leaf-spring AFOs are indicated as follows:
- isolated dorsiflexor weakness
- no significant problem with tone
- no significant mediolateral instability
- no need for orthotic influence on the knee or hip

Source: From Ref. (12). *International Society for Prosthetics and Orthotics. Report of a Consensus Conference on the Orthotic Management of Stroke Patients.*

it allows the ankle joint to be locked in any position from dorsiflexion to plantar flexion or be free moving throughout the range. Dorsiflexion and plantar flexion stops can be used when partial range of motion is required. Such adjustability allows the mechanical ankle joints to accommodate changes in the range of motion as the individual progresses.

In AFOs, three-point force systems are used as needed in the sagittal plane to control plantar flexion/dorsiflexion and in the coronal plane to control hind foot inversion and/or forefoot adduction (Figure 36.1B–D). Shaping the AFO to match the foot ensures comfort while controlling deformity. The forces should be applied as far apart as possible to maximize lever arms and over large areas to reduce pressure (67).

When a rigid nonarticulated AFO or an AFO with a plantar flexion stop is used, it is important to account for footwear heel height when casting and keep the heel height of the shoe constant, as changes in footwear heel height can alter the indirect effect of the AFO at the knee (78). Rigid devices may be used to maintain the ankle in a fixed position and prevent spasticity, as a spastic response tends to rapidly diminish when joints are immobilized but may persist with even small amounts of motion. Although it has long been considered standard practice to cast the ankle at neutral (i.e., 90 degrees), recent literature suggests that the angular relationship between the shank and floor is more important for function, especially in a rigid nonarticulated AFO (5,63–65,67) and that gastrocnemius length should be considered when deciding ankle alignment (79). When sagittal alignment of the foot cannot be fully corrected owing to tight plantar flexors, wedging can be added to the underside of the AFO to accommodate the lack of range but still create a stable base of support (67) (Figure 36.2).

A tuned AFO-FC consists of a rigid, nonarticulated AFO in which ankle angle and shank to vertical angle are considered separately. *Ankle angle* refers to the angle of the ankle in the AFO and is based on measurements of muscle length (79), whereas *shank to vertical angle* refers to the angle of the tibia with respect to vertical during standing and walking (64). Modified footwear is used in addition to wedges under the heel of the AFO and/or shoe to "tune" the shank to vertical angle (63). "Tuning" focuses on manipulating segment kinematics, in particular shank (i.e., tibial) kinematics, to improve the relationship of the vertical ground reaction force vector to the knee and hip during stance. When the AFO positions the tibia in a vertical alignment, the ground reaction force cannot be simultaneously aligned in front of the knee and behind the hip, unless the knee hyperextends, which is undesirable. Progressively adding wedges under the heel to incline the tibia can optimize ground reaction force alignment at both joints. The rationale for this approach is that controlling tibial alignment and progression in mid to late stance transfers forward momentum to the thigh, facilitating knee and hip extension in terminal stance if there is sufficient gastrocnemius length, placing the limb in a more appropriate alignment for transfer of body weight to the contralateral limb, and commencing swing phase with the ipsilateral limb. There is some evidence that alignment of the orthosis at terminal stance and/or preswing will influence step length, gait symmetry, speed, and energy consumption (67,80). However, when using a tuned AFO-FC, additional gait training may be required to derive maximum benefit. Use of the AFO-FC approach has been advocated for stroke (67), with plans proposed for a randomized control trial to investigate the effect of tuning on gait (81).

AFO alignment can also be used to enhance knee stability during stance where the knee extensors are weak and unable to support body weight during single support. Floor reaction or ground reaction AFOs (FRAFO or GRAFO) are rigid, nonarticulated AFOs that hold the ankle in slight plantar flexion to create an external knee extension moment during stance. For these designs to be effective, they must provide good rotational control and should not be used in the presence of a knee hyperextension deformity.

AFOs that incorporate neurophysiologic modifications are sometimes referred to as *dynamic* or *tone-reducing AFOs*. In these orthoses, control of muscle tone may be attempted by positioning the toes in extension, applying pressure points over strategic locations on the plantar surface of the foot and muscle insertions, providing static immobilization through total contact, and stimulation of antagonist muscle groups (7,8). For example, a toe spreader or toe separator may be used independently or in conjunction with an AFO to inhibit tonic foot reflexes such as the toe grasp reflex, which may cause excessive toe clawing, leading to pain and impeding forward advancement of the lower limb over the foot. Inhibition of abnormal tone in the toes allows the foot to become a better weight-bearing surface over which the body may progress during stance (1). Function of toe spreaders/separators is based on the premise that abduction and extension of the toes release intrinsic tone. Tone-reducing AFOs often incorporate total contact principles, with greater contact of the dorsal surface of the foot, to facilitate neutral alignment of the subtalar joint, which is purported to reduce tone in the foot while allowing motion at the ankle joint (70). However, there is little evidence to support the ability of orthoses to reduce tone during ambulation (7,8).

Recently, it has been suggested that triplanar dynamic response orthoses may lead to greater functional improvements than plastic orthoses, through better control of segment alignment and motion (82) (Figure 36.9). These orthoses are made from thermosets, such as graphite composites, to provide sufficient rigidity to support body weight during stance and control forces in all three planes yet allow sufficient flexibility to absorb and return energy. Unfortunately, there is as yet no evidence of their efficacy or applicability to individuals with spasticity and hypertonicity.

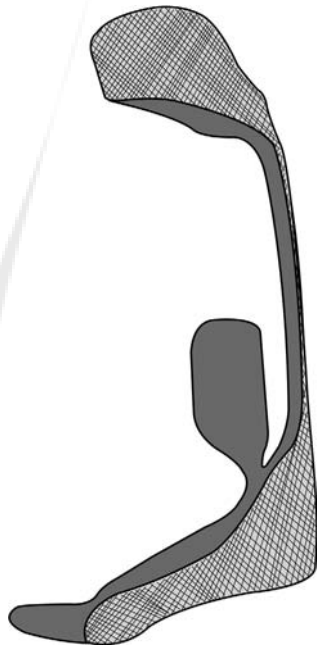

FIGURE 36.9 Graphite composite, triplanar control dynamic response AFO with lateral flange (Dynamic Bracing Solutions, San Diego, CA).

Knee–Ankle–Foot Orthoses

KAFOs are used where a need exists for direct control of the knee joint in addition to the ankle and foot (29) (Figure 36.10). A KAFO is also useful when there is lack of control of the hip extensor muscles (1). All KAFOs provide coronal plane knee stability by default, and the ankle section may be articulated or nonarticulated.

Orthoses that encompass more than one joint, such as KAFOs, are usually bulky and cumbersome, and individuals with weakness, as often occurs in stroke, are unable to tolerate bulky, heavy devices (1). Traditionally, only two basic knee control options were available for use in KAFOs: unlocked or locked. A KAFO with unlocked knee joints provides coronal plane knee stability, with sagittal plane stability of the knee during stance predicated on geometric alignment. This may be achieved with posterior offset knee joints where the mechanical axis of rotation is located posterior to the anatomical axis of rotation, resulting in an external knee extensor moment at the mechanical joints in early

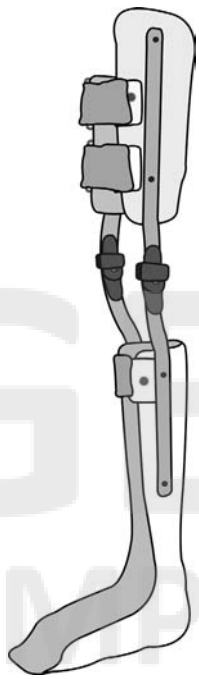

FIGURE 36.10 Hybrid metal and plastic knee–ankle–foot orthosis (KAFO) with drop-lock knee joints.

stance (29). These joints are not entirely reliable, especially on uneven terrain and slopes, and are indicated only where the individual retains adequate hip musculature strength and control, proprioception at the knee, and good balance to ensure stumble recovery should geometric stability not be achieved.

A KAFO with locked knees provides both coronal and sagittal plane control of the knee throughout stance, but also remains locked during swing phase, necessitating compensatory maneuvers during walking to achieve ground clearance of the extended limb during swing. As we progress proximally, immobilization of lower-limb joints increases energy expenditure during functional activities, with immobilization of the knee being particularly detrimental (58). Hence, KAFOs have been used infrequently, owing to their increased weight and energy demands when walking.

Stance-Control KAFOs

Stance-control orthoses incorporate knee joints that automatically stabilize the knee during stance phase but release it during swing phase to allow knee flexion. These relatively new joints, and the availability of strong, lightweight materials, have renewed interest in the potential use of KAFOs in individuals with stroke (12,77,83). It has been suggested that stance-control KAFOs may be particularly useful during the early rehabilitation phase after stroke, as they may facilitate appropriate limb alignment and provide support of the weakened limb during gait training (84). This may decrease the development of abnormal postures, especially proximally, and lead to better long-term functional recovery. Stance-control orthoses may be of benefit both as a temporary poststroke gait-training aid and as an ongoing gait assist for individuals with permanent knee extensor weakness. Different stance-control knee mechanisms are commercially available (e.g., Stance-Control Orthosis™, Horton's Orthotic Lab. Inc., Little Rock, AK; UTX® and Model 9001 E-Knee™, Becker Orthopedic, Troy, MI; UltraSafeStep™, Ultraflex Systems Inc., Pottstown, PA; FreeWalk™ and SensorWalk™, Otto Bock HealthCare, Minneapolis, MN; Swing Phase Lock, Fillauer LLC, Chattanooga, TN), which require different strategies to engage and disengage the knee joint. Hence, not all the available stance-control knee mechanisms may be appropriate for individuals following stroke.

FUNCTIONAL ELECTRICAL STIMULATION

FES is a technique that uses electrical currents to stimulate nerves to activate muscles that have been affected by paralysis secondary to traumatic brain injury, neurologic disorders, spinal cord injuries, and stroke. FES is a long-standing treatment modality that has historically been used therapeutically and in controlled settings. For those individuals who present with upper motor neuron lesions, FES is thought to provide reciprocal and recurrent inhibition that may reduce involuntary stimulation of spastic muscles (85). It is thought that with inhibition and subsequent relaxation of muscles, there is greater opportunity to reduce pain when present and to improve passive range of motion. In recent years, there has been a steady increase in the use of FES, either in conjunction with an orthosis or as an alternative to orthotic management, with an increased emphasis on using FES in a functional capacity (86). FES for functional use has been described using terms such as neuroprosthesis and neuromuscular electrical stimulation (NEMS). The FES/orthosis hybrid design or FES alone has been used with the stroke, cerebral palsy, spinal cord, multiple sclerosis, and traumatic brain injured populations. Although there has been utilization for both the upper and lower limb, the former has tended toward a hybrid design (87) and the latter toward standalone FES use. Common commercial devices for lower-limb application include the Bioness L300 (Bioness Inc., Valencia, CA), Walkaide (Innovative Neurotronics, Austin, TX), and Odstock Dropped Foot Stimulator (ODFS; Department of Medical Physics and Biomedical Engineering, Salisbury District Hospital, Salisbury, Wiltshire, UK). The most common commercial device for the upper limb appears to be the Bioness H200 (Bioness Inc., Valencia, CA), formally referred to as the Handmaster®. Despite this apparent increase in the utilization of FES, the evidence for lower-limb use is limited (86), and that for upper-limb use is even scarcer.

Orthotic Management and FES for the Upper Limb

FES use for the upper limb has primarily focused on wrist/hand function, with particular emphasis on restoring grasping (88). Currently, the most common design is a WHO that incorporates FES. The WHO is able to maintain wrist/hand alignment, whereas the FES stimulates repetitive muscle contractions for either therapeutic or functional use of the hand. Initial training and calibration may require daily use for up to 1 week and, depending on the protocol, 20 to 180 minutes of daily utilization (11,89). Hence, use of this system should include training time and follow-up in the overall treatment plan. This commitment should be conveyed clearly to patients so they can determine for themselves the costs and benefits of utilizing the device.

There is some evidence that the hybrid FES/WHO has short-term benefits while being worn or shortly after being worn by persons with poststroke hemiplegia (88). Reported benefits include increased passive range of motion, reduced edema, diminished hand/wrist impairment, improved overall arm function, and decreased pain. In some instances, although there were no observed benefits, patients chose to continue wearing hybrid devices, suggesting that the patients perceived benefits that were not measured. Investigations of upper-limb FES applications have assessed effectiveness based on motor and sensory recovery, reduced edema, improved passive range of motion, and long-term utilization of hybrid devices. In future, it may be necessary to include more global, patient-oriented assessments (e.g., Goal Attainment Scale) to better determine the benefit of the hybrid devices perceived by individuals with hemiplegia.

Orthotic Management and FES for the Lower Limb

The efficacy of FES use in the lower limb of hemiplegic patients is difficult to define owing to limited evidence and heterogeneity in assessment methods. Studies have explored the physiological effects of FES on voluntary ankle motion; investigated orthotic, carryover, therapeutic, and total effect of FES use; compared FES to AFO use with regard to both effects on gait and perceived value; and evaluated the long-term effects of FES use. A collective understanding of these studies will help the clinician to consider FES as a functional intervention.

When the poststroke patient attempts to voluntarily move the foot and ankle, the physiologic effect of stimulation to the common peroneal nerve during the swing phase of gait is to dorsiflex and, depending on placement of the electrodes, evert the foot (Figure 36.11). With this ability, FES is capable of addressing both the equinus and varus components usually observed in hemiplegic gait. However, FES devices that are exclusively for peroneal nerve stimulation do not provide mediolateral ankle stability, nor do they provide tibial control during the stance phase of gait. Patients who require stability any time between initial contact and terminal stance are likely to require more substantial support. There is evidence to suggest that stimulation of the common peroneal nerve may also lead to inhibition of the plantar flexors (90).

Collective improvement across these areas leading to a change in gait and attributable to FES has been referred to as an *orthotic effect*. The orthotic effect can be described as a change, typically in gait, when the FES is in the "on" position. A number of studies have reported a positive orthotic effect particularly in walking speed and physiological cost index (PCI) (91–93). Another study, using an activity monitor, showed a correlation between use of the FES and gains in walking speed (94). Generally, it has been easier to demonstrate an FES orthotic effect in the chronic stroke population than in more acute presentations where there is the possibility of spontaneous improvement irrespective of the intervention. The orthotic effect, though beneficial, does not describe changes in gait that may remain after the FES is turned off.

The effects on gait observed after the FES is shut off are referred to as the *carryover effect*. This expanded scope of FES capability has led to a growing number of investigations examining the carryover effect (95). Initial observations suggested a short-term carryover effect of FES use that dissipated over time. Subsequent studies have found that the carryover effect may last longer than previously thought, possibly as a result of long-term and repeated FES use (96). Consequently, there has been a shift from the term *carryover effect* to *therapeutic effect* (referring to a patient's presentation before and after FES use). Like other interventions where long-term and repeated therapy constitutes all or a portion of the treatment plan, the therapeutic effect of FES is now being viewed in much the same way. In this same manner, the total effect of the FES now becomes a function of both the orthotic and therapeutic effects.

Thus far, results of studies investigating the therapeutic effects of FES on gait have been less convincing than those demonstrating an orthotic effect (91). In particular, it has been difficult to draw conclusions about the therapeutic effects of FES on walking speed. One study observed improvements in walking speed at 3-, 6-, and 12-month intervals, but also had a simultaneous decline in the original cohort of subjects, suggesting a possible attrition bias (94). In another study, 12 individuals received a single 30-minute FES intervention and then performed ambulation without the FES intervention. Though there was some carryover improvement in standing balance, it was difficult to determine if there was an immediate carryover effect in walking velocity and whether there would be long-term sustainability (97).

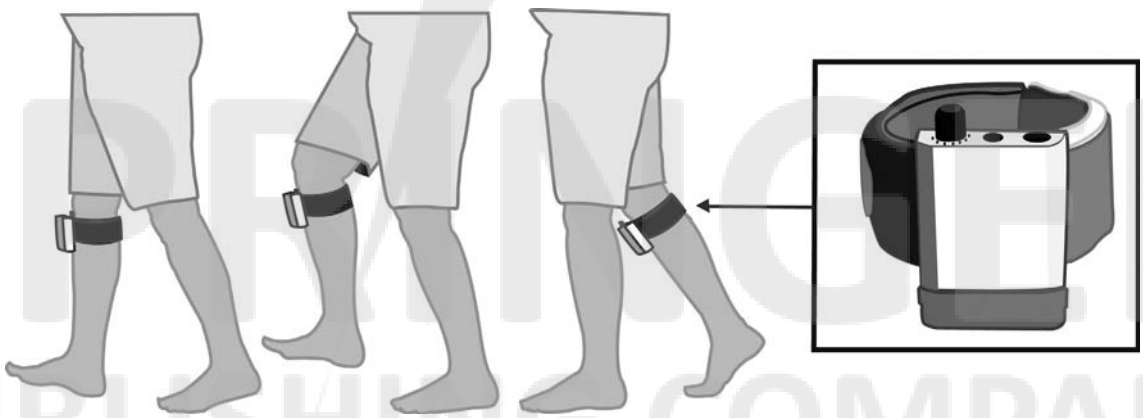

FIGURE 36.11 Example of stand-alone FES device for lower-limb application (Walkaide, Innovative Neurotronics, Austin, TX). The FES device can be adjusted for stimulation to occur to the common peroneal nerve at the time of swing phase for dorsiflexion activation to improve clearance of the foot during swing. In this case, the FES is being used independent of conventional treatment (e.g., AFO).

More recently, there have been investigations comparing the more traditional treatment method (an AFO) to FES intervention. However, small sample sizes and variability in AFO design across subjects and studies make it difficult to draw conclusions about the reported findings. Trends have been observed that may have clinical relevance, but they should be considered with caution. In one study, a subject exhibited improvement in functional ambulation compared to no intervention, but when compared to similar subjects performing the same task with an AFO, functional ambulation tended to be lower (98). In a study by Kottink et al. (99), a randomized control design was used to compare an implantable peroneal nerve stimulator to conventional treatment with an AFO over 26 weeks of use. Neither group showed improvements in walking speed with their respective devices (AFO or FES), nor did they show improvements over time. Finally, a study by Ring et al. (100) comparing FES to AFOs found no appreciable difference during initial application in gait asymmetry index, variability in swing phase duration, and walking speed; however, after four weeks of use, the FES users demonstrated a significant improvement in all areas except for walking speed.

Although quantitative gait data such as walking speed are relevant and important measures, equally important is the patient's perception of function with AFOs compared to FES (101,102). A recent study by Bulley et al. (101) explored the perception poststroke patients had of using an AFO compared to FES. Subjects described greater independence, faster walking, more normal-looking gait, and ease of shoe selection as some of the benefits of FES. Benefits of the AFO included equipment reliability, ease of donning, ease of day-to-day use, and usefulness in emergencies. Drawbacks of FES use included lack of equipment reliability, inability to function in certain situations (e.g., near water), difficulty in donning, and difficulty of wear when traveling. Drawbacks of AFO use included lack of comfort, lack of shoe compatibility, and the fact that it remains in place when not needed, for example, while sitting. Although most subjects preferred the FES, some subjects indicated that they could not rely upon the FES exclusively and still required the use of the AFO for certain tasks. The results of this study are a good reminder for the clinician regarding the limitations of both FES and AFOs; although neither is likely to address all of the patient's needs when used independently, they may do so to a larger extent when used in concert with each other. This is one reason why patient goals and expectations must be clearly defined. It will help determine if utilization of both devices is a better treatment plan than independent use of either design.

In sum, FES as an alternative form of lower-limb orthotic treatment has shown promise during real-time utilization but demonstrated less consistent therapeutic effects. Improvement in walking speed with the FES "on" and patients' positive perception of the FES suggest that it is a feasible treatment option that requires more investigation to determine who would benefit most. Caution should be taken not to prematurely abandon conventional treatment such as the AFO in favor of FES treatment alone. Both options have value for the patient depending on function and task-specific activities. Contraindications and precautions must also be considered, including, but not limited to, the patient's cognition, skin condition, range of motion, use of a pacemaker, and anticipated or current pregnancy (103). Tolerance for FES during daily activities, ability to effectively place electrodes, and ability to maintain the device must also be evaluated. With these considerations in mind, FES offers the medical team an added treatment option that may help to further optimize function for certain individuals with hemiplegia.

RESEARCH FRONTIERS IN THE ORTHOTIC MANAGEMENT OF STROKE

Recent reviews (67,71,104) suggest that, generally, symmetry of gait improves with use of AFOs compared to walking without orthoses. Studies also suggest that nonarticulated AFOs increase weight bearing through the affected limb during walking and standing. AFOs with resistance to plantar flexion, whether articulated or nonarticulated, improve the ankle angle at initial contact and mid swing. There is some indication that nonarticulated or plantar flexion stop AFOs can control knee recurvatum and reduce the external knee extension moment during stance, especially if set in dorsiflexion or anterior tibial inclination. There is also some suggestion that nonarticulated AFOs may control supination of the foot. A few studies have demonstrated that nonarticulated AFOs decrease the energy cost of gait compared to walking without orthoses. Generally, subjects report that AFOs improve their walking and are comfortable when compared to no device, but tend to prefer FES devices in certain circumstances (101).

Although orthoses are commonly used in the management of stroke and empirically have been found to be of benefit, a 2004 consensus conference on the orthotic management of stroke concluded that evidence for the orthotic management of stroke is generally low, both in terms of quality and quantity (12). There exists a need to demonstrate efficacy more objectively, especially within the current medical paradigm of evidence-based practice. For example, there is no evidence in the literature regarding the most appropriate timing of lower-limb orthotic management following stroke; the long-term or carryover effect of lower-limb orthoses has not been demonstrated; and the ability of an AFO to influence range of motion of the hip during gait is unconfirmed by experimental studies on stroke subjects (12). As much of the literature regarding the orthotic management of stroke is based on small numbers of subjects, with the orthoses often poorly described, it has been recommended that well-controlled, multicenter trials involving large numbers of subjects are urgently needed (5).

Although there are still few randomized control trials or studies involving large numbers of subjects, several recent studies have been identified that better define both the characteristics of AFO interventions and the physical presentations of the study subjects, making their findings

more relevant to clinicians (65,73,105–107). As this trend continues, the published literature will better guide clinicians as they create orthotic treatment plans for individual patients. In addition, more studies of orthotic management are utilizing clinical outcome measures such as the 6-minute-walk test (100,108–112), timed-up-and-go (113–117), Berg Balance Scale (114,115), and the modified Emory Functional Ambulation Profile (98,110,118,119), expanding our understanding of the functional effect of orthoses beyond what can be observed in a motion analysis laboratory and providing clinicians with information to which they can more directly compare their patient outcomes. Similarly, insights are being gained into the sensitivity of outcome measures for assessing the effects of an orthosis. For example, Geboers et al. (120) used both the 10-meter-walk test and 6-minute-walk test to evaluate patients with foot drop walking with and without an AFO. The 10-meter-walk test showed no improvement when the AFO was used, but the 6-minute-walk test did. One explanation for these results is that persons with foot drop are able to compensate for gait deficits over short distances but not over extended periods of activity (121). This suggests that gait lab-based studies, with their typically short bursts of walking, may underestimate the effectiveness of AFOs when compared to the functional benefits implied by their widespread clinical use. It also suggests that we may need to consider dosage of orthosis use based on activity level and fatigue, as examples.

Recent literature reviews have shown that the outcome measures used most frequently to evaluate walking ability after stroke are those that assess walking over a short distance at a self-selected walking speed or at a fast pace (122,123). Although informative, such outcome measures provide a relatively limited assessment of the ability of the individual to ambulate in the everyday environment. Outcome measures that assess walking under different conditions, although used sparingly in stroke research, reflect more recent attempts to measure the influence of the environment on mobility (122,124). A core battery of outcome measures appropriate for the evaluation of orthotic management of stroke has been proposed (125). These measures address impairments (muscle activity, joint motion/torques, balance, pain), function (manual dexterity, mobility, walking endurance), falls, and goal attainment. They also span the spectrum from instrumented measures to patient-reported measures. However, most of these outcome measures are generic and do not account for changes in orthotic design and use over time. This may be particularly pertinent to stroke patients who could conceivably progress from using a KAFO in the acute poststroke phase to a nonarticulated AFO and subsequently an articulated or leaf-spring AFO as recovery occurs. The only stroke-specific, performance-based outcome measure that we have identified that attempts to address this issue is the modified Emory Functional Ambulation Profile (126,127). It allows for a weighting factor to be applied to the score to account for changes in orthotic assistance over time.

Another area that has received some attention when it comes to orthotic management of stroke is the effect of AFOs on balance. A recent systematic review suggested that leaf-spring AFOs may have positive effects on balance in adults with stroke-induced hemiplegia, whereas for other types of AFOs, there was some evidence to suggest that balance outcomes were dependent on the design of the device: rigid designs seemed to be beneficial in static balance tasks and more flexible designs superior under dynamic balance conditions (128). However, the descriptions of AFO design presented in the reviewed articles were considered quite poor. This results in a low level of confidence in these conclusions, particularly in the light of more recent concepts regarding the importance of alignment and tuning of AFOs and footwear on function (64), which were not reported. A randomized control trial protocol has been proposed to assess the importance of tuning for orthotic management of stroke (81). In addition, the type of information that should be reported regarding AFO design has been described (129,130).

It has been proposed that improved quality of life and independence are nonbiomechanical effects of orthotic use after stroke (67), suggesting that mobility may affect both biomechanical and nonbiomechanical outcomes. These nonbiomechanical outcomes are rarely reported in the literature.

With regard to the upper limb, evidence as to whether orthoses can improve function and/or impairments remains limited (131). Controversy still exists as to whether static, rigid WHOs prevent deformity or contribute to it; the long-term effects of contracture management, based on either stress–relaxation or creep, are unknown; the optimal protocol for the application of stretch to spastic muscle is unclear; the interaction between orthoses and other therapies remains largely unexplored; and the benefits of hybrid orthoses incorporating FES remain to be defined.

In general, the science of orthotics is immature. Although orthotic technology continues to advance, especially with the application of new materials, microprocessors, and active elements such as motors (132) and pneumatics (133–135), our understanding of how best to apply that technology lags behind. In the past, most orthoses were passive, whereas today there is a growing interest in active orthoses that might, for example, power gait by providing propulsion at push-off (134), assisting knee flexion torque in preswing when the knee is stiff (136), or assisting/resisting knee motion during sit-to-stand, walking, and stair-climbing activities (132). Most active orthoses are currently limited in their clinical application by the size and weight of the devices, in large part as a result of being tethered to the power sources required. One recently developed device, the AlterG Bionic Leg (previously the Tibion Bionic Leg (132)) has overcome some of these obstacles, resulting in a portable, wearable, powered knee orthosis that provides assistance to patient-initiated knee motion. Although promising, use of this device in persons after stroke has to date been reported in only two case studies (137,138). Both studies utilized the device as part of a task-oriented functional training program in chronic subjects and reported improvements in balance (138)

and mobility (137,138) that were retained at one (137) to three months (138) follow-up, suggesting that neural remodeling or reorganization may be possible. Although active devices may be applied to weak limbs in a reasonably safe manner, we need to develop a better understanding of how to safely apply active devices where spasticity and hypertonicity are present and there may be unpredictable resistance to the torque provided by the active orthosis. In addition, active orthoses may not be as effective as anticipated if underlying abnormal neuromechanical coupling exists between lower limb joints (136).

Alternative, Complementary, and Integrative Medicine and Therapy

Arlene A. Schmid, Marieke Van Puymbroeck, and Samuel C. Shiflett

Complementary and alternative medicine, commonly referred to as CAM, and most recently as integrative medicine or therapies, is defined as diverse systems, practices, and products not typically considered to be included in conventional medicine (1). In this chapter, CAM is used to represent all therapies in this area. The World Health Organization defines *traditional medicine* as "the sum total of knowledge, skills, and practices based on the theories, beliefs, and experiences indigenous to different cultures that are used to maintain health, as well as to prevent, diagnose, improve or treat physical and mental illnesses" (2).

Many alternative therapies currently practiced in the West have their origins in the ancient medical traditions of Eastern cultures, such as traditional Chinese medicine and the Ayurvedic tradition of India. These ancient approaches treat the body and its health as an integrated system, and illness is seen as an imbalance or disharmony of vital energy and dynamic forces within the whole body. Treatment of illness is thus seldom focused on the symptoms of the illness but on the believed underlying imbalance of subtle energy. Restoring the body to equilibrium or improvement in self-regulation may require a set of integrated interventions that focus on the body, mind, and soul (3). As a result, traditional Chinese medicine has an arsenal of treatments that include not only various forms of acupuncture, but also a vast pharmacopeia of herbs and supplements barely known in Western medicine; various physical movement and physical manipulation techniques such as tuina, a technique similar to chiropractic manipulation; and exercises designed to strengthen the body and to move and balance the subtle energy (chi or qi), including tai chi and qi gong. Many meditation and breathing techniques supplement these physical interventions. The same is the case for Indian medicine, where yoga postures (asanas), Ayurvedic herbs, meditation, sound, and breathing exercises may all be prescribed for a particular disease, all focusing on the restoration of the health of the overall system.

Even though these ancient models often do not seem to have any relationship to modern (Western) concepts of physiology, anatomy, and the ontogeny of disease, many of the techniques that have been generated over the centuries continue to be practiced today and are often considered helpful by practitioners. Interestingly, many of these ancient techniques have parallels in modern therapies, which are sometimes derived from these early traditions and, in other cases, were developed independently of them. Thus, stretching exercises, massage, and other techniques routinely used by rehabilitation therapists are surprisingly similar to the alternative techniques of tuina, yoga, and pranayama (breathing exercises), and so forth. Additionally, recent secondary data analyses of the 2007 National Health Interview Survey of more than 20,000 people indicates that people with functional limitations and people with neurological conditions are more likely to engage in some form of CAM when compared to other adults without such limitations or conditions (4,5).

The use of alternative or nonconventional therapies by individuals to supplement or complement conventional medical treatments has been commonplace for many decades. CAM therapies have historically been used without the knowledge of the patients' health care providers, thus raising the risk of unknown interactions with standard medical treatments. This phenomenon was first brought to the attention of the medical community with the publication of a major national survey published in 1993, along with a follow-up survey confirming the findings seven years later (6,7). Coupled with information from a 2012 systematic review of CAM use (which excluded prayer) by the general public, data support continued and increased use of CAM, with 41% to 63% of older adults using some aspect of CAM (8). These past surveys not only demonstrated the widespread use of CAM, but also indicated that more resources were being spent on these therapies than on conventional medicine (6,7). These findings spurred a major move toward improved understanding of the nature and mechanisms of CAM through the development of a major research agenda initiated by the National Institutes of Health (NIH). The majority of this research is funded and monitored by the National Center for Complementary and Alternative Medicine (NCCAM, http://nccam.nih.gov), a division of the Office of the Director of NIH.

According to NCCAM, there are multiple types of CAM, which may be grouped into the following broad categories:

1. Natural products (i.e., herbal medicine or botanicals, vitamins, minerals, probiotics)
2. Mind and body medicine (i.e., meditation, yoga, acupuncture, guided imagery, tai chi, etc.)
3. Manipulative and body-based practices (i.e., spinal manipulation, massage therapy)
4. Movement and energy therapies (i.e., Pilates, Feldenkrais® method, light therapy, Reiki)
5. Whole medicine systems (i.e., complete systems of theory and practice such as homeopathy or traditional Chinese medicine)

Definitions and additional examples of each of these categories can be found on the NCCAM website (www.nccam.nih.gov). Although many therapies included in CAM are not considered traditional medicine, others may be considered mainstream or alternative, depending on who is doing the categorizing. For example, many supplements and herbal extracts considered alternative in the United States have been used routinely for decades or centuries in European or Eastern medical practice.

The question of what is alternative becomes even more problematic when specifically discussing the field of physical medicine and rehabilitation (PM&R). The modern medical field of PM&R developed as an identifiable discipline during World War II as physicians and therapists utilized a number of complementary treatments that addressed not only the broken body but also the mind, spirit, and soul, with the goal of uplifting and restoring the whole person into a meaningful and productive life, rather than simply focusing on physiological or anatomical healing (9). This can also be seen in occupational and recreational therapies, each of which enjoys a long history of whole body or holistic mind–body therapies and mental health interventions. Occupational, physical, and recreational therapy credit the work of reconstruction aides in World War I for providing the momentum for the development of the professions (10) where the aides focused on treatments to heal the mind and body of soldiers. More recently, yoga, a specific type of CAM, was discussed as an "ancient occupational therapy" and as a holistic modality that may become an aspect of routine daily personal care (11).

Over the years, many complementary treatments involved in rehabilitation have become accepted as standard of care, and the evidence base for these treatments is slowly growing. The holistic nature of this field means that, more than is the case in most medical disciplines, rehabilitation therapists and physicians are willing to explore and utilize potential new therapies that appear to be beneficial even when those same therapies are being subjected to the time-consuming and costly process of evaluation by randomized controlled trials. In fact, many modern and alternative movement and manipulation techniques have emerged from the field of rehabilitation medicine. Examples include such movement and manipulation techniques as Feldenkrais®, Rolfing® or Structural Integration, and Trager® psychophysical integration. Thus, the distinction between complementary/alternative medicine and conventional medical therapy is not always clear in rehabilitation. For example, most conventional category systems defining CAM, including that of the NCCAM, include biofeedback as an example of a mind–body alternative therapy. Biofeedback is typically offered at most New Age and alternative health clinics; however, various forms of biofeedback have been available at many rehabilitation centers for many years. Thus, the status of biofeedback as alternative versus conventional medical therapy is unclear.

The Ottawa Evidence-Based Clinical Practice Guidelines Development Group recently published an extensive and exhaustive review of therapies for poststroke rehabilitation (12). They reviewed a broad range of rehabilitation interventions, both conventional and nontraditional, including biofeedback and constraint-induced therapy, along with other ostensibly alternative therapies such as massage, electrical stimulation, transcutaneous electrical nerve stimulation (TENS), tai chi, and acupuncture. These evidence-based clinical practice guidelines did not refer to any of these therapies as alternative or complementary. Therapies were included because there was research literature providing evidence for or against the effectiveness of the therapeutic intervention. This approach epitomizes the need for evidence-based medicine rather than a focus on alternative versus conventional medicine, as issued by the *JAMA* editors in the first special issue on CAM ever published in that journal (13).

The major premises of this chapter are that the ideas of nontraditional therapies should not be thought of as alternative, and that CAM therapies are not expected to replace conventional therapies in the current standard of care. Rather, the use of CAM therapies is expected to be complementary or integrative, used alongside and absorbed into regular rehabilitation care.

Many of the therapies discussed herein are presented with an explanation of their proposed mechanism(s) of action and evaluated in terms of supporting research evidence for inclusion as an aspect of stroke rehabilitation. The evidence varies in quality, from moderately strong to very weak. The remainder of the chapter is organized around most of the categories proposed by NCCAM, with the exception that the whole medical systems category is not used here; rather, certain specific therapies within those systems are assigned to one of the more specific NCCAM categories.

The chapter concludes with a discussion of strategies for managing therapies that appear promising and safe but for which empirical evidence of efficacy is not yet available.

NATURAL PRODUCTS

Supplements, Herbs, and Homeopathic Remedies

A number of nutritional supplements and herbs have been suggested for the prevention of stroke and related diseases with varying degrees of research evidence. However, there

is little evidence that these compounds can help in stroke recovery, except perhaps in their ability to reduce the likelihood of a recurrence of a stroke (14). With more than 100 clinical trials of allegedly neuroprotective agents, so far none have proven effective as a way to intervene with the cascade of detrimental cellular events that occur with stroke (15,16). However, investigations into the molecular components of Chinese medicine drugs and herbs provide some evidence that many of the drugs and herbs may contain the components necessary for neuronal change (17). Natural agents, such as the antioxidant alpha lipoic acid, certain traditional Asian herbal mixtures, and some homeopathically prepared remedies, have been studied as a means of reducing infarct size. A number of nutrients and herbs have been proposed to assist in treatment of the secondary effects of stroke, such as pressure sores, urinary tract infections, and pneumonia (14,18). Currently, only vitamin D has been found to be useful in preventing poststroke falls (a secondary effect of stroke), although the mechanism is unknown (19). There is evidence that a nutritional supplement that is calorie-dense with high protein and fat for individuals considered to be undernourished may be related to improved outcomes during stroke rehabilitation efforts (20).

A meta-analysis of traditional Chinese medicine drugs was completed in 2007, in which the authors indicated that most published trials of Chinese medicine have been conducted using poor-quality methodologies (21). The authors of the meta-analysis concluded that there was not sufficient or good-quality evidence to support traditional Chinese medicine as a mechanism to prevent death or dependency after stroke. They did state that there is enough evidence to support future research regarding the use of Chinese medicine to manage the secondary effects of stroke. At this time, the evidence is insufficient to recommend herbal and homeopathic treatment options as adjuncts in stroke prevention, treatment, and rehabilitation. Moreover, some of these supplements may have interactions with conventional medications, such as warfarin, anticonvulsants, and so forth. Physicians should inform patients of these concerns and should review the appropriateness of any proposed herbal or nutritional supplement before patients initiate usage. The reader is referred to a more thorough review of these adjunctive treatments, including the more than 100 herbs recommended and used in traditional Eastern medicine for stroke prevention, treatment, and rehabilitation (14,18).

Ginkgo Biloba

The one herbal supplement for which there is a substantial amount of research in neurologic and vascular disorders is an extract of the *Ginkgo biloba* leaf (22). The leaf of the ginkgo tree has been part of the traditional Chinese pharmacopoeia for 5,000 years. It has been shown to increase cerebral blood flow (23), and is therefore commonly used in Chinese medicine in the treatment of stroke. Standardized extracts of the ginkgo leaf are widely used in Asia, Germany, and France and are increasingly being used in the United States.

Ginkgo shows promise in the treatment of some of the most salient and debilitating symptoms associated with stroke, cognitive functioning in particular, and other vascular and neurologic disorders. One example of this evidence reported that 50 patients with subarachnoid hemorrhage who were administered ginkgo extract in a placebo-controlled, double-blind study showed significant improvements in attention and verbal short-term memory (24). Similarly, in another placebo-controlled study of patients with multi-infarct dementia or Alzheimer's disease showed modest, but significant, improvement in cognition on a geriatric assessment scale (25). The evidence for the use of ginkgo has been extensively reviewed by Diamond et al. (22,26), and their conclusions were that the evidence for ginkgo's effectiveness is mixed but encouraging. More recently, however, a systematic review (27) concluded that gingko as a sole herb appears to have no consistent benefit in treatment of acute ischemic stroke; however, its role as part of a more traditional combination of traditional drugs and herbs was not assessed (28). The results of the Cochrane review for stroke indicates that although there is no convincing evidence for the routine use of *Ginkgo biloba*, there are studies that show a relationship between the herb and improvement of patients after an ischemic stroke (27). Discrepancies in the results of these reviews may be related to the stringency of the criteria for inclusion. The clinical applications and precautions for ginkgo use are discussed in detail by Diamond et al. (22). One important caveat is that ginkgo has an anticoagulant effect and should be administered with caution in the presence of warfarin or aspirin and in individuals who have had a hemorrhagic stroke.

Hyperbaric Oxygen Therapy

Hyperbaric oxygen (HBO) therapy is defined as the provision of oxygen at pressures above sea level (1 atmosphere absolute or ATA). This is normally accomplished by enclosing the patient within a pressurized (hyperbaric) chamber. HBO has been primarily used to treat decompression sickness and air embolism, but has been proposed as a treatment for stroke. Advocates note that people with stroke experience a deprivation of oxygen to areas of the brain and suggest that this treatment might enhance neuronal viability by its ability to increase the amount of dissolved oxygen in the blood without changing blood viscosity (29).

The evidence for HBO therapy in chronic stroke is limited and controversial at best. Early, poorly controlled studies and surveys suggested that it might be helpful, but more recent studies have come to the opposite conclusion (30). The treatment parameters remain uncertain, with a range of 1.5 to 2.5 ATM proposed, and some suggest treatment with pressures as high as 3.0 ATM for the initiation of therapy (31).

A recent, small clinical trial (32) randomized a small sample of chronic stroke patients to receive either 60 minutes of HBO in a chamber at 2.5 ATA versus a control treatment of 100% oxygen treatment in an HBO chamber at

1.14 ATA. The small amount of additional pressure in the control group was designed to facilitate blinding patients. Results indicated that a very low pressure of 100% oxygen (1.14 ATM) (intended as a control therapy) was more effective than a treatment at 2.5 ATM. Safety and toxicity have been concerns regarding HBO therapy (33–36). A 2010 review of the evidence concluded that there is no consistent evidence to support use of HBO for acute stroke, but that the potential for clinical benefit cannot be ruled out at this time (30).

Chelation

Chelation is a chemical process in which a substance is used to bind molecules together so that they can be removed from the body. Ethylene diamine tetra-acetic acid (EDTA)-chelation therapy has long been FDA-approved for removing heavy metals (e.g., lead) from the blood; however, its use for other purposes is controversial. It has been advocated for the treatment and prevention of cardiovascular and cerebrovascular disorders, but there are no controlled trials to substantiate its use. In one uncontrolled trial, cerebral arterial occlusion was measured in 57 patients before and after treatment with 10 to 46 sessions of chelation therapy. Eighty-eight percent of the patients improved, with the criteria for improvement not stated, and cerebral arterial stenosis was reported to be reduced from a mean 28% to 10% (37). A retrospective analysis was conducted, in Brazil, of 2870 patients who were treated with chelation therapy between 1983 and 1985 (38). These patients had a variety of vascular and degenerative diseases, with about 18% of the patients diagnosed with cerebrovascular disease or degenerative CNS disease. The investigators reported "marked recovery" in 24% of the patients and "good recovery" in 60%. Animal studies with another chelating agent, deferoxamine, show that the hypoxic-ischemic injury is reduced if deferoxamine is administered soon after the injury (39–41). Currently, there is a large (n = 1708) double-blind, randomized controlled trial of EDTA chelation therapy for people with coronary artery disease being conducted (Trial to Access Chelation Therapy [TACT]) (42). The study is funded in part by the NCCAM and the National Heart, Lung, and Blood Institute. Stroke rates are included as an important primary end point. Preliminary results suggest some benefit in reducing the risk of cardiovascular events, but final results have not been published as of this writing. At present, the evidence of efficacy and safety is insufficient to recommend this treatment for stroke survivors.

MIND AND BODY MEDICINE

Mind–Body Therapies

The mind–body category of NCCAM contains a huge number of diverse interventions. Mind–body interventions, as the name implies, focus their therapeutic efforts on the interrelationship between mental and physical activities. In Eastern models, the two, mind and body, are inextricably intertwined, so physical and cognitive techniques are often discussed together in Eastern treatments of the subject. Techniques in this area can focus primarily on the mind (e.g., hypnosis and meditation), on the body through physical movements (e.g., tai chi and yoga), or on a combination of both (e.g., yoga with meditation). For clarity and to more directly reflect the categories often used in PM&R, we divide these techniques into two sections: mind-focused and movement interventions.

Mind-Focused Therapies

This section includes interventions focused directly on cognitive processes that are intended to favorably affect the whole body.

Optimizing Self-Healing Through Expectations and Beliefs

Virtually all alternative therapies acknowledge the inextricably intertwined nature of the mind and the body. Alternative systems of therapy seldom use only a single intervention; instead, they use multiple interventions that work on various aspects of both the mind and the body. Thus, a traditional Chinese medicine practitioner might use acupuncture, herbs, massage (tuina), and energy healing (qi gong and so forth) in a systematic and integrated treatment of the whole body, including the mind, rather than focusing on a single diagnosis or symptom. Similarly, in Ayurvedic medicine, herbs are a basic part of a treatment, but they are usually combined with physical manipulations (yoga and marma therapy), breathing exercises, mantras or healing sounds, and meditation to quiet the mind and reduce stress. All of these systems of intervention work on both the mind and the body.

In Western medicine, the connection between the mind and the body is also well known and acknowledged as a legitimate way of conceptualizing the way the body maintains a healthy state. Well-defined fields such as behavioral medicine, psychoneuroimmunology, psychiatry, and psychology all recognize and focus on the mind–body connection in health and healing. However, with the advent of powerful surgical and pharmacologic interventions, conventional medicine has tended to push the mind part of the equation into the background, considering it to be a minor, if not irrelevant, component of the healing process. In fact, these belief-based processes have often been considered confounders in clinical research that is designed to look at the pure underlying mechanisms and healing ability of a medical intervention, free of any artifacts that might make the treatment look better or worse than it really was. The unwanted effects of these beliefs and expectations have come to be called *placebo*, from the Latin for "I please," in effect implying that patients are mindlessly following their doctor's suggestions. Rigorous, placebo-controlled, clinical research protocols have become the only true test of the underlying effectiveness of a treatment because they control, not only for the placebo effect, but also for placebo-like effects such as natural healing and other artifacts in the healing process.

Recently, some biomedical researchers have begun to look at the placebo effect more closely, not merely as a confounding phenomenon that occurs in research designs, but also as a possible source of healing per se (43–45). In an extensive review of the literature on the placebo effect, Walach and Jonas (45) have suggested that the placebo process should really be called something that reflects the fact that it is a "meaning attribution" process. They provide suggestions, based on the literature, for enhancing the process whereby positive meaning is given to a clinical situation. From a therapeutic point of view, the placebo response can best be defined as the effect that is caused by the meaning of a therapeutic intervention for a particular patient and context (45). Notice that this "meaning response" definition acknowledges that humans are not deterministic machines mechanically reacting to external causes such as drugs, physical therapy, and so forth; rather, we respond in part as a result of our interpretation of what is happening to us, including the meaning attached to a particular treatment and the manner in which the health care giver presents it. To the extent that a patient responds to the extracausal components of the intervention itself, it must be considered to be a real effect. If the environmental cues send a negative message about the therapy (technically referred to as a *nocebo*), we should expect to see a poorer result from the treatment. Similarly, if the cues are positive and supportive, the pure effects of the therapy can be expected to be enhanced. And the changes in treatment effectiveness are not simply because of willfulness or weak-mindedness on the part of the patient; they are real effects that emerge from the patient's attribution of meaning to the situation.

Health care providers who are developing and integrating CAM approaches to medicine, involving both conventional and nonconventional therapies, have begun to stress the importance of this mental component of the healing process. They are encouraging its use in the clinic and even conducting research designed specifically to assess the extent of and effectiveness of various placebo-inducing factors. It is also being argued that the term *placebo* should no longer be used to characterize this phenomenon, because it has the negative connotation of weak-willed compliance to an authority figure (43). The suggestive component of this process not only includes the bedside manner of the caregivers, but also includes the physical environment itself. More and more clinics are utilizing a healing environment approach to their space. Walls and equipment are in warm colors. Soothing music is available in the waiting room as well as in the clinical suite. Invasive and complex-looking equipment is placed as unobtrusively as possible, and so forth. Research on the effectiveness of these techniques is still in very early stages, but the importance of harnessing this meaning aspect of the placebo effect must be recognized (43,45–47).

A useful list of ways to enhance the healing effects of a therapeutic intervention based on research literature on placebo has been presented by Walach and Jonas (45). Based on their literature review, they propose a number of ways to enhance the meaning attribution process in a clinical setting, which is presented here in Table 37.1.

Even though not all of these interventions may be easily applicable to a rehabilitation setting, they should suggest, by generalization, the types of things a clinician can do and say that will encourage the patient and facilitate the healing

TABLE 37.1 Ways a Health Care Provider Can Optimize the Meaning Attribution Process in the Doctor–Patient Relationship

- Always work with—not against—patient's expectations.
- If patients' expectations are unhealthy or harmful, work to change them first before jumping from intervention to intervention.
- Talking can induce a response toward cure. Rapport between doctor and patient is an important vehicle for suggesting therapeutic effects and enhancing expectations.
- One of the greatest skills of a doctor—and a topic often left out of the debate around evidence-based medicine—is individualization. It is in the subtle changes to therapy and how they are delivered by a skilled healer that the meaning response is harnessed to its fullest.
- Raising hope and alleviating anxiety in a credible way is one of the most therapeutic acts in general.
- It has been shown empirically that a simple act, such as giving a clear diagnosis and prognosis, improves outcome.
- A frequent assumption is that only specific causal effects count, like those produced by drugs or surgery. Other effects also count.
- Giving placebos is not identical to using the meaning response therapeutically. One need not give sugar pills. However, in some cases, the use of nonactive or minimally active drugs might be a better option than continuous medication with toxic, but effective, therapies.
- Therapeutic rituals might be helpful in eliciting the meaning response. It may be useful to help patients develop their own rituals, like taking a drug after a morning bath, in a special room, before or with prayer, or having it administered by a friend.

process. A whole body of research is emerging in which the effects of these interventions are being tested in rigorous research designs (43,44). In the meantime, clinicians should take to heart the fact that the mind is a major component of healing and, over time, can facilitate or thwart the effects of even the most powerful physically focused intervention.

Meditation

There is little to no evidence for the use of meditation or mindfulness-based stress reduction after stroke. There is limited evidence that mindfulness-based stress-reduction intervention, including meditation, may improve poststroke fatigue (48). Recent meditation literature completed in adults without stroke has demonstrated neural changes after meditation; neuroimaging was used to identify increased cortical thickness and brain connectivity (49–52). Such neural changes may be associated with improved motor, cognitive, and emotional recovery for people who have sustained a stroke.

With regard to stroke prevention, the most robust finding from the extensive research literature on meditation is the success of meditation for reducing hypertension (53–57). Currently, a large randomized clinical trial is underway, the hypertension analysis of stress reduction using mindfulness meditation and yoga (HARMONY) study, to study mindfulness meditation (and yoga) as a modality to control hypertension for individuals with high blood pressure (58). Given the success of meditation for reducing hypertension and the fact that hypertension is a primary predisposing factor for stroke and recurrence of stroke (59), it seems reasonable to conclude that meditation may be effective in reduction of risk of recurrent stroke.

Biofeedback

Biofeedback is a therapeutic technique originally developed for muscle relaxation, but it has also been used recently in a number of other ways as well. It is a good example of a family of techniques that remains on the boundary between alternative and mainstream medicine and therapy, despite a substantial body of research evidence, including several meta-analyses (60–62). However, a more recent Cochrane review did not find treatment benefit for biofeedback when added to therapy to improve motor function after stroke, but the authors indicate that the included studies were small and of poor design (63).

The Ottawa Panel on Evidence-Based Clinical Practice Guidelines Development Group reviewed and recommended several forms of electromyographic biofeedback (EMG-BFB). Their guidelines support the use of EMG-BFB for upper and lower extremities at all stages of stroke recovery (12). The Ottawa Panel concluded that there is strong support for audio and video feedback training for unilateral neglect reduction in subacute stroke and general facilitation EMG-BFB training for upper and lower extremities, including rhythmic positional training in chronic stroke. They concluded that EMG-BFB should be included as an intervention for poststroke patients who have a high level of motor return and where gait and standing are the focuses of rehabilitation. More details on the specifics of the use of EMG-BFB in stroke rehabilitation can be found in the Ottawa Panel report (12).

Positive, but less conclusive, research evidence for other uses of BFB in stroke recovery has been reported and should be considered when other interventions are not successful (63). For example, BFB may be helpful in controlling urinary incontinence (64–66). It appears to assist with some aspects of the rehabilitation of hemiparesis and mobility and gait recovery (67,68) and may be useful in the rehabilitation of swallowing in patients with dysphagia (69–71). Interestingly, Nelson identifies biofeedback as a modality that has mixed success, but notes that it may have a positive impact with improvements in self-confidence, change in locus of control, and ability to instantly integrate feedback on motor and mental activity (64). It may be that the change in motor function is less important than the perceived improvements and improved self-confidence to complete a movement or task.

A newer form of feedback is EEG-based feedback, or neurofeedback (64). In this approach, electrodes monitor the EEG activity at one or more scalp locations, and a computer displays information about the brain's activity to the patient. Then, operant conditioning combined with various cognitive strategies or functional tasks is used to train the patient to alter his or her own EEG activity in the desired direction. Given the relationship between EEG activity in particular frequency bands over specific cortical locations and metabolic rates of various cortical structures (72), this approach has been hypothesized to allow the therapist and patient to alter cortical metabolism and thereby influence neural activity and neuroplasticity in various regions of the brain (73,74). Neurofeedback has been hypothesized to alter or accelerate the processes of functional reorganization of the cortex following stroke, thereby enhancing or accelerating functional recovery. Aside from two case reports in chronic stroke survivors suggesting improved cognitive functioning (75,76), this technique remains untested in stroke patients, and its efficacy remains speculative at this time.

Interactive Metronome Therapy

Another novel technique for cognitive rehabilitation following stroke is Interactive Metronome Therapy (64). This technology uses operant conditioning of an individual's motor planning, sequencing, timing, and attention by having him or her engage in simple, repetitive motor tasks such as clapping the hands or tapping the feet in time with a set beat. The system provides both visual and auditory feedback to indicate how far off beat each repetition of the task is (in milliseconds) and whether the repetition was early (before the beat) or late (after the beat) to allow the individual to alter the rate of movement on a beat-by-beat basis. The tempo of the beat is adjustable. Thus, in the course of just over a second, the individual receives audio and visual feedback about his or her last response, tracks the next beat, adjusts his or her behavior accordingly, and makes the next response. This deceptively simple task is cognitively demanding, and

many patients find it frustrating and confusing in the beginning of their treatment. The research on Interactive Metronome technology has focused largely on the remediation of attention deficit disorder in children (77,78). At this time, there is no published research evidence for its efficacy in stroke rehabilitation; only that it may be feasible to add to occupational therapy (79) and may improve upper-extremity function and perceived stroke recovery (80).

Mental Practice/Motor Imagery

Mental practice, or motor imagery, is a technique by which physical skills are mentally rehearsed in a safe, repetitive manner. Mental practice increases motor skill learning and performance in elderly individuals (81,82), and the same neural and muscular structures are activated when movements are mentally practiced as during physical practice of the same skills (83–85). Other similarities between mental practice and physical practice include:

1. The time taken to mentally and physically perform movements is highly similar (86).
2. During mental practice, the speed/accuracy trade-off is maintained (87).
3. Mental practice produces similar autonomic events as physical practice of the same skills (88).

Pilot data suggest that the addition of mental practice to motor therapy may actually yield greater motor improvement than conventional motor therapy in subacute (89–91) and chronic stroke (92–97). Of interest, a randomized placebo-controlled trial for people with chronic stroke demonstrated significantly different improvements for individuals who received mental practice plus 30 minutes of therapy than those only receiving 30 minutes of therapy (98). Subjects who received mental practice showed less physical arm impairment, increased arm function, and new ability to engage in valued activities. A 2006 review of the literature indicates that mental practice may be beneficial after stroke, but that further research is required (99).

Movement Therapies

A number of movement-based therapies, such as balance training and dance therapy, are utilized in physical rehabilitation, and a few can be thought of as alternative. Because of the limited mobility of many stroke patients, however, the application of these approaches is limited and often must be modified and simplified to safely accommodate their capabilities. Nevertheless, there is some evidence, often with nonstroke elderly patients, suggesting that these approaches should be considered and developed for future clinical use. Three movement therapies are briefly discussed here: tai chi, qi gong, and yoga.

Tai Chi and Qi Gong

Tai chi and the closely related qi gong are whole body movement approaches based on traditional Chinese medicine that use gentle, rhythmic, and ritualized movements of the arms and legs. Tai chi is associated with and has emerged from the martial arts; qi gong, although using similar movements, generally refers to the use of breathing as well as stylized movements for healing purposes. Qi gong can also refer to a form of subtle energy healing in which subtle energy or chi is emitted from a master into another person for healing purposes. In this chapter, qi gong refers to the stylized movements of a person with the purpose of moving the chi within his or her own body.

Tai chi has been used with success in improving balance and reducing falls and fear of falling in fall-prone elderly subjects (100–102), and appears to be safe for people with chronic disease and disabilities (100,102). Research for tai chi after stroke is growing, as evidenced by a published review in 2012 (103). At the time of the review, five randomized, controlled trials of tai chi for stroke were available and included. Results of the review show an improvement in multiple variables after tai chi was introduced to people with stroke, including improvement in quality of life, balance, and mental health. At this time, more research on this promising technique is warranted.

Yoga

Yoga is a philosophical system that originated in India approximately 5000 years ago and was primarily intended as a means of increasing self-awareness. The term *yoga* means "union," or yoke referring to the universal self, and includes any practice designed to enhance this self-awareness. Thus, meditation, study of the Scriptures, pure devotion to God, repetition of a mantra, selfless service, physical postures, and many other practices are all forms of yoga. In the West, however, the term *yoga* usually refers to Hatha yoga, considered the foundation of all other yoga practices, and encompasses a number of systems focusing on the physical body, using postures (asanas), diaphragmatic breathing (pranayama), and meditation (dhyana). Although not well understood, there is evidence to suggest that the combination of postures and breathing is most beneficial (104) and more therapeutic than traditional exercise (105–109). Yoga postures are designed to prepare the body for maximizing self-awareness. One advantage of yoga is that many poses can be performed in sitting or supine positions, so they may be safer and easier to perform for people with limited mobility.

The U.S. Department of Health and Human Services recently stated that "yoga is often recommended as a form of total-solution exercise for older adults, although there is little scientific evidence to support this recommendation" (110). There is a real need to further explore yoga as a viable aspect of rehabilitation therapies among populations with different diagnoses.

Although there are numerous studies on the effect of yoga on hypertension and cardiovascular physiology, which have some relevance to stroke prevention, a 2007 systematic review of the literature found no controlled trials of yoga for stroke rehabilitation (111). However, at the time, only one case study had been completed (112). Since then, two small

case series (111,112), one qualitative study (113), and a randomized pilot study (114) have been reported.

One case series involved four chronic (six months to eight years after stroke) patients with hemiparesis who completed biweekly yoga sessions for eight weeks (112). Study participants reported improvement in several outcome measures (Berg Balance Scale, Timed Movement Battery, and Stroke Impact Scale domains of physical, cognitive, emotional, and social participation). The yoga therapy program included a number of classical seated, supine, and standing yoga postures, a short period of breathing exercises (pranayama), and a short meditation period.

Lynton et al. presented the results of a small pilot study involving yoga in chronic stroke patients (111). The 3 participants in this study attended yoga classes twice a week for 12 weeks and underwent pre- and postassessments using the O'Connor Tweezer Dexterity test, a timed test in which the participant places pins in a peg board with tweezers, and the Boston Aphasia Exam for speech. Each of the three subjects improved in dexterity (the O'Connor Tweezer Dexterity Test) and speech (Boston Diagnostic Aphasia Exam) scores. A qualitative study indicates a perceived improvement in strength, ROM, and gait and an acceptance of a "different body" after yoga (113).

These studies indicate that people with stroke can physically and cognitively engage in and enjoy the physical, psychological, and emotional benefits from yoga, yet it is unknown how these benefits generalize to the chronic stroke population. In spite of the minimal published evidence on the utility of this treatment, a number of clinical rehabilitation programs do offer yoga as an option to patients, given its favorable safety profile and favorable anecdotal patient reports. Most recently, Schmid et al. (114) completed a randomized pilot study of yoga versus usual care for people with chronic stroke. Results indicated that people with chronic stroke were able to complete eight weeks of seated, standing, and floor postures and could engage in the physical postures, breathing, and meditation of a modified yoga program (Table 37.2). The study was not powered to see differences between groups, but those randomized to the yoga intervention benefited from significant improvements in balance, balance self-efficacy, and quality of life. Results were more impressive for those individuals who "completed the intervention" by completing at least 5 of the 16 sessions; in addition to improved balance, they also had increased self-efficacy and quality of life. The small sample size makes it impossible to draw definite conclusions, but the positive trends in these studies suggest that further research examining the usefulness of yoga in stroke recovery is warranted.

Acupuncture

Acupuncture has been used for more than 2000 years to treat stroke in China and other parts of Asia. According to traditional Oriental medical theory, upon which acupuncture is based, the body contains a system of energy channels called *meridians*. These meridians are not physical vessels that can be identified by anatomical dissection; rather, they are hypothetical pathways through which energy flows. The energy that flows through these meridians is considered a life force and is referred to as *qi* or *chi* (both spellings are pronounced "chee"). Illness is viewed as an imbalance in the flow of qi throughout the body. Acupuncture and related traditional Chinese medicine therapies are all designed to alter the flow of qi and to return the body to a state of health and balanced qi. Numerous variations have evolved over the centuries, including the relatively recent use of electrical stimulation of needles at some acupuncture points during treatment sessions. Other (nontraditional Chinese medicine) potential mechanisms by which acupuncture might be effective for certain conditions have been proposed as alternatives to traditional Chinese medicine theories (115).

A modest amount of research on the effectiveness of acupuncture in stroke recovery has appeared in the Chinese research literature for several decades. Unfortunately, most of this early research does not meet current standards of clinical research methodology, so it is of limited utility in evaluating the effectiveness of acupuncture. Beginning in the early 1990s, research with improved rigor began to appear, with variable findings regarding the efficacy of acupuncture to facilitate stroke recovery (116). The evidence in favor of therapeutic efficacy for stroke recovery was sufficiently strong to warrant a conclusion by the 1997 NIH Consensus Development Conference on Acupuncture (117) that there was limited and encouraging evidence for the relationship between acupuncture and stroke recovery, although not sufficient to recommend its use as a medical procedure.

In the extensive meta-analysis by Sze et al. (118,119), the authors concluded that acupuncture is associated with a weak to moderate effect on motor recovery and activities of daily living, but the authors dismiss the relevance of these findings, attributing this effect to a true placebo effect rather than an effect specific to acupuncture. However, a review and reanalysis of these studies was conducted (120,121); after accounting for methodological flaws in several of the clinical trials, this reanalysis concluded that the evidence may support the efficacy of acupuncture. Many of the clinical trials of acupuncture do not statistically analyze the data as improvement (change) scores, but rather as absolute performance levels at follow-up. The use of change scores helps correct for baseline differences among subjects, an important issue given that baseline functional ability has been shown to be a key predictor of functional outcome after stroke. A Cochrane review from 2006 and (edited in 2009) maintains the lack of clear evidence for acupuncture as an aspect of stroke rehabilitation, but does recommend additional trials due to the current published data (116).

There is some evidence that the anatomy and severity of a stroke play an important role in the responsiveness to acupuncture therapy and perhaps other treatment modalities as well. Naeser et al. (122) studied CT scan findings for 20 stroke survivors treated with acupuncture and found that efficacy correlated with stroke location and extent. Subjects who responded to acupuncture were found to have less than

one-half of pyramidal tracts and periventricular white matter infarcted on the CT scan. This preliminary study suggests that stroke anatomy and severity should be included when characterizing participants in acupuncture studies in stroke survivors. The possibility of both floor and ceiling effects for acupuncture therapy should also be further explored to determine if patients with excessively severe or very mild strokes are unable to benefit from this treatment. Failure to consider this possibility poses a risk of diluting clinically meaningful effects in the moderately affected population.

The systematic reviews of acupuncture have focused on motor recovery and global measures of functional outcome, but several other aspects of recovery have been prioritized in specific studies. People who received acupuncture after stroke have also demonstrated improved ability to maintain postural control in the presence of perturbation (123) and improved walking (124,125) (see Figure 37.1). Other research has shown that acupuncture may be a viable treatment option for dysphagia in people with stroke; using video fluoroscopic swallowing study (VFSS) as an assessment tool, it was found that people with stroke who received acupuncture had fewer episodes of choking while eating or drinking (126,127).

The evidence for the efficacy of acupuncture after stroke is still best described as mixed, and definitive conclusions for or against the efficacy of this technique seem premature. In the absence of any specific medical contraindications, acupuncture generally seems safe and well tolerated by people who have sustained a stroke.

MANIPULATIVE AND BODY-BASED PRACTICES

Manipulative and pressure-based therapies encompass any of a number of techniques that involve touching the body with an external object, such as massage therapy, or a penetrating needle, as in acupuncture. Manipulative therapies are used in the treatment of a number of medical and physical conditions and are also used as a general technique for relaxing the body and generating a feeling of well-being in otherwise healthy individuals. Many fundamental therapies, such as massage, myofascial adjustments, or osteopathic manipulation, have numerous variations, with different names based on the particular variations in the application of the fundamental technique.

Massage and Acupressure

Acupressure is a form of manual therapy that is based on the same traditional Chinese medicine theory underlying acupuncture. Based on this meridian system, acupressure, like acupuncture, aims to balance the flow of qi and is used either preventatively or as a means of healing an illness. Acupuncture involves the insertion of needles in specific points along the meridians; acupressure, instead, uses the fingers to press these points. Because the same points are used in acupuncture as in acupressure, there is a general assumption that both techniques should have similar effects, although nonpenetrating acupressure might be expected to show milder effects. Practitioners suggest that acupressure might be appropriate for situations where acupuncture seems desirable but the subject or patient is not willing to submit to needle insertion or acupuncture was unacceptably painful.

Many different types of Oriental bodywork therapies use acupressure. Among the most widely used in the United States are:

- Shiatsu (literally translated as "finger pressure" in Japanese)
- Jin shin jyutsu ("the art of circulation awakening")
- Jin shin do ("the way of the compassionate spirit")

What is common to all of the different acupressure systems is the use of sequenced applications of pressure to the meridian points (or *acupoints*) in order to tonify (acupuncture technique for strengthening the body) or sedate them (128,129). Fundamental differences between the different forms of acupressure relate to the amount of pressure applied to the points, length of application, the intent of treatment (e.g., overall relaxation or balance versus treating a specific condition), and philosophy (e.g., the extent to which the treatment approach is integrated with other methods, such as Western manual manipulation techniques, dietary or herbal methods, or psychology) (128). Only a few studies have examined acupressure after stroke. In a small, poorly controlled study, Hogg (130) found that acupressure was more effective on several outcome measures than a control treatment consisting of light laying-on of hands (therapeutic touch). In a Korean study, the use of acupressure was tested in a small randomized trial (131). Individuals who received acupressure in addition to usual care enjoyed significantly improved upper-extremity function, activities of daily living, and depression compared to the usual care control group. Thus, at this time, continued interest and additional research are warranted.

Marma Therapy

Marma therapy is a massage-based therapy originating in Indian Ayurvedic medicine. It uses energy "chakras" and special energy points, or Marma points, with vigorous pressure to "unblock the channels of energies" and to promote healing (132). In stroke, the pressure would typically be applied primarily to the affected side. There are 107 Marma points where flesh, veins, arteries, tendons, bones, and joints meet (132). The points are related to the yogic system of channels through which prana flows (nadis) rather than to the acupuncture meridian system. The effectiveness of Marma therapy is supposed to be related to the sensitivity of these points. Marma points are therefore selected on the basis of their sensitivity; the therapy is reduced as function returns (132).

What appears to be the first controlled study of Marma therapy for stroke is a small (n = 30), nonrandomized, controlled pilot trial on stroke patients in an acute stroke unit (132). Outcomes of Marma therapy (three 45-minute sessions plus standard rehabilitation) were compared to outcomes of standard rehabilitation only. Although no statistically significant effect was detected on the Barthel index at 12 weeks after treatment, scores showed greater improvement for the Marma group at both 6 and 12 weeks after treatment. The authors have indicated that even though the recruitment to the study was challenging, the Marma treatment was believed to be both beneficial and acceptable by patients (132). Despite its methodological limitations, this study demonstrates promise for this therapy and a larger, randomized, controlled trial seems appropriate. Similarly, further formal study of related Ayurvedic and yoga-based interventions is needed.

MOVEMENT AND ENERGY THERAPIES

According to the NCCAM definition of *energy medicine*, this category includes any form of stimulation with external energy, such as electricity, as well as the more controversial forms of subtle energy, such as chi, Reiki, and so forth. The latter forms of energy are controversial because they cannot be detected with currently existing technology, hence the NNCAM's use of the term *putative* for these forms of energy. Because there is so little evidence for the subtle-energy forms of therapy, except where observable interventions are used to influence this energy (as in tai chi), they are not discussed further here.

Electrical Stimulation

Various forms of electrical stimulation have been used in treating specific medical problems associated with stroke. TENS is used to stimulate nerves in an effort to control pain, and therapeutic electrical stimulation is often used to stimulate paretic muscles in an effort to induce recovery of muscle function. The conventional applications of these techniques are covered in detail in Chapter 21.

Electroacupuncture is another type of electrical stimulation used in stroke survivors. Unfortunately, the use of electricity with acupuncture in these studies is quite variable (different needle sites, length of time the needle is maintained, etc.) and inconsistent from study to study, so few conclusions can be drawn regarding the direct effects of the electrical stimulation independent of the effects caused by acupuncture per se. These studies were included in the general discussion of acupuncture earlier.

At least one study in which acupuncture is the primary focus used a form of TENS as the control condition (124). In this study, surface electrodes were applied to acupuncture points, and either a strong current (TENS) or an extremely low, undetectable current (sham TENS) was applied to acupuncture points, so the effectiveness of TENS relative to sham TENS, as well as (electro)acupuncture, could be estimated. No difference between acupuncture-point TENS and sham TENS was seen for functional and motor recovery, though, on reanalysis, electroacupuncture appeared more effective than either in improving functional independence or walking speed (121). In a study by Wong (133), *electrical acupuncture* was defined as the application of electricity via surface electrodes over acupuncture points. In other words, it was a nonconventional form of TENS. Subjects with this form of treatment, combined with rehabilitation, did better on several neurologic and functional outcomes when compared to a rehabilitation-only control group. Additionally, when electroacupuncture was compared to acupuncture, it appears that the electroacupuncture group enjoyed significantly more improvement in the management of stroke-related spastic paralysis (134). Electroacupuncture and tuina manipulations for poststroke shoulder pain led to improved outcomes when compared to typical rehabilitation (135). When combined with typical rehabilitation, increased electroacupuncture hertz was associated with greater improvements in poststroke gait and motor assessments (136). Based on these studies, the evidence for what could be called electroacupuncture, or acupuncture with TENS, appears encouraging enough to warrant further research.

CONCLUSION

The therapies presented in this chapter are by no means an exhaustive listing. The research-based evidence for the therapies discussed here varies from minimal to moderately positive. Many other CAM therapies have and will be proposed in the future, often with little empiric or theoretical basis for their use. Even though many of these therapies may be innocuous, ultimately the criterion for incorporating any therapy into routine treatment (mainstream or nonconventional) must be the existence of research, showing evidence of safety and efficacy. Some maintain that this fundamental requirement will eventually erase the distinction between conventional and alternative medicine (13). Unfortunately, this evidence base is likely to be long in coming.

Even though the same evidence-basing procedures must be applied to all therapies, whether traditional or nontraditional, it is important to recognize that many alternative therapies have a low risk of adverse reactions. In the absence of clear evidence of efficacy, but with a low risk of harm,

many patients and their caregivers are willing to accept CAM therapies to treat symptoms that are otherwise not yet amenable to proven therapies.

Most CAM therapies will be used in conjunction with other rehabilitation therapy, and the most judicious use of alternative or complementary therapies will generally be as an adjunct to well-established conventional therapies that are considered to be standard of care. In some cases, alternative therapies can be explored when other therapies appear to have run the course of their effectiveness. In many cases, the use of CAM therapies is initiated by patients; clinicians must understand the need of patients to try alternative options and determine how to deal with such requests. Communication with patients, including an honest appraisal of the evidence base for both conventional and CAM therapies, is the best approach to safe and appropriate use of these therapies in clinical practice.

Seating, Assistive Technology, and Equipment

Rory A. Cooper, Rosemarie Cooper, Katya Hill, Patricia Karg, Amol Karmarkar, Amy Karas Lane, Roger Little, and Tamara L. Pelleschi

Assistive technology (AT) plays a significant role in the lives of individuals with disabilities to help maintain, increase, or improve the functional activities of daily living (ADLs) within the home and community. Appropriate selection and application of technology has a great potential not only to contribute to, but also to improve the quality of life of the individual.

This chapter provides a brief overview of the range of AT available and applicable to individuals who have experienced physical impairments as a result of a severe stroke. An important step to ensure appropriate selection of AT is to start with an AT team that consists of qualified AT professionals who have a keen interest in including and encouraging active participation of the end user in the AT evaluation and selection process, as described in the AT service delivery model. Sections covered in this chapter include AT interventions in wheelchair seating and mobility, electronic aids for daily living, augmentative and alternative communication (AAC), adaptive driving, and wheelchair transportation safety, as they may be applied and fit into the individual's stroke recovery and rehabilitation process.

AT SERVICE DELIVERY MODEL

A successful AT service delivery model requires specialized knowledge in the design and application of AT, as it has tremendous potential for a positive impact on the community integration of people with disabilities. The specialized knowledge starts out with the AT assessment team that consists of physiatrists, occupational and/or physical therapists, speech–language therapists with specialty training/certification, rehabilitation engineering technologists, and qualified equipment suppliers. Other professionals may also be consulted depending on the needs and goals of the client. Rehabilitation counselors, nurses, personal care assistants, and other similar professionals can also make important contributions to the AT service delivery team.

To assure that specialized knowledge is present within the AT assessment team, the Rehabilitation Engineering and Assistive Technology Society of North America (RESNA) (www.resna.org) offers a credentialing program in AT to clinicians and suppliers. RESNA offers three levels of credentials, as outlined in the following paragraphs: assistive technology professional (ATP), the seating and mobility specialist (SMS), and rehabilitation engineering technologist (RET).

Through the ATP credential provided to suppliers and clinicians, RESNA recognizes "demonstrated competence in analyzing the needs of consumers with disabilities, assisting in the selection of appropriate assistive technology for the consumer's needs, and providing training in the use of the selected device(s)" (1). To attain the ATP credential, an individual must demonstrate compensated employment in the field of AT and pass an examination that consists of fundamental elements and case-based scenarios.

To identify clinicians who specialize in seating and mobility service provision, RESNA created the SMS credential. RESNA's justification of the creation of the SMS is as follows: "[W]hile the ATP is a broad-based exam covering all major areas of assistive technology, the SMS exam is focused specifically on seating, positioning, and mobility. The program is intended for clinicians, suppliers, engineers and others involved in seating and mobility service provision."

For engineers and technicians who have been supporting AT clinics, RESNA created the RET credential. The RET credential first requires an individual to hold an engineering or technology degree. After a suitable period of clinical AT service delivery experience, individuals are eligible to sit for the ATP examination and the supplemental RET examination. However, at the time this chapter was updated, RESNA has stated that "RET certification is active for current certificates but is under review and is not currently available to new applicants." These credentials help consumers to identify individuals who have acquired specialized knowledge of AT and are committed to providing high-quality services.

The design and application of the AT service delivery starts out with the introduction of the client to the AT assessment team and empowerment of the client to be an active decision-making member of that team.

A proper assessment begins with an initial interview that involves listening and paying attention to the client's needs, concerns, and goals for a device. It is important to understand

the medical variables—assessed by the physiatrist and shared with the team on how underlying medical conditions may impact the prescription of a AT device—as well as the physical and functional variables assessed by the therapists on how physical capacities and limitations affect mobility and instrumental ADLs. It is important to know how the client performs tasks, where the deficits are, and how AT can compensate for deficits to augment task performance. The user is given an opportunity to try the equipment to determine how he or she best performs and assesses this. Transportation variables are also important to consider if transporting the wheelchair and seating system are essential goals. The person who will be stowing the device should get an opportunity to try doing so before the final prescription being written.

The AT team members will explain the outcomes, reasons, and facts upon which they based the final recommendation of the device to the client. However, the final decision on the mobility device lies with the client, the family, and/or caregivers.

The assessment and service delivery process is completed during delivery of the new device to the client, and the therapist signs off on the correctness of the final fitting and operation of the new AT device.

FIGURE 38.1 Example of an Ergo contoured seating system.

SEATING/MOBILITY

Seating

AT for seating and positioning for a person after a stroke can vary according to the individual's needs. Several seating challenges can occur following a cerebrovascular accident (CVA). These challenges are secondary to but not limited to two main factors:

1. Poor trunk balance and muscle tone caused by hemiplegia
2. Increased extensor tone more notably evident following a left CVA with right-sided involvement

Several residuals from the stroke can affect the person's ability to complete many daily tasks that he or she was able to perform prior to the stroke. These residuals include impairments of motor skills, cognition, and vision. It is important that the individual requiring the use of a mobility device become more functionally independent with his or her ADL needs while seated in the wheelchair. A key to functional seating involves stabilizing the pelvis. A rule of thumb to remember with seating is that pelvic stability leads to enhanced upper trunk stability.

In fact, stabilizing the pelvis is the first step in improving upper trunk mobility, thus increasing ability to perform ADL skills. There are several seat cushions available in the market, which include solid and contoured bases (Figures 38.1 and 38.2). If pressure management is an issue, seat cushions can be comprised of air, gel, or simply just a soft foam. Knowing your patient's skin integrity is crucial to cushion selection.

A contoured seat base can be utilized for the individual with hemiplegia. The contour of the base will aid in maintaining the pelvis, hips, and lower extremities in neutral alignment. The degree of the contour will depend on the amount of support that the individual needs to maintain the position. An anti-thrust cushion will prevent the individual with extensor tone from sliding forward on the seat (Figure 38.3). The anti-thrust cushion is higher in the front, thus providing a shelf that makes it difficult for the individual to overcome. Placing

FIGURE 38.2 Example of a contour molded cushion with gel-filled inserts.

FIGURE 38.3 Example of anti-thrust cushion.

a seat dump (a structure where, the front of the seat frame is higher than the back) in the frame of the wheelchair can provide the same effect as the cushion.

Thigh guides placed along the lateral aspect of the upper portion of the lower extremity will provide lower-extremity support and alignment (Figure 38.4). The thigh guide will prevent external rotation and abduction of the hip joint.

Adductor pads can be placed lateral to the knee joint to provide support and prevent adduction, thus improving neutral alignment. An abductor pad for lower-extremity alignment will prevent abduction and internal rotation of the hip. The abductor is placed between the knees. This can be an external pad that is removable, or it can be incorporated into the contoured seat base. A solid seat provides a static surface on which the cushion can be placed. This support prevents the cushion from contouring to the surface it is placed upon. A pelvic belt will also assist in maintaining the pelvis in position. The belt can be a standard two-point or a four-point. The point value refers to numbers of attachment to the frame. Four points of attachment provide greater contact, thus controlling and supporting the pelvis.

Lower-extremity alignment and support are critical in maintaining pelvic stability. It is necessary for the individual to achieve full foot contact and placement on the footplates. Without foot support, the individual will slide and shift on the seat. The hanger angle of the wheelchair frame is an important part of achieving foot placement. A range-of-motion assessment will provide information needed to determine the appropriate legrest hanger configuration. When using elevating legrests, the individual should maintain foot contact as well as knee extension throughout the elevation process. Angle-adjustable footplates can be adjusted to assure foot contact in the event of decreased ankle range of motion or ankle instability at neutral posturing.

Stability of the upper trunk can be achieved by utilizing a variety of back supports. Back support can be provided through the use of a solid or flat surface, a contoured (mild, moderate, or deep) surface, or upholstery (Figures 38.5–38.7). The decision on the type of back support to be utilized depends largely upon the individual's trunk balance. A large variety of back supports not mentioned is also available and is more specific for spinal deformities.

FIGURE 38.4 Example of thigh guide placement.

FIGURE 38.5 Flat solid back.

FIGURE 38.6 Moderate contoured back.

A solid back support provides static stability. The solid support allows for greater wheel strikes when propelling, as the upper extremities have full range of movement without contact of an external source. A lateral support can be utilized with the solid back to prevent the individual from leaning sideways when sitting or traveling.

The contoured back support provides lateral stability for the upper trunk. The amount of contour depends on the amount of support the individual requires to remain upright. Adjustable tension back upholstery can provide upper-trunk stability without the need to utilize a back support

FIGURE 38.7 Deep contoured back.

FIGURE 38.8 Example of adjustable tension back upholstery.

(Figure 38.8). This will aid in keeping the overall weight of the wheelchair down for the individual who is a self-propeller.

Lateral trunk supports attached to the side frame of the wheelchair provide stability and support of the upper trunk. The sizes of the supports vary and should be ordered according to the individual's size. Placement of the support is also crucial; it should not be placed directly under the axilla because it may cause nerve impingement.

Support of the affected upper extremity for the individual with hemiplegia is also important. Assortments of arm troughs are available on the market. The arm trough will provide full contact and support of the distal portion of the upper extremity, thus preventing it from falling from the armrest (Figure 38.9). The palmar portion of the arm trough can be provided in a variety of shapes, depending on the individual's hand positioning needs. The arm troughs are attached to the frame of the armrest. Height-adjustable armrests are necessary, as they assure adequate shoulder placement and support. A subluxation is often evident with hemiparesis, so proper height adjustment is needed to assure the shoulder joint is placed properly in the socket. A lap tray can also be utilized for upper-extremity support. The tray can be a full design or half design.

FIGURE 38.9 Example of seating system with arm trough with custom palmer support and lateral trunk supports.

FIGURE 38.10 Example of tilt-in-space seating system.

Other seating features that can be incorporated into the frame of the wheelchair are tilt-in-space and recline. Tilt-in-space can be utilized for the individual who is unable to sit upright against gravity. The tilt-in-space provides a gravity-decreased plane, thus improving sitting (Figure 38.10). Tilt-in-space can also provide pressure relief for the individual who is unable to independently change position and shift the weight for effective pressure relief maneuvers. When utilizing a tilt-in-space seating system, it is recommended to add a headrest for cervical support and stability. Headrests also come in a large variety of shapes and sizes, and selection is based on comfort and functional support.

The reclining-back wheelchair can first be utilized in the event that the individual has systemic issues that may prevent him or her from sitting upright. Overall, the use of a reclining-back wheelchair is typically not beneficial to the individual with hemiplegia. Reclining the back opens the hip angle, thus decreasing the stability of the pelvis.

The lack of control of the pelvis can lead to poor support and alignment of the upper and lower trunk. Tilt-in-space is the preferred alternative to meet an individual's seating and positioning needs.

This section was completed as an attempt to provide a basic insight into the specific seating and positioning needs for persons after CVA. For more in-depth reading on this topic, please refer to the reference list at the end of this chapter.

Mobility

Use of wheelchairs, including both manual and electrically powered, could be a transient or long-term need for individuals after CVA. Therefore, as with any other piece of AT equipment, the wheelchair selection, customization, and delivery process after CVA has to be an individually tailored procedure. Also, utilization of wheelchairs could significantly alter limitations that could result after CVA, which could be based on changes in physical functioning and use of alternative mobility aids, especially during the first year after CVA (2). Periodic assessments before wheelchair prescription are key, and should include physical, sensory, cognitive, perceptual, behavioral, and environmental assessment along with identification of other barriers for use of a wheeled mobility device. Recent literature suggests use of Wheelchair Skills Test (WST) and Wheelchair Collision Test (WCT) as screening measures specifically designed for individuals after CVA for identifying problems related to use of wheeled mobility devices, which could also serve as a guideline for customization of the prescribed device (3,4).

Manual Wheelchairs

For individuals after CVA, manual wheelchair (MWC) propulsion can become very tiresome because of several factors, such as primary use of one upper/lower extremity for propulsion, limited coordination between the available extremities, and problems with visual-perceptual abilities. Despite

FIGURE 38.11 Attendant-propelled with tilt-in-space (Quickie IRIS).

these difficulties, MWCs have been considered a primary aid for independent mobility for this population (5).

Attendant-Propelled

This type of MWC is typically used as a dependent mobility option for individuals who are not able to functionally self-propel any type of MWC because of physical and/or cognitive limitations (Figure 38.11). An attendant-propelled MWC frame usually comes equipped with a tilt/recline combination seating system for gravity-assisted postural support. Also, in the early post-CVA stages, attendant-propelled wheelchairs could be a safer option, as self-propulsion could result in dislocation of joints of extremities with flaccid muscle tone. The previous notion was that self-propulsion in early stages after stroke could result in increased abnormal muscle tone, resulting in further physical disability. However, recent studies have indicated no such detrimental effect of self-propulsion wheeled mobility on physical disability in early post-CVA stages (6).

Manual Self-Propelled

The traditional self-propelled MWC can be classified into five basic categories for medical justification purposes:

- Standard wheelchairs
- Standard hemi (low seat)
- Lightweight
- High-strength lightweight
- Ultralightweight wheelchairs

The hemi wheelchairs have low seat-to-floor height, with provisions for modifications that enable a person after CVA to be able to use a wheelchair with one side of his or her body (upper and/or lower extremity). Self-propelled MWCs can fall in the following three categories.

Pushrim-Activated Propelled

Even though this is the most commonly used interface, it could result in repetitive strain injuries (RSI), which, coupled with preexisting conditions of muscle weakness, reduced physical capacity, pain, and fatigue, could make MWC propulsion significantly inefficient. Pushrim-activated power-assisted wheelchairs (PAPAWs) have recently become an alternative option to MWCs to reduce the risk of RSI and maintain physical conditioning of the users (Figure 38.12). Studies investigating individuals with spinal cord injury reported effectiveness of PAPAWs in improving mechanical efficiency of propulsion by significantly reducing energy expenditure, stroke frequency, upper-extremity range of motion, and power requirement for wheelchair propulsion (7). A PAPAW should be considered as a therapeutic intervention for addressing learned nonuse, as the individual

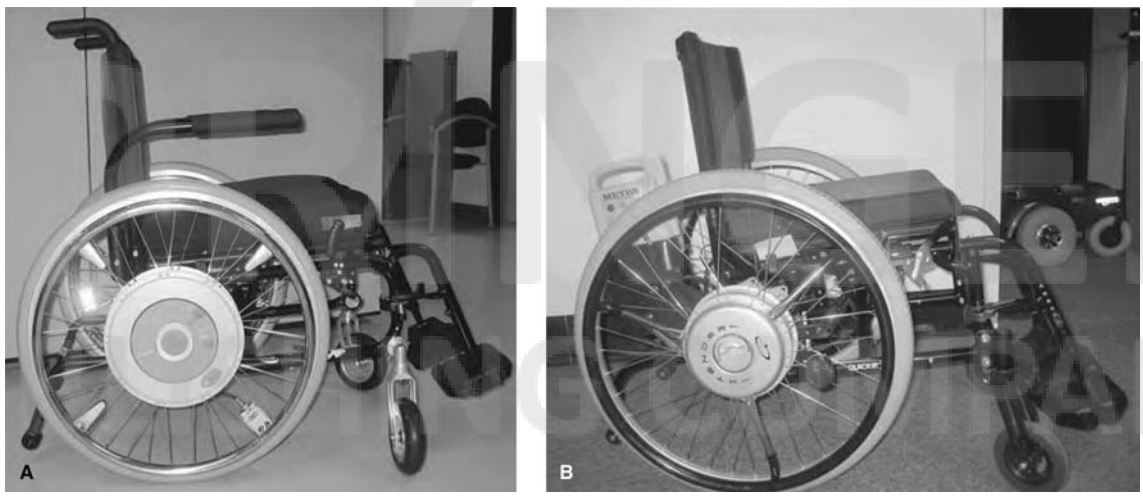

FIGURE 38.12 (A) PAPAW (e.motion); (B) PAPAW (Quickie Xtender).

FIGURE 38.13 Lever drive system.

wheels of the PAPAW system may be programmed separately to enhance and encourage function of the affective side during self-propulsion.

Lever Drive

Lever drive mechanisms, which may be attached to the MWC on either one or both sides, indirectly transfer push or pull forces that are applied to the rod/lever system to the wheels (Figure 38.13). This mechanism facilitates use of the shoulder and elbow muscle group and reduces tiring effects on wrist and hand muscles. Also, this form of propulsion method was reported to be energy efficient, inducing less physical restraint as compared to unilateral/bilateral pushrim use (8).

Foot-Propelled

This form of propulsion method has been reported to be physiologically efficient, resulting in faster speed of propulsion as compared with the traditional mode of propulsion after CVA using one side of the body (hand and foot; 9). However, assessment of the client is a prerequisite before prescribing the system. The assessment must include seat-to-floor height to allow for heel strike and toe pulling, appropriate seat depth to allow for knee flexion, a stable back and seat support, and high friction surfaces for seat and shoe (10).

Power Wheelchairs

One concern, and sometimes a limiting factor for prescription of power wheelchairs (PWCs), after CVA is a visual-perception deficit known as *unilateral neglect* (UN), which can be defined as neglect of one side of the environment during any task performance. UN raises safety concerns for individuals with right-side affected CVA to use power mobility safely and independently (11).

Computer-assisted training was reported to be effective in reducing unsafe driving behavior that may cause incidents and improving ability to complete a real-world wheelchair obstacle course for individuals with UN (12). Similarly, use of a virtual reality (VR) environment is suggested as one of the intervention techniques for improving safety with an application to provide wheeled mobility training for individuals with CVA and UN (13). PWCs can be classified in three major categories according to the Centers for Medicare and Medicaid (CMS) Healthcare Common Procedure Coding System (HCPCS).

Standard Power Wheelchair

Standard PWCs do not have any option for customized programmability and/or customized seating and postural support (Figure 38.14). These low-cost and very basic PWCs are commonly prescribed for individuals diagnosed with CVA for anticipated use in low-active indoor environments. A study conducted by Pearlman et al. (14) revealed that these chairs do not meet the American National Standards Institute (ANSI) and RESNA standard requirements testing, as they are unstable and have limited durability. Caution is advised when prescribing this type of power wheelchair.

Programmable Power Wheelchair

These PWCs provide options for customization of control parameters for speed adjustment, tremor damping, acceleration control, and braking. This type of PWC can be equipped with customized power seat options and is therefore preferred for individuals with CVA (Figure 38.15).

FIGURE 38.14 Example of a standard power wheelchair.

FIGURE 38.15 Example of a programmable power wheelchair.

Lightweight, Portable Power Wheelchair

Lightweight, portable PWCs are base-equipped with basic seating designed for ease of transportation (Figure 38.16). This type of PWC should be considered only for end users with very limited and specific mobility needs.

Customized, Motorized Power Wheelchair

Customized, motorized PWCs are base-equipped along with a provision of other seating options like elevating seat and footrest, tilt and recline, lateral tilt, and standing frame. These PWCs are typically equipped with high-performance motors, the batteries needed to support increased weight capacities, and higher-performance power seating systems. Precise and sound medical justification is needed when prescribing this type of PWC. Typically, this type of PWC is not frequently recommended for an individual diagnosed with CVA who weighs less than 300 pounds and has average body structure.

Justification of an appropriate PWC that can meet all requirements of the end user and is a safe option in terms of durability and ability to withstand repeated use is a complicated process, in spite of previous research indicating higher durability and cost-effectiveness of customizable PWCs as compared to standard PWCs (14). Besides the CMS classification system, PWCs can be divided into three main categories

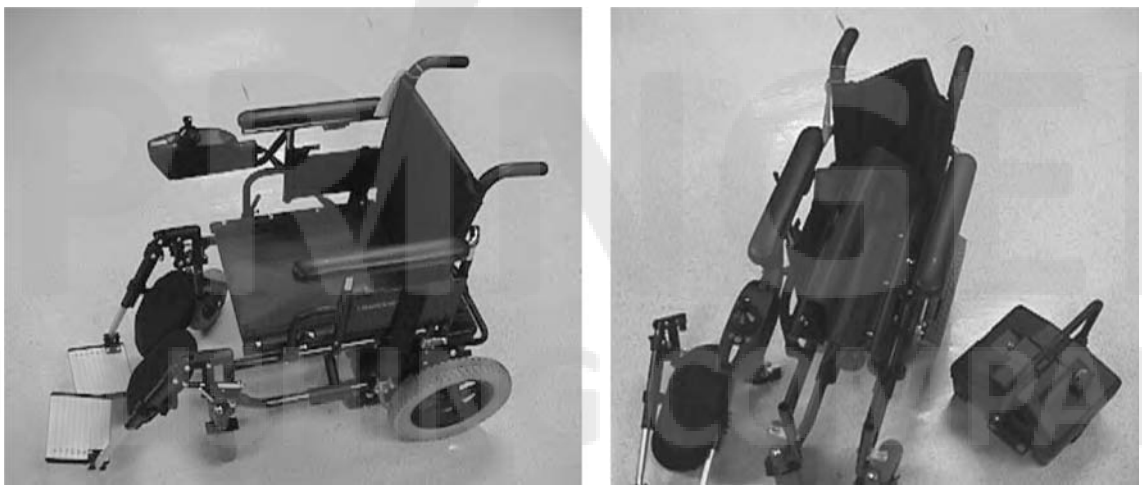

FIGURE 38.16 Example of a portable power wheelchair.

FIGURE 38.17 Three categories based on the presence of drive wheels in relation to seat of user: (A) front-wheel drive (FWD), (B) mid-wheel drive (MWD), and (C) rear-wheel drive (RWD).

based on the presence of drive wheels in relation to the seat of the user (Figure 38.17):

Front-wheel drive (FWD)
Mid-wheel drive (MWD)
Rear-wheel drive (RWD)

For FWD, the drive wheels are located in the front of the seat, and it is effective over uneven ground and rough terrains. The main disadvantage of FWD is the fish-tailing effect, where the PWC tends to sway laterally while going up and down ramps. MWDs are the most efficient PWC for indoor use with availability of limited space because their turning radius is small. However, MWDs sometimes pose problems when traversing uneven ground or rough terrains. RWDs are considered to be the fastest PWC, and they can provide good stability on most surfaces. However, they require a good amount of space for turning and could be unsafe while going up a ramp (15). Decisions regarding types of PWC are based on several factors, especially frequency of usage and environment of use.

ELECTRONIC AIDS FOR DAILY LIVING

Electronic aids for daily living (EADLs) are devices used to access, operate, and control electrical appliances. EADLs can be used in a home, school, or workplace. The primary purpose of an EADL is to enable a person to independently perform daily functions that he or she could not otherwise accomplish. Typical functions that an EADL enables people to perform include alerting caregivers of needs, using the telephone, changing bed positions, managing lights and room temperature, opening and securing doors, operating TV/stereo equipment and operating remote/security video cameras. Other names for EADLs are environmental control systems (ECSs) and environmental control units (ECUs) (16). Examples of EADL devices are shown in Figure 38.18.

Persons who use and benefit most from such devices are those with severe physical limitations that affect mobility and the upper extremities. Individuals with the diagnosis of quadriplegia, muscular atrophy, muscular dystrophy,

cerebral palsy, multiple sclerosis, and amyotrophic lateral sclerosis (ALS) are often aided by the use of an EADL. Persons with fewer physical limitations, such as paraplegia, amputations, or a CVA, can also benefit from such devices, but often are not considered candidates for the typical funding sources. In fact, this technology has been limited largely because of funding barriers (7,17,18). However, age appropriateness for vocational potential, skill base, and demonstration of need can increase the funding possibilities.

EADLs are controlled through a switch input, touchscreen, or voice recognition or can be integrated with other controls such as alternate computer access, wheelchair controls, and augmentative communication devices. Using

integrated controls to operate an EADL is helpful and often necessary when a person has a limited number of switch/control sites available.

Continuum of Devices

EADL devices have been categorized in different ways including: (a) inputs received, (b) complexity of the system, and (c) control provided. Often, devices do not fall neatly into these categories, and as new or different products appear on the market, the categorization process becomes less defined. Therefore, EADL devices can be considered as a continuum of inputs, system complexity, and control provided.

Inputs

Inputs are the mechanisms that activate the system. Inputs can include one or more of the following: (a) single switch; (b) dual switch; (c) direct select; (d) voice; (e) indeterminate system; and/or (f) automatic. A single switch either limits the user to one function control, such as turning a light on/off, or requires the system to scan through a menu of choices. When using a single switch to scan through menu choices, the user's speed is limited to the scanning speed set by the device. A dual switch provides more control by allowing the user to regulate the scanning speed before making a selection. Direct select allows the user to select from a menu of choices and reduces or eliminates the need for scanning to the desired item. Voice recognition provides direct control of functions by using predefined voice commands. Intermediate systems include speech generating devices (SGDs), wheelchair controls, and alternate computer access. For example, if a person is using powered mobility, she or he can enter a mode to send a switching signal to the EADL. Alternately, some wheelchair controllers can directly send infrared, Bluetooth, or radio frequencies directly from the wheelchair to the device a user would like to control. Some portions of an EADL system can be controlled automatically, such as turning on lights for a given space by sensing motion, or starting a sump pump when moisture is detected.

Complexity

Complexity of an EADL system incorporates (a) the number and types of inputs/outputs available, (b) the user interface, and (c) the functional depth.

Inputs/Outputs. As discussed, there are a number of possible inputs. An EADL can vary from accepting a single input and providing a single control output to accepting multiple types of inputs and providing multiple control outputs. The control outputs most typically include X-10, Insteon®, radio frequency (RF), infrared (IR), Bluetooth, and direct connection. They are discussed under "control provided."

User Interface. The user interface of an EADL can vary greatly. The device may provide either a static or a dynamic interface and usually provides visual and/or audible feedback. Static interfaces do not change. A common example of a static interface is a TV remote: the labels and buttons remain in the same position. With a TV remote, the feedback provided to the user is the consequence of the button push—that is, the volume is increased or the channel is changed. Often, EADL devices that scan have static labels or icons. When using static labels, a light beside the label may brighten when that option is available. If static icons are used, the icon often lights up when the option is available. Dynamic interfaces, in contrast, present information that varies according to the previously selected item. For example, an EADL device may present the options of using the phone, operating the TV, or controlling lights. In this example, once the user selects the phone option, the interface choices provided will change from phone, TV, and light to specific phone functions such as answer, hang-up, or dial. Dynamic interfaces can provide more information and be less confusing; they are generally found on more complex devices.

Visual feedback can be a blinking light, highlighted or colored text/picture, or changing text/picture. With some systems, the entire display can change to indicate the context, such as showing a phone or room layout with the items that can be controlled. Likewise, audible feedback can range from a simple beep to unique sounds to voice prompts and confirmations. Some devices even provide instructional assistance.

Functional Depth. The functional depth of a device is related to its sophistication. The functional depth is noted in areas such as the level of functionality provided, the ease of setup, the amount of programming available to the user, the ability for the user to switch input methods, macro abilities, and wireless capabilities. For example, two devices may be able to operate a phone. However, one may have to use an IR-controlled phone whereas the other may be able to operate a standard landline phone. The EADL that uses the IR phone will require the person to be directly in front of the phone (line of sight) and may require him or her to use the phone on speaker. Furthermore, the options for using the phone may be limited to answer, hang up, and dial from a pool of preprogrammed speed dials. Alternatively, a more sophisticated EADL may allow the user to control the phone from another room, enjoy a private conversation, allow preprogrammed speed dials such as "Mom," "bank," "Jim," and so on; these systems may also enable the user to spontaneously dial numbers and input phone cards, bank numbers, and so on. Some even provide an automated answering function.

Another example of functional depth can be seen in X-10 control. X-10 is discussed in the "Control provided" section. X-10 can provide on/off control of 16 devices on 16 different house codes for a total of 256 control signals. Some EADLs can only be set by the user to use one house code at a time. This limits the control signals to 16. Therefore, because one X-10 signal is used to turn a device on, and another to turn it off, only eight devices can functionally be controlled. Some very basic EADLs can only control a few X-10 devices.

A more sophisticated device can take advantage of all 16 house codes, allowing 16 signals per code.

In terms of IR control, basic EADL devices may allow the user to control a limited number of functions such as TV on/off, volume up/down, and channel up/down. An EADL that has more functional depth will provide the user with many more functions that are often provided by a standard IR remote.

Control Provided

Common types of electrical appliances controlled by EADL are telephones, lights, door openers, door locks, fans, drapes, blinds, beds, audiovisual equipment, home climate controls, call systems, and security cameras (19). The control provided by the EADL is related to the possible outputs previously listed: X-10, Insteon®, RF, IR, Bluetooth, and direct connection.

X-10 is a RF signal that is carried over the existing home wiring to turn devices on/off. X-10 is inexpensive, has been available for many years, and requires no special wiring. Insteon® (www.insteon.net) is similar to X-10, but in addition to placing the signal on the home wiring, it also produces an RF signal that travels through the air. This provides redundancy in the signal and is therefore a more reliable way to control a device. RF allows control in all directions and through walls. However, it is susceptible to interference from other RF devices. IR is able to control a wide array of functions, and an EADL device can often "learn" the IR codes, thus making them easy to program. The main limitation of IR is that it must be in line of sight of the device that is being controlled. Bluetooth is a wireless means of transmitting a signal, but the maximum range is limited to about 30 feet. Directly connecting a device to an EADL ensures that the signal will reach its target; this is often used with bed controls, telephones, or specialized equipment.

EADL Evaluation Considerations

When considering an EADL for someone, many personal factors must be considered (Figure 38.19). Personal factors include accessibility needs, preferences, cognitive and physical abilities, comfort with using technology, desire to use technology, degenerative conditions, voice quality, and voice changes. Factors to address when considering equipment include the places where the device will be used, the layout and size of each area, the devices to be controlled, the electrical condition of the controlled environment, mounting to bed/chair, switch type, required integration with existing AT equipment, and particular EADL limitations and benefits. Funding factors include cost and the goals/requirements of the funding agency.

Costs

The basic cost of full EADL systems can range from $700 to $6000. A completely installed system with door openers and other options can cost $2000 to $15,000. Typically, the only funding available for EADL systems comes from vocational

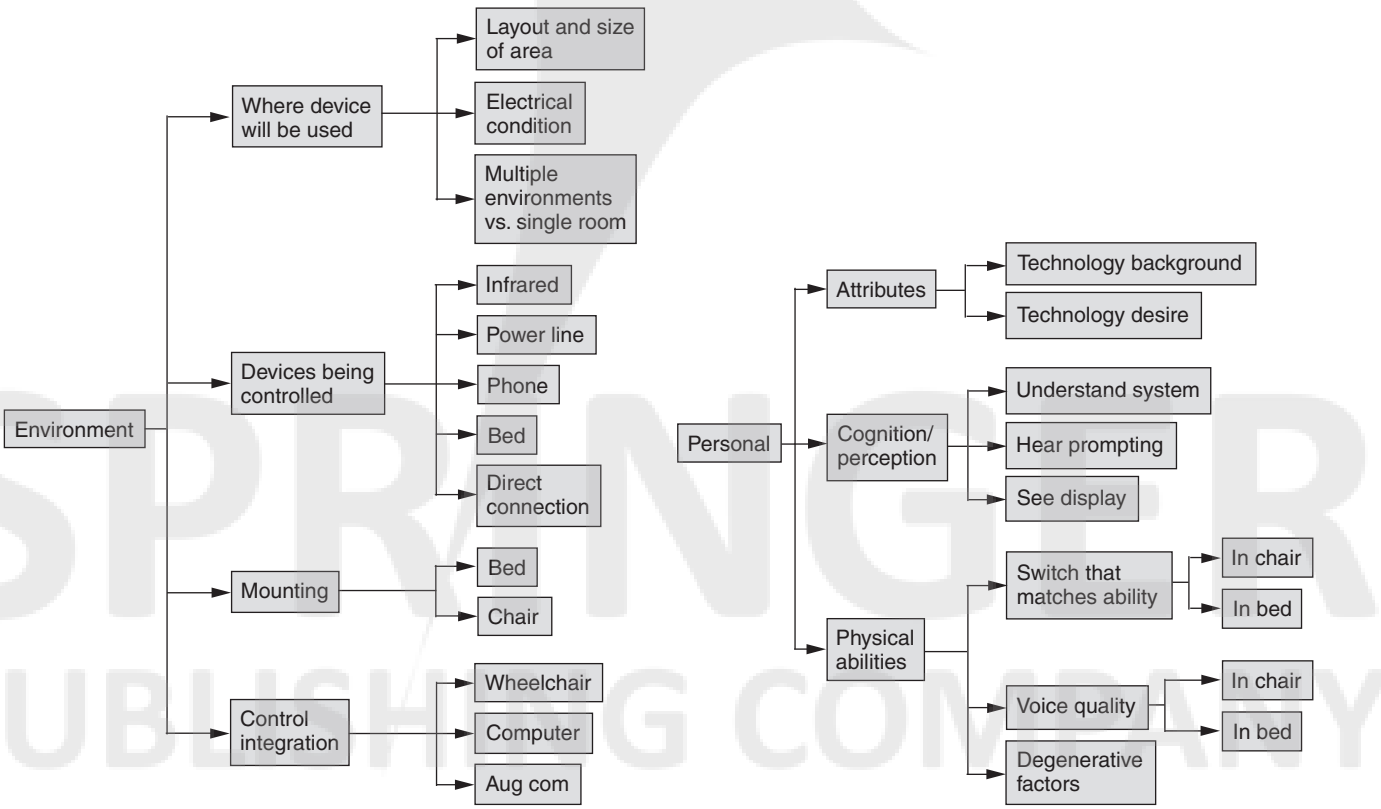

FIGURE 38.19 EADL evaluation considerations.

rehabilitation agencies, the Veterans Administration, worker's compensation, civil and nonprofit organizations, and philanthropists. Medical insurance does not cover EADLs.

Lower-Cost Alternatives

Persons diagnosed with a CVA often have function on one side of the body. Such persons may find it helpful to consider lower-end home automation options. Specifically, a large-button, universal remote can assist by decreasing needed hand dexterity and making it easier to see the buttons. A remote control that combines IR features with X-10 capabilities can lessen the need to get up to turn on lights or open or lock doors, and provides a means to signal assistance from someone in another room. Switch-activated telephones and cell phones are also available. These devices can give a person more security and independence. For persons whose speech is significantly affected, switch-activated telephones that call and play a prerecorded message can be considered.

AUGMENTATIVE AND ALTERNATIVE COMMUNICATION

The process of achieving communication success for individuals who have had a stroke and could benefit from AAC may be perceived as an insurmountable challenge by their families and those providing clinical services. Yet, the goal of AAC intervention is to optimize the communication of individuals with significant communication disorders (18). AAC AT provides a viable rehabilitation solution to assist individuals who cannot speak to regain various degrees of function and improve communication performance and outcomes.

Individuals recovering from stroke who are candidates for AAC may have a motor speech disorder, language impairment, or a combination of both speech and cognitive–linguistic considerations that affect body structure and function, daily activities, and full participation in life experiences (20). These considerations, as identified using the World Health Organization's (WHO) International Classification of Functioning, Disability and Health (ICF), present issues that influence the selection and intervention of AAC AT (21). In addition, candidates for AAC will have immediate short-term needs for technology as well as possible long-term use beyond rehabilitation. Regardless of the duration of use for an individual, the AAC AT must be considered based on how language is represented and generated using the system before specific technologies or devices are considered. These primary language considerations include whether the AAC system provides for spontaneous novel utterance generation (SNUG), prestored messages, or both, and how core and extended vocabulary is stored and accessed on the system (22). Several AAC systems may be considered, trialed, and recommended over the course of rehabilitation and a lifetime. How the systems handle these language considerations and transitions and maintain consistency when change occurs is important to achieving long-term effective communication performance and desired outcomes.

Graphic symbols are used on AAC AT to construct messages. AAC language representation methods (LRMs) refer to the ways that symbols are used to generate communication. The three commonly used LRMs in AAC have been identified and described as alphabet-based methods, single-meaning pictures, and multiple-meaning symbols (23). Understanding the characteristics of each method is important when taking into consideration the specific characteristics and degree of a possible cognitive–linguistic impairment. In addition, people with aphasia may have impaired resource capacity and resource allocation abilities that will influence their use of AAC interventions (24). Therefore, language considerations (cognitive–linguistic functioning) should take priority in selecting AAC AT to match technology features to how language is best represented for an individual. Many AAC systems provide multiple methods to access vocabulary and generate messages. Research has shown that the communication performance for the different methods varies significantly (25). Consequently, selecting the LRMs based on the client's communication abilities, needs, and potential for improvement is critical for achieving the best possible performance.

A thorough appreciation of AAC LRMs is needed to evaluate how LRMs may be accessed using the range of aided AAC technology and types of AAC display technology recommended for individuals with acquired communication disabilities. High-performance technology solutions can then be identified as nondedicated or dedicated AAC systems. Nondedicated systems include computers, iPADs, tablets, PDAs, and other mass-market hardware with software applications designed to support communication. For example, Lingraphica® is software run on a laptop computer that is designed specifically for persons with aphasia (Figure 38.20). The voice output used with computers is

FIGURE 38.20 A laptop computer designed specifically for persons with aphasia.

TABLE 38.1 Components of Dedicated AAC Technology (Hill©)

LANGUAGE REQUIREMENTS	CONTROL INTERFACE (HARDWARE)	HARDWARE COMPONENTS	SELECTION METHODS	ACCESSORIES	ADDITIONAL CONSIDERATIONS

synthesized speech (text-to-speech), and a variety of male, female voices and accents/languages are available. Dedicated systems are designed specifically for the purpose of communication and can be classified into low, light, and high-performance technology. The range of aided technology increases as availability of power, voice output, electronics, and computer components become part of the system. Table 38.1 shows the complex nature of decision making for selecting AAC technology once a comprehensive assessment of speech, language, communication, vision, hearing, physical abilities, and client preferences, values, and expectations has been conducted by the speech–language pathologist and AAC/AT team (26).

The display technology used to generate messages can be a static keyboard or touchscreen that comes in various sizes and thus influences the number of possible selections on the display. The display configuration supports any of the chosen LRMs or multiple LRMs. The appearance of the display can vary in the number, arrangement, shape, color, size, and organization of the keys. The applications used with individuals with acquired communication disorders include visual scenes, various grid organizational patterns, and a core and activity row pattern. Single-meaning picture or multimeaning icons may be used on visual scenes and grids or page-based displays, whereas alphabet-based methods are configured on a grid display. The core and activity row pattern is used exclusively with Semantic Compaction™ for one-hit access as a single-meaning picture method or with sequencing (27). Most AAC manufacturers provide a range of devices that offer one or more display configurations on a system. For example, visual scenes may be used for one communication activity, such as retelling a story, whereas a core/activity row would be used for another level of participation, such as requesting, commenting, or questioning (28). A careful exploration of the features and components of systems is critical to understanding how the technology may support language/communication functioning and intervention goals.

An important aspect of successful AAC intervention is the considerable training and practice required to regain skills and/or become a more efficient and effective communicator (29) after a stroke causes a severe communication disorder. Today's technology includes tools and features to monitor performance and outcomes for AAC intervention. Many AAC systems have built-in language activity monitoring (LAM) to collect data on the use of an AAC system (30). Any AAC system under consideration can be compared with other possible options for making the most informed choice. LAM data can be analyzed using the Performance Report Tool (PeRT) to generate a report of quantitative summary measures of communication (31). Clinical data on the number of symbols and/or words used, frequency of methods used to generate utterances, and frequency of vocabulary use provide insights for intervention. Outcome measures based on the type of activity and participation, along with preferred use, that indicate strong user satisfaction with AAC intervention have been reported (32).

Because communication is so important to the life experience of people who use AAC and have had strokes, significant clinical effort should be focused to optimize performance. Identifying the tertiary components of AAC AT services that are important to a person with a disability can maximize the potential use of an AAC system (Table 38.1). AAC systems can be mounted on wheelchairs or positioned for access anywhere in the home or office. AAC AT can function as a keyboard emulator to provide access to computers and enhance access to email and the Internet. AAC systems with IR technology can support environment controls and enhance independence. LAM tools can support telerehabilitation services for persons recovering in remote areas and with other transportation and health issues (33). Internet resources and support organizations specific to AAC, such as the AAC Institute (www.aacinstitute.org), provide the most current information to practitioners, family members, and consumers to support the complex questions about AAC AT.

ADAPTIVE DRIVING

One of the many important goals in the rehabilitation recovery process after a stroke is the ability to return to independent living in one's community. Community mobility, specifically driving, can contribute to a person's quality of life. Transportation into the community allows access to activities outside the confinement of one's home. Individuals who are no longer able to drive are more likely to report worsening depressive symptoms (34). Many stroke survivors express an interest in returning to driving during their rehabilitation process. It has been reported that 30% of stroke survivors who drove prior to their stroke are said to resume driving after their stroke (35).

Stroke can cause physical-motor, cognitive, visual, and psychological impairments that can impact a person's driving performance. A Certified Driving Rehabilitation Specialist (CDRS) can provide a comprehensive driving evaluation to assess the extent of the neurologic impairments and determine the ability of a person to operate a vehicle safely after a stroke (36). A typical comprehensive driving evaluation consists of a clinical assessment and on-road assessment. The clinical assessment evaluates the basic skills necessary for driving, such as vision, perception, cognition, physical functioning, and knowledge of driving. This aspect of the process can help to identify strengths or deficit areas related to driving. Actual driving skills then can be assessed in a vehicle with consideration of information gathered from the clinical assessment. The vehicle can be modified with adaptive equipment that the person may need to use for improved independent operation of the vehicle.

After completion of the driving evaluation, education and training may be indicated with or without the use of adaptive equipment. Adaptive equipment can be recommended by a CDRS to compensate for the loss of functional skills after a stroke. Adaptive equipment for the individual's vehicle is prescribed after completion of a comprehensive driving evaluation and training program and only after it is determined that the person will be able to develop competency to drive with the prescribed equipment.

A steering device, such as a spinner knob, can be attached to the steering wheel to allow a person to steer with one hand (Figure 38.21). A left-sided accelerator can be used if a person is unable to use his or her right foot to operate the gas or brake pedal (Figure 38.22). A turn signal crossover (Figure 38.23) shows the relocation of the turn signal indicator from the left side of the steering wheel to the right side. This allows a person without the use of his or her left hand to access the turn sig-

FIGURE 38.21 Spinner knob attached to the steering wheel.

Courtesy of Howell Ventures Ltd.

FIGURE 38.22 Left foot accelerator with gas pedal guard.

Courtesy of Howell Ventures Ltd.

nal using only his or her right hand. Other secondary vehicle controls, such as windshield wipers, lights, and horn, can be relocated onto the steering wheel next to the steering device or at any other location within the vehicle. This can be done so that the driver is able to access all vehicle controls quickly and accurately with his or her dominant hand. If sitting balance is impaired and the person tends to lose his or her balance as the vehicle goes around a curve in the road, a chest harness may be indicated. This affords additional trunk control beyond what a seat belt provides, but it does not replace the use of the seat belt. A strap or other modifications can be used for seat belt retrieval if the person is unable to grasp or reach his or her seat belt. A parking brake extension can be attached to a floor-mounted parking or emergency brake pedal (Figure 38.24). Using this type of device, the person without the use of his or her left foot then can apply the parking brake using his or her hand. Partial loss of visual fields or the presence of scotomas can sometimes be compensated for by the use of specially placed mirrors. As with all adaptive equipment, specialized education and training are required to assure correct placement and proper use of the additional mirrors (37).

FIGURE 38.23 Right side turn signal.

FIGURE 38.24 Parking brake extension.

Courtesy of Mobility Products and Design.

The ability to drive depends on a set of visual, perceptual, cognitive, and psychological skills. Impairment in any or all of these areas will affect the individual's driving performance. These deficit areas can be more challenging and difficult to compensate for, as compared to the physical impairment areas, especially when driving a vehicle in an ever-changing dynamic environment.

Common driving behaviors that may be observed in an individual after a stroke and would require additional training and education for remedial purposes include (38):

- Difficulty in maintaining a centered lane position or drifting across the lane lines into other lanes
- Poor speed modulation (driving either too fast or too slow)
- Poor judgment of distances (positioning too close to other vehicles)
- Delayed response or reaction time
- Poor decision-making skills
- Difficulty in completing lane changes, merges, and blending with traffic
- Poor anticipation of other drivers or pedestrians
- Missing of traffic signs and signals
- Near misses, close calls, and frequent blowing of horns by other drivers directed at the driver

Unfortunately, not all functional deficits caused by a stroke can be easily compensated for by means of adaptive equipment or dedicated training. Severe cognitive impairments, uncontrolled spasticity, and significant visual field loss (e.g., visual homonymous hemianopsia or unilateral visual attention deficits) are examples of problems that may permanently prevent a person from driving a vehicle after a stroke. When it is determined that an individual is no longer

FIGURE 38.25 Turning automotive seat and wheelchair lift.

Courtesy of Bruno Independent Living Aids, Inc.

able to drive, suggestions and materials should be provided for alternative means of transportation. The individual's family and friends are encouraged to support the no-driving recommendation and assist the stroke survivor with ongoing access to the community (36).

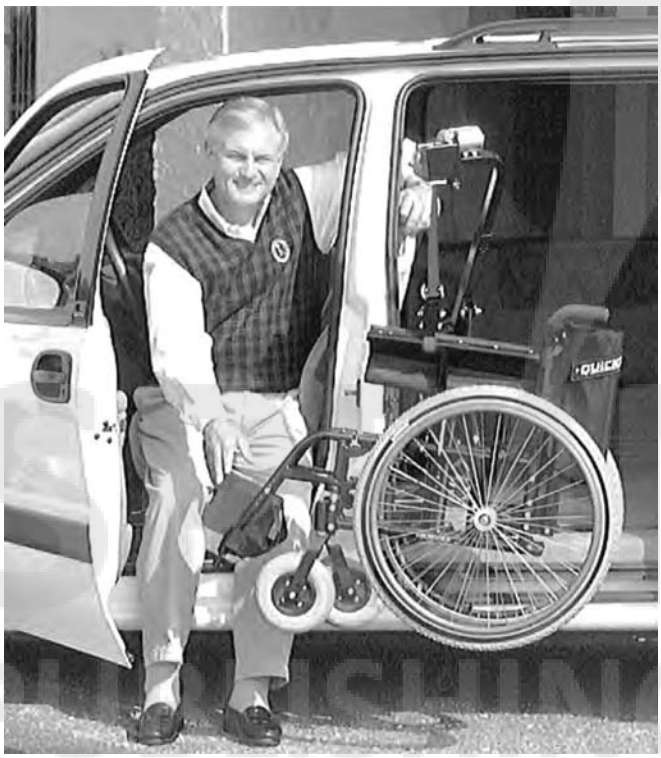

FIGURE 38.26 Wheelchair lift-side door application.

Courtesy of Bruno Independent Living Aids, Inc.

A variety of adaptive equipment and vehicle modifications can be used for vehicle ingress and egress. Persons with impaired hand function can use automatic car door openers (also known as keyless entry), built-up key holders, or key turners. Power-based seats can be installed in the car seat to allow a driver or passenger to transfer from a wheelchair to the vehicle seat. These power-based seats have options that allow the car seat to swivel out, glide out of the vehicle, and then lower to a desired level for ease in transfers. Wheelchair lifts (Figures 38.25 and 38.26) are available to load and unload mobility equipment, such as MWCs, PWCs, or scooters, into the vehicle without significant vehicle modifications. A car topper is another type of lift that attaches to the top of a sedan-type vehicle and can lift and store a MWC. Wheelchair or scooter users may require a vehicle ramp or lift to either get into their vehicle or lift their mobility device into the vehicle. These major vehicle modifications are typically prescribed by a CDRS and installed by a mobility equipment dealer. It is critical that, prior to prescribing and installing the adaptive equipment in the vehicle, compatibility between the individual, mechanical device, and vehicle is assured. Obviously, this must be done before the vehicle is modified.

WHEELCHAIR TRANSPORTATION SAFETY

Individuals recovering from a stroke may travel in a motor vehicle to seek medical care and continue to participate in family and community activities. It is safest to ride seated in a vehicle seat using the vehicle's seat belt system that complies with federal safety standards. However, an individual relying on a wheelchair for mobility may not be able to safely transfer to a vehicle seat. If transferring is not feasible, the

person must ride while seated in the wheelchair. When this occurs, it is very important to ensure the safety of the wheelchair-seated occupant by using after-market safety systems that meet voluntary standards (39).

To ensure the safety of the wheelchair-seated occupant during vehicle transportation, the entire wheelchair transportation safety system must be considered. This system includes three main components: the wheelchair, the wheelchair securement, and the occupant restraint. This section address selecting crashworthy wheelchairs and wheelchair securement equipment, securing the wheelchair, and properly restraining the occupant.

The Wheelchair

It is best to have a wheelchair that has been designed and tested for use as a seat in a motor vehicle. This means that the wheelchair has been designed to withstand forces generated in a crash, provides the occupant with effective support during impact loading so that the occupant's restraint belts remain properly positioned, considers access and fit of the vehicle occupant restraints, and provides attachment points to secure the wheelchair to the vehicle. Such wheelchairs comply with voluntary standard ANSI/RESNA WC19 or ISO 7176-19 and are referred to as WC19, transit, or transit option wheelchairs (40,41). These wheelchairs have four, crash-tested, and clearly labeled securement points for attachment of tie-down/securement straps or hooks (Figure 38.27). If a WC19 wheelchair is not an option, a wheelchair with an accessible frame to allow securement straps to be attached to nonremovable frame junctions is the next best choice. It is best to keep the wheelchair back at an angle of no more than 30 degrees to the vertical. Hard wheelchair trays should be removed and secured elsewhere during travel. Medical and other equipment should be secured to the wheelchair or vehicle to prevent it from breaking free and causing injury in an accident.

Wheelchair Securement

The wheelchair must not add to the forces on an occupant during emergency maneuvers or an accident. Therefore, the wheelchair must be secured using a means independent of restraining the occupant. For example, the same strap should not be used to restrain the occupant and secure the wheelchair. The securement system must be designed to attach to the wheelchair frame, prevent excessive movement or tipping during driving events, and withstand crash forces.

The wheelchair should be positioned facing forward in the vehicle and secured using a system that has been crash-tested and complies with the voluntary standard ANSI/RESNA WC18 or ISO 10542 (42,43). The system should be installed according to the manufacturer's instructions by a reputable vehicle modifier. The most common type of securement is the four-point tie-down system (Figure 38.28) (44). This system consists of four tie-down straps that anchor to the vehicle floor and four points on the wheelchair (two front and two rear). The end fittings that attach to the wheelchair can be hooks or loops that wrap around the wheelchair frame or designated securement attachment points. Although this system can be used with a wide variety of

FIGURE 38.27 WC19-compliant wheelchair securement point with required label.

FIGURE 38.28 Example of a four-point tie-down system used to secure a wheelchair.

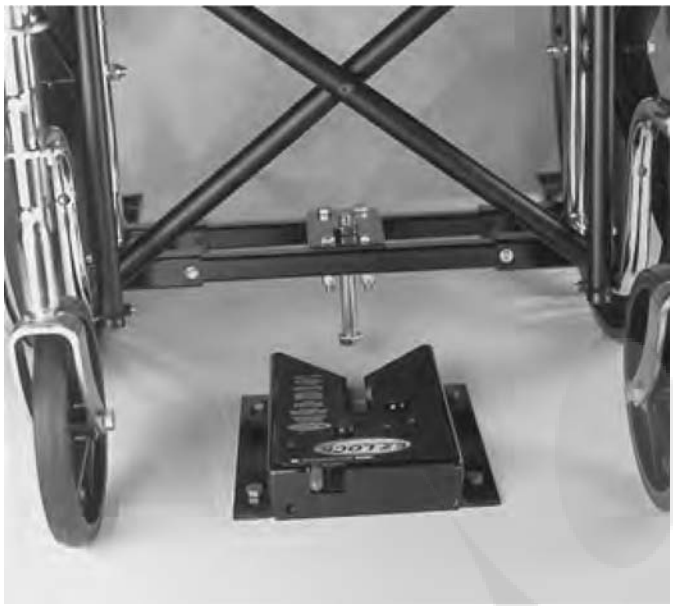

FIGURE 38.29 Example of a docking-type wheelchair securement system.

Courtesy of EZ Lock Incorporated.

wheelchairs and does not require additional hardware to be placed on the wheelchair, it does require an attendant or caregiver to secure and release the wheelchair.

If the wheelchair is not a WC19 wheelchair with four designated securement points to attach the four tie-down straps, the straps should be attached to the welded junctions of the wheelchair frame. The attachment points should be as close to the seat surface as possible to improve the stability of the wheelchair and result in rear tie-down strap angles preferably between 30 and 45 degrees to the horizontal. Tie-down straps should not be attached to removable or adjustable components of the wheelchair, such as armrests, footrests, or wheels. The four straps should be tightened to remove any slack.

Wheelchairs can also be secured using automatic docking systems. This type of securement utilizes a wheelchair adaptor (i.e., special hardware mounted on the wheelchair), which engages with a docking station or receptacle mounted to the vehicle floor or sidewall. The advantages of wheelchair docking technology have been demonstrated by proprietary systems that have been used for independent securement of wheelchairs in private vehicles for many years (Figure 38.29). These systems offer increased independence for the wheelchair user and reduced attendant intervention (38). They also remove the need for human judgment, resulting in more consistent and proper use of the systems. However, they require that a unique proprietary adaptor be retrofitted to the wheelchair; this may add unwanted weight, affect ground clearance if mounted underneath, or add to the overall length if mounted in the rear. Docking systems also tend to cost more to purchase and maintain than the traditional four-point tie-down system. Docking systems should also have been crash-tested to meet voluntary safety standards and should have been successfully crash-tested with the specific wheelchair model being used.

Occupant Restraint

In addition to wheelchair securement, a crash-tested occupant restraint system is necessary to prevent occupant ejection from the vehicle or contact with the interior structure of the vehicle. Postural supports are not designed to withstand crash forces and are often not positioned correctly for effective restraint in a crash. Both pelvic and shoulder restraints are needed to safely limit the excursion of the head, chest, and pelvis (39,43). The pelvic belt should be placed across the front of the pelvis near the upper thighs, not over the abdomen, at an angle between 45 and 75 degrees to the horizontal when viewed from the side. To allow proper placement on the pelvis, the pelvic belt should not be routed around armrests. This can often be avoided by inserting the lap belt under the armrest or between the armrest and the seatback. The shoulder belt should cross the middle of the shoulder and the center of the chest and connect to the lap belt near the hip. The shoulder belt should be anchored to the vehicle above and behind the occupant's shoulder to allow proper contact with the shoulder and chest. A WC19-compliant wheelchair has the option of a crash-tested pelvic belt that is anchored to the wheelchair, increasing the ease of achieving proper fit. This crash-tested pelvic belt will have labeling to indicate that it complies with ANSI/RESNA WC19. A vehicle-mounted shoulder belt should be attached to the pelvic belt to provide complete protection. A headrest positioned directly behind and in close proximity to the head can help protect the head and neck in rear impact. Space around the wheelchair rider should be as clear as possible to reduce the chance of injury from contact with items in the vehicle's interior during travel or a crash.

RESEARCH FRONTIERS—FUTURE TECHNOLOGIES

People with reduced functional capabilities who are aging into or with disability have become a large and growing segment of the world population. Recent advancements in technology such as computation, robotics, machine learning, communication, and miniaturization of sensors bring us closer to a futuristic vision of compassionate intelligent devices and technology-embedded environments. Even though many intelligent systems have been developed, most of them are for manufacturing, military, space exploration, and entertainment. Their use for improving health-related quality of life has been treated as a specialized and minor area. AT, for example, has fallen into the cracks between medical and intelligent-system technologies. The missing element is a basic understanding of how to relate human functions (physiological, physical, and cognitive) to the design of intelligent devices and systems that aid and interact with people.

A dilemma faced by clinicians is reconciling the fact that observations of patients only occur during (infrequent) face-to-face meetings in a clinic or laboratory, whereas what is really needed are assessments that reflect the patient's

capabilities in the real world, where distractions are present and multitasking performance is often required. As such, there is a need for ecologically valid tests that can provide information about a patient's ability to function in a real-life environment. One way to obtain ecologically valid measures is through the use of ubiquitous computing.

People with cognitive impairments often have difficulty with executive functions and prospective memory, including such tasks as organizing a schedule, initiating activities, and remembering to perform the appropriate task at the correct time. External cueing systems can assist people with cognitive disabilities by reminding them to perform a task at the appropriate time or providing guidance through a task. Such systems can range from low-tech paper-and-pencil solutions to mainstream voice recorders and PDAs, to specialized software designed for people with cognitive impairments. Despite attempts at using simple reminders (timers, pressure monitors, and PDA reminders/surveys), user's guides (handouts and note cards), and consumer booklets developed to promote clinical practice guidelines, users do not seem to follow clinicians' instructions. Novel approaches are emerging that use machine learning and artificial intelligence for real-time coaching of the person with disabilities, both for long-term monitoring of the person's use of the equipment and for providing hard information for clinicians to use to augment their education of people with disabilities. This research is patient-centered and is likely to allow clinicians and people with disabilities to take more proactive roles in the ways technology can enhance their lives, for example, by avoiding detrimental health effects of prolonged seated postures.

One problem with current technology is that effectively combining manipulation and mobility assistance with perception and decision making wherever a person goes is quite difficult. When end users were consulted, they reported they wanted a zero gap in mobility and manipulation between them and an unimpaired person. A primary challenge is to overcome the shortcomings and unmet needs with a device that provides coordinated mobility and manipulation. Some of the new functionalities required are to detect and/or predict user intent, provide coordinated movement between a power base and multiple manipulators, include natural and intuitive user interfaces and control modes, and incorporate real-world navigation and docking assistance. To make interaction easier, a wide range of natural and intuitive interfaces that reduce the time to complete tasks and produce fluid, human-like motions are needed.

STROKE CARE SYSTEMS AND OUTCOMES

39

Stroke-Specific Functional Assessment Instruments

Chiung-ju Liu, Nancy K. Latham, and Alan M. Jette

The manifestations of stroke are heterogeneous and depend on many factors, including the size of the lesion, the affected brain region, and the patient's premorbid status. Although no two stroke patients are exactly the same, the ultimate goal of treatment for stroke survivors is to diminish sequelae of the disease and help patients return to community life. Functional assessments evaluate a patient's abilities beyond the primary affected cerebral functions related to movement, cognition, and language.

As evidence-based practice and initiatives to improve the quality of health care have grown worldwide, recognition of the need to measure functional status in all health care settings has also increased (1). There are many instruments that have been used in clinical practice and research to assess functional outcomes in patients who have suffered a stroke (2,3). Some are designed for general use (usually called generic instruments), and others are designed for use specifically in patients with a stroke (called condition-specific functional instruments). The most commonly used generic instruments in stroke are the functional independence measure (FIM) and the Barthel index (BI) to assess basic daily activities, and the Short Form-36 (SF-36) to assess health-related quality of life. The use of these generic measures in stroke has been extensively reviewed elsewhere (4–7). The focus in this chapter is on reviewing condition-specific instruments that have been designed for use with patients who have suffered a stroke.

Functional status instruments vary widely in the scope of functional content included in the instrument. Some focus on the assessment of specific body movements or discrete functional tasks, even as others assess a patient's ability to accomplish self-care activities. Another group of measures addresses more broadly defined concepts of quality of life. The selection of an appropriate functional assessment measure is a complex process, and many factors must be considered, including the scope of the instrument, the purpose for which it was developed, the administration and scaling methods used, and the psychometric properties, as well as its feasibility in a particular context.

The aim of this chapter, therefore, is to provide readers with a conceptual framework for reviewing functional assessment instruments, introduce the range of condition-specific functional status instruments that are available to use with patients who have suffered a stroke, review some of the key criteria to guide selection among the variety of available instruments that might best meet a user's specific needs, and highlight some newer methodological techniques available to improve the assessment of function with patients who have experienced a stroke.

WHAT IS FUNCTIONAL ASSESSMENT?

Before selecting a functional assessment measure, it is necessary to have a clear understanding and definition of the concept being assessed and the range of functional content to be considered for a particular application. Currently, there is no clear and commonly accepted definition of functional status or a clear delineation between instruments that assess function and those that assess other health concepts. As work to define and quantify health concepts has evolved, many different types of instruments designed to assess overlapping health and functional concepts have been developed. These include instruments that purport to assess disability, function, activities of daily living, activity performance, advanced activities, physical performance, health, health status, quality of life, and health-related quality of life. In the past, there was no consensus on how these terms should be used or measured (8).

The World Health Organization's (WHO) International Classification of Functioning, Disability, and Health (ICF) tried to address this concern by providing the field with a useful conceptual framework for considering the definition and scope of functional assessment in stroke rehabilitation (9). In 2001, the WHO released the ICF to provide researchers and clinicians with a biopsychosocial view of health states from a biological, personal, and social perspective. Over the past decade, the application of the ICF has grown in the field of stroke rehabilitation because the model provides a universal language to facilitate communication and a comprehensive structure to cover the rehabilitation care of stroke (10–12). The ICF organizes concepts in two parts. The first deals with function and disability, and the second deals with contextual factors. The function and disability domains of the ICF, expressed in either neutral or negative

terms, are described from the perspective of body systems, the individual, and society. *Body functions and structures* are defined as physiological functions of body systems or anatomical elements such as organs, limbs, and their components. Hemiparesis is an example of a common impairment in a body function following the onset of a stroke. *Activity*, in contrast, is defined as the execution of specific tasks or actions by an individual. An example of the activity concept is a person's ability to walk independently or transfer from bed to chair. Finally, *participation* is described as encompassing one's involvement in life situations, such as the ability to return to one's former occupation following a stroke. The ICF organizes the areas of activity and participation into several domains that include the following:

- Learning and applying knowledge
- General tasks and demands
- Communication
- Mobility
- Self-care
- Domestic life
- Interpersonal interactions and relationships
- Major life areas
- Community, social, and civic life

Health-related quality of life includes aspects of all three ICF dimensions, but it is a distinct concept that usually includes domains that assess social functioning, emotional well-being, and life satisfaction, as well as physical functioning. We focus on stroke-specific measures of activity, participation, or health-related quality of life in this chapter.

The two contextual elements of the ICF are *environmental factors* and *personal factors*. Environmental factors are all aspects of the external or extrinsic world that form the physical, social, and attitudinal circumstances in which people live and conduct their lives. Personal factors include gender, race, age, lifestyle, habits, social background, and other individual characteristics or experiences that are not classified elsewhere in the ICF. Even though these contextual factors may act as facilitators or barriers as they affect functioning and disability, they are not directly included within a functional assessment instrument.

Purpose of Functional Assessment

A patient's functional status can be assessed for several different purposes that have bearing on the criteria that should be considered when choosing an assessment instrument. For this chapter, we focus on two distinct purposes to which functional assessment instruments are typically applied. The first can be characterized as discrimination. Discriminative functional instruments are designed to differentiate among patients at a point in time. At the level of a group of patients, a discriminative functional assessment can be done for the purpose of describing a patient population or for selection purposes in recruiting patients for a study; at an individual patient level, discriminative assessment can be done to set patient treatment goals or to gauge a patient's prognostic potential. Alternatively, a functional assessment can be used for evaluative purposes. In this situation, the assessment instrument has to be adequate to measure meaningful change in function over time. At the group level, this type of index can be used to evaluate hypotheses pertaining to the impact of therapeutic interventions on function when applied in clinical studies. At the individual patient level, evaluative instruments can be used to monitor change in a patient's functional status or to modify treatment approach during an episode of care.

Key Psychometric Properties

In addition to considering the scope of the functional content needed in a functional assessment, a user should consider the psychometric quality of the functional assessment instrument for the purpose to which it will be put, be it discrimination or evaluation. For discriminative instruments, standards of validity and reliability must be achieved. For the purpose of evaluation, the additional criterion of responsiveness must also be considered.

Validity

Validity concerns the degree to which the functional assessment instrument actually measures what it is intended to measure. There are several approaches to examining an instrument's validity. If the score represents the specific theoretical domain or universe of content, the assessment has content validity. For example, a questionnaire on quality of life should contain items that are related to the concept of quality of life but not gait control. If the score is in accordance with an established functional measurement administrated at the same time, the assessment has concurrent validity. For example, a new self-care measure should be highly correlated to the BI, an established measure of this concept. If the functional score can predict a future criterion score, the assessment has predictive validity. For example, results of a patient's functional assessment at hospital admission may predict functional outcome at discharge.

Reliability

Reliability of an assessment is the extent to which repeated measurements yield the same outcome. The concepts of validity and reliability are related. An instrument with poor reliability will have diminished validity as well because it gives different outcomes at each measurement. However, it is possible that a highly reliable instrument still cannot measure the intended concept well and thus have poor validity.

Reliability assessment can include how consistent the result of an instrument is if readministered over time by the same person (test–retest) and/or if administered by different people (inter-rater reliability). Similar results should be obtained regardless of who administers the assessment. For example, scores should be nearly the same when the assessment is administered by a therapist or a nurse. Internal

consistency reliability reflects how consistent items are under the same category in an assessment. For example, items that measure self-care activities should have a higher correlation with each other than with items that measure instrumental activities of daily living (IADLs).

Responsiveness

Choosing a functional assessment with suitable responsiveness is a crucial criterion if the intended application is evaluative. A functional assessment with good responsiveness is sensitive to clinically meaningful change over time within a patient and the change is responsive to intervention effects (13). Good reliability and validity do not guarantee that an assessment also has good responsiveness. Responsiveness can be seen as a form of longitudinal validity, meaning that a functional instrument should be able to detect changes in function in patients whose function actually changes and no or small changes in persons whose function remains stable over time (13).

Additional Factors to Consider

Validation in Stroke Population

When evaluating the psychometric properties of a stroke functional assessment instrument, it is important to consider the population in which the psychometric testing was performed. A generic instrument should be tested in a stroke population before it is used in research or clinical practice. For stroke-specific instruments, the similarity of the validation population to the target population must be considered. Ideally, the psychometric testing will have been performed in a representative sample of stroke patients that has a broad range of important characteristics. If a more restrictive sample of stroke patients was used, it is important to consider whether the type of stroke, severity of stroke, degree of functional limitation, and the timing of the assessment after stroke are adequately similar between the two groups.

Feasibility

Many factors affect the feasibility of using a particular instrument. The setting of use and the subjects' severity of stroke will influence the amount of time that can be spent doing the assessment and the number of items that can be used. Even if a functional instrument is ideal in other ways, if an assessment requires special training, takes an excessive amount of time to administer, or has a complex scoring procedure, it increases the burden for health care professionals and may rarely be used.

Mode of Assessment

Many functional assessments rely on self-reported functional abilities rather than observed direct performance by an assessor. Some instruments are designed to rely primarily on the patient's self-report, whereas others rely on caregivers or family members. The focus of self-report assessments is on the activities that people regularly perform in their own environment.

Use of Proxy Reports of Function

It is sometimes necessary to rely on proxy reports of function if a patient has a problem in communication because of affected cognition and language, and, as a result, an interview with the patient is not possible. In contrast, when a patient does not have severe loss in cognition and functional level, the use of proxy reports of function may not be needed. A high agreement on basic and IADLs was found between patients' self-report and proxies' report in this case (14,15). Proxy reports might be more suitable when trying to obtain data from patients with severe functional problems. One study has found that a proxy was more likely to complete a mail survey if the patient had more functional limitations (16).

Because the source of information can influence reliability and validity of the functional assessment, it is important to clarify whether the score obtained from a proxy provides the same information as that obtained from the patient's own self-report, especially with patients who experience cognitive and communicative problems. When a proxy is used to provide a functional assessment, the agreement between the proxy and patient should have been assessed.

Self-Report Versus Direct Performance

An alternative approach to self-report functional assessments is to observe participants directly while they perform a series of set functional tasks. Direct performance tests can be a useful alternative when patients have communication or cognitive problems that limit their ability to report their function. In addition, the direct performance tests can provide an accurate assessment of a person's capacity to do specific functional tasks, including tasks that he or she might not regularly undertake as part of his or her daily activities. Many studies have shown that direct performance measures provide similar but slightly different outcomes than self-report assessments (17). This is probably because direct performance tests are evaluating what a person is capable of doing under set conditions, and self-report assessments ask people what they actually do in their own environment.

Overview of Stroke-Specific Functional Assessments

This section of the chapter describes the most commonly used stroke-specific measures of activity, participation, and health-related quality of life. For each measure, we summarize the instrument's background, scope, purpose, and psychometric properties. Table 39.5 (provided at the end of the chapter) summarizes the intended purpose, ICF conceptual domains covered, mode of administration, and psychometric properties of the nine stroke-specific functional assessments reviewed.

American Heart Association Stroke Outcome Classification

The American Heart Association Stroke Outcome Classification (AHA.SOC) was developed by a multidisciplinary panel to measure the full range of deficits following a stroke (18). The global classification identifies the severity and extent of neurologic impairments as well as the level of independence according to basic ADLs (BADLs) and IADLs. Therefore, the instrument covers all the three domains in the ICF: body structures and functions, activities, and participation. The primary purpose of the instrument is to serve as a standardized and comprehensive classification system to document the impairments and disability resulting from a stroke. A secondary aim is to gauge the effect of treatment.

The AHA.SOC contains three scales. The first scale, AHA.SOC-Domain, classifies the extent of neurologic impairments in six domains: motor, sensory, vision, affect, cognition, and language. The scale ranges from 0 (0 domains impaired) to 3 (more than two domains impaired). The second scale, AHA.SOC-Severity, classifies the severity of neurologic impairments into one of three levels: A (no/minimal neurologic deficit because of stroke in any domain), B (mild/moderate deficit because of stroke in one or more domains), and C (severe deficit due to stroke in one or more domains). The third scale, AHA.SOC-Function, classifies the dependency in BADLs and IADLs. The scale ranges from I (independent in BADLs and IADLs and tasks required of roles that patient had before the stroke) to V (completely dependent in BADLs in more than five areas and IADLs). The classification score is meant to document the limitations resulting from the most recent episode of stroke. It is recommended that clinicians use clinical examinations and standardized assessments to support their rating decisions for each scale (18). Time to complete the classification was not reported, but it may depend on the completion of standardized assessments.

Concurrent validity was assessed by correlations with the modified Rankin Scale (r = 0.70), the BI (r = –0.87), Lawton IADL Scale (r = –0.85), and physical function in SF-36 (r = –0.70) (19). The inter-rater reliability is good for the number of impaired neurologic domains classification (k = 0.56) and excellent for the severity of impairment classification (k = 0.76) and for the functional disability classification (k = 0.77) (18). It can discriminate ADL-related disabilities after one, three, and six months after a stroke (19).

The AHA.SOC is a comprehensive clinical assessment of impairment, severity, and function after a stroke and a useful tool to classify stroke severity. Although the classification covers all the three conceptual domains in the ICF, the AHA.SOC-Function assesses BADLs and IADLs together and shows no clear division between activities and participation. Administration of AHA.SOC may require experienced health care professionals to obtain required information and to decide the rating. It is recommended that the classification not be completed unless related standardized assessments are available.

Modified Rankin Scale and Oxford Handicap Scale

Rankin initially described functional recovery of a group of stroke patients on a five-level scale (20). The scale later was used as a global disability measure. To avoid ambiguity, the scale was revised to have six levels and clearer wording to differentiate levels one and two (21). The scale was renamed the modified Rankin Scale and has become a popular outcome measure for stroke clinical trials (22,23). The instrument was changed a third time by changing the word *disability* to *handicap*, and the term *lifestyle* was incorporated to expand the scale to measure handicap. This version is referred to as the Oxford Handicap Scale. Both scales are classification instruments to discriminate functional levels of patients. The modified Rankin Scale covers the conceptual domain of activities whereas the Oxford Handicap Scale covers activities and participation.

Administration relies on professional judgment. Both scales have six grades ranging from 0 (no symptoms) to 5 (severe disability; bedridden, incontinent and requiring constant nursing care and attention in the modified Rankin Scale; or severe handicap-totally dependent patient requiring constant attention night and day in the Oxford Handicap Scale) (21,24). Time to complete the scale varies, depending on how familiar the clinician is with the patient. The structured interview takes approximately 15 minutes (25).

Concurrent validity of the modified Rankin Scale was determined by comparing this scale with the BI (26). Concurrent validity of the Oxford Handicap Scale was assessed by a regression with multiple functional health indicators, including the BI and subscales of the Sickness Impact Profiles (SIP) (27). The results showed that the Oxford Handicap Scale is a global functional health index but with a focus on physical disability (27). The inter-rater reliability of the modified Rankin Scale is moderate for raters with similar professional backgrounds (k = 0.56) but low for raters with different backgrounds (k = 0.25) (21). A structured interview was suggested to improve its inter-rater reliability (28). However, the effect of this approach is not well supported (29). The inter-rater reliability of the Oxford Handicap Scale showed moderate agreement (k = 0.42) (24). The test–retest reliability was only available for the modified Rankin Scale (k = 0.81) (28). The modified Rankin Scale was less responsive to change when compared with the BI and the FIM in a group of stroke patients who received a rehabilitation service (30). For a comprehensive review of psychometric properties of the modified Rankin Scale, please see elsewhere (31).

The modified Rankin Scale and the Oxford Handicap Scale are simple outcome measures designed for use with patients after stroke. The broadly defined scale categories may be time efficient and adequate to classify patients in a clinical setting, but appear less psychometrically adequate for evaluating change. The Oxford Handicap Scale captures the domain of participation restrictions following a stroke, but is not designed for use with inpatients because it measures lifestyle issues that are not relevant while a patient is in the hospital. The lack of standardized criteria for administering both scales reduces the reliability of the scales.

TABLE 39.1 Chedoke-McMaster Stroke Assessment Disability Inventory

Gross Motor Function Index
1. Supine to side lying on strong side
2. Supine to side lying on weak side
3. Side lying to long sitting through strong side
4. Side lying to sitting on side of the bed through strong side
5. Side lying to sitting on side of the bed through weak side
6. Standing
7. Transfer to and from bed toward strong side
8. Transfer to and from bed toward weak side
9. Transfer up and down from floor and chair
10. Transfer up and down from floor and standing

Walking Index
11. Walking indoors
12. Walking outdoors, over rough ground, ramps, and curbs
13. Walking outdoors several blocks
14. Stairs
15. Age and sex appropriate walking distance (in meters) for 2 minutes (2-point bonus)

Independence (no helper)
7. Complete independence (timely, safely)
6. Modified independence (device)

Modified dependence (helper)
5. Supervision
4. Minimal assist (subject = 75%)
3. Moderate assist (subject = 50%)

Complete dependence (helper)
2. Maximal assist (subject = 25%)
1. Total assist (subject = 0%)

Chedoke-McMaster Stroke Assessment

The Chedoke-McMaster Stroke Assessment includes two outcome domains: a physical impairment inventory and an activity inventory (previously called a *disability inventory*) (32). The physical impairment inventory is a discriminative measure that is based on the body structures and functions conceptual domain in the ICF. The activity inventory is an evaluative measure that assesses change in mobility function, which is part of the activities conceptual domain in the ICF (Table 39.1).

The Chedoke-McMaster Stroke Assessment is a direct performance exam. Time to complete the assessment is approximately 1 hour. Administration and scoring rules are provided in a users' manual (33).

The physical impairment inventory has six dimensions: shoulder pain, postural control, the arm, the hand, the leg, and the foot. Each dimension is measured using a seven-point ordinal scale corresponding to the stage of motor recovery. The activity inventory has two subscales: gross motor function and walking. There are 10 items measuring rolling, sitting, transferring, and standing in the gross motor function subscale and 5 items measuring walking indoors, outdoors, stairs, and distance in the walking subscale. The activity inventory is suggested to be used with the Uniform Data System for Medical Rehabilitation, which includes the FIM (32). Scoring for each item is on a seven-point Likert scale based on the assistance needed, except for the last item, a 2-minute walk test. A higher score indicates more independence. The maximum score of the activity inventory is 100.

Concurrent validity of the physical impairment inventory was assessed with correlation with the Fugl-Meyer Test ($\gamma = 0.95$), and the activity inventory with the FIM ($\gamma = 0.79$) (32). All the reliabilities were estimated with intraclass correlation coefficient (ICC) (32). The internal consistency of the six dimensions in the physical impairment inventory ranges from 0.93 to 0.98. The inter-rater reliability of the physical impairment inventory is 0.97, and of the activity inventory is 0.99. The test–retest reliability of the activity inventory is 0.98. Variance ratio was used to assess the responsiveness between admission and discharge of a group of stroke patients (32). The Chedoke-McMaster Stroke Assessment was 1.92 times more responsive when compared with the FIM.

The Chedoke-McMaster Stroke Assessment is a stroke-specific instrument that has demonstrated high levels of validity and reliability. The two-inventory design can facilitate measurement of treatment effects because it provides a way to classify stroke survivors into homogeneous subgroups based on motor recovery. However, the scope of the activity inventory may be too narrow if administered alone, because it only measures mobility function. To fully assess functional domains commonly affected after a stroke—for example, self-care and communication—supplemental assessments are necessary.

Frenchay Activities Index

The Frenchay Activities Index (FAI) is a 15-item questionnaire that assesses activities performed inside and outside the home, including 1 mobility, 7 IADLs, and 7 indoor or outdoor social/role activities (34,35). The instrument covers activities and participation domains in the ICF. The FAI is designed as an evaluative instrument, which intends to obtain information on the premorbid lifestyle and up to three to six months after a stroke to help determine rehabilitation goals and record progress in activities (34,35).

The FAI measures three domains: domestic (preparing main meals and washing clothes), leisure/work (reading books and gainful work), and outdoor activities (local shopping and outings/car rides). Administration can be done through self-report of patients and/or relatives (36). The questionnaire takes less than 10 minutes to complete, which makes it feasible to use in a clinic. Scoring is based on a four-point Likert frequency scale ranging from never (1) to the highest frequency (4). The use of a frequency scale is assumed to reduce the subjective judgment of quality of an activity (35).

Concurrent validity was assessed by examining correlations with the BI ($\gamma = 0.66$) and subscales of the SIP scale (γ range is from –0.14 to –0.73) (35,36). A more recent study showed moderate correlations with the stroke impact scale (SIS) and the motor activity

log (Spearman's rho range: 0.3–0.6) (37). The FAI has excellent inter-rater reliability ($\gamma > 0.80$) (35,38). The test–retest reliability over one week in most items is excellent (kappa range: 0.25–1.00) (39). There is a high agreement between patients and their proxies on the FAI (ICC = 0.87 for the total FAI; ICC = 0.85 for the domestic domain; ICC = 0.63 for work/leisure domain; ICC = 0.87 for outdoor activities domain) (40). The FAI has been shown to detect change in patients who received a three-week stroke motor intervention (standardized response mean = 0.5) (37).

The FAI allows health care professionals to understand premorbid lifestyle of patients, so rehabilitation goals can be set to fit individual needs. Although items in the three domains cover concepts of activity and participation in the ICF, the two concepts are merged in the three domains. The FAI has been validated in older patients; the coverage of activities may be not sufficient for younger age groups, who have different social roles and task demands (41). For example, a young female patient may have to fulfill a mother's role and carry out caring activities that are not covered by the FAI. Moreover, items of leisure activities lack diversity to capture the experiences of younger patients who may have different hobbies, which could further affect the responsiveness in this population.

Hamrin Activity Index

The Hamrin Activity Index (AI) was specifically designed for a study to measure an activity program for patients with stroke in nursing care in Sweden (42). The AI is an evaluative instrument. The instrument includes 16 items in 3 domains: mental capacity, motor activity, and ADL function. These items cover the conceptual domains of body structures and functions and activities in the ICF.

Administration involves a structured interview with the patients and relatives (42). It may take up to one hour to have the assessment done properly. The mental capacity domain includes four subscales: degree of consciousness; orientation in time, space, and person; ability to communicate verbally; and psychological activities. The maximum score of this domain is 32, with a higher score indicating a better capacity. The motor activity domain measures functions of the four extremities with six subscales: right arm, right hand, right leg, left arm, left hand, and left leg. Scoring is from a functional point of view in relation to ADL performance, such as functional grip. The maximum score is 24, with a higher score indicating higher functioning. The ADL function domain includes six subscales: ambulation, personal hygiene, dressing, feeding, and continence with two items, emptying function of bladder and bowels. Scoring is based on the assistance needed to complete the activity. The maximum score is 36, with a higher score indicating more independence.

The concurrent validity was tested through a correlation with the Rankin disability scale, but the value of correlation was not reported (42). Similarly, the internal consistency was assessed but not reported (42). No inter-rater reliability was specifically assessed because mainly one researcher conducted the interviews in the activity intervention study (42). The instrument did not demonstrate responsiveness in patients 3 and 12 months after stroke (43).

One feature of AI is that it measures the patient's ability to communicate verbally, which may be affected by the disease. However, the application of the scale to patients with communication or language deficits has not been tested. Moreover, motor activity only focuses on unilateral motor function, whereas most daily activities require coordination between right and left extremities to complete. The application of this instrument can be limited given that AI was created within a research context to evaluate specific outcome domains of an intervention program. In addition, psychometric properties should be carefully assessed before applying this instrument.

Nottingham Extended ADL Scale

The Nottingham Extended ADL Scale was initially developed by clinicians and researchers in Nottingham, United Kingdom, to assess functional status in stroke patients after returning home (44). It is a questionnaire that includes 22 activities in 4 categories—mobility, kitchen, domestic, and leisure; therefore, it covers the conceptual domains of activities and participation in the ICF (see Table 39.2). The questionnaire is easy to understand and can be self-administered. Patients are asked whether they do the activity, rather than *if* they can do it, on four levels of responses: not at all, with help, on my own with difficultly, on my own. The original scoring of the scale is coded as dichotomous [0, 0, 1, and 1] to indicate whether a patient is dependent [0] or independent [1] (44). This scoring is recommended (personal communication), although researchers have applied a 4-point Likert scale to correspond to the four levels of responses [0, 1, 2, and 3] (45,46).

The concurrent validity was established with correlations to the BI, Nottingham Health Profile, Geriatric Depression Score, and the London Stroke Satisfaction Score (Spearman's rho range: –0.70–0.84) (47). Each category of the Nottingham Extended ADL Scale—mobility, kitchen, domestic, and leisure activities—showed acceptable values on Guttman scaling, which means each formed a unidimensional, hierarchical scale (48). Although the test–retest reliability over 2 weeks in all items ranges from "poor" to "excellent" (kappa range: 0.29–1.00), the kappa value is greater than 0.75 in 19 items (44). The scale is also sensitive to change within 1 year after stroke (effect size range: 0.04–1.40) (47).

The Nottingham Extended ADL Scale measures daily activities beyond self-care activities and is designed to be used as a postal assessment (44). The scale has the potential to reduce data collection burden and research expense in rehabilitation studies that track stroke patients' recovery in the community. Although a sum score of the four categories indicates an overall functional level of a stroke patient, the sum score might be questionable because the scale has not been shown to be a unidimensional measure of ADLs (49). For this reason, the category scores may be used to evaluate patients' functional change over time.

TABLE 39.2 Nottingham Extended ADL Scale

The following questions are about everyday activities. Please answer by ticking ONE box for each question. Please record what you have ACTUALLY done in the past few weeks.

DID YOU.	NOT AT ALL	WITH HELP	ON YOUR OWN WITH DIFFICULTY	ON YOUR OWN
1. Walk around outside?				
2. Climb stairs?				
3. Get in and out of a car?				
4. Walk over uneven ground?				
5. Cross roads?				
6. Travel on public transport?				
7. Manage to feed yourself?				
8. Manage to make yourself a hot drink?				
9. Take hot drinks from one room to another?				
10. Do the washing up?				
11. Make yourself a hot snack?				
12. Manage your own money when out?				
13. Wash small items of clothing?				
14. Do your own housework?				
15. Do your own shopping?				
16. Do a full clothes wash?				
17. Read newspapers or books?				
18. Use the telephone?				
19. Write letters?				
20. Go out socially?				
21. Manage your own garden?				
22. Drive a car?				

Rivermead ADL Scale

The Rivermead ADL scale was designed to evaluate ADLs for stroke patients in the United Kingdom (50). Activities selected in the scale were considered important for people's daily life. It is an evaluative instrument that records the functional progress of stroke patients. The instrument measures a patient's ability to perform specific tasks, so it reflects the conceptual domain of activities in the ICF.

The Rivermead ADL scale is a task performance exam. The administrator follows a standardized procedure, and patients are required to demonstrate each task. The evaluation is terminated after three consecutive failed items. The instrument includes 16 ADLs and 15 IADLs and uses a hierarchical scaling: the order of the items reveals increasing difficulty. Scoring is based on three levels:

- 1 = Independent with or without aid
- 0v = Independent but verbal assistance is required
- 0 = Dependent

The administration time varies from 30 to 60 minutes.

The validity of the Rivermead ADL scale was established through Guttman scaling. The results showed the existence of a valid cumulative and unidimensional Guttman scale with acceptable reproducibility (coefficients ≥ 0.89) and scalability (coefficients ≥ 0.79) (51). The inter-rater reliability ($\gamma = 0.89$), and the test–retest reliability are excellent ($\gamma = 0.95$) (50). Whether the scale is responsive to clinically meaningful change is unknown.

The application of hierarchical scaling is one advantage of the Rivermead ADL scale. The total score not only reflects the functional limitation, but it also shows the actual items that the patient can do. Although the standardized procedure and direct physical performance increases the instrument's reliability, substantial time may be required for proper training and administration. Its responsiveness remains unknown. Some activities in the scale may be culturally sensitive, and a cross-cultural comparison should be conducted before applying the instrument to the U.S. population.

Stroke-Specific Quality of Life Scale

Domains and items for the Stroke-Specific Quality of Life Scale (SS-QOL) were developed from interviews with patients with ischemic stroke (52). It is an evaluative instrument for stroke-specific, health-related quality of life (Table 39.3).

The SS-QOL is a self-report measure that is interview administered. Time to complete the interview is not reported. Twelve domains in the scale cover areas that may be affected by a stroke: energy, family roles, language, mobility, mood, personality, self-care, social roles, thinking, upper-extremity function, vision, and work/productivity. Concepts underlying the SS-QOL can be linked to body function, activities and participants, and environmental factors of the ICF (53). All items are rated on a five-point Likert scale, with higher scores indicating desirable outcomes.

The concurrent validity was initially assessed by comparing SS-QOL scores with established measures for each domain (52). Patients with language and cognitive deficits were excluded from this validation study, and, as a result, there was inadequate variation in the scores for the language, thinking, and social role domains to allow the assessment of their validity. A study later applied confirmatory factor analysis to validate the SS-QOL and found acceptable factor loadings (greater than 0.40) on items in each domain (54). The

TABLE 39.3 Stroke-Specific Quality of Life Scale

DURING THE PAST WEEK:

		COULDN'T DO IT AT ALL	A LOT OF TROUBLE	SOME TROUBLE	A LITTLE TROUBLE	NO TROUBLE AT ALL
SC1.	Did you have trouble preparing food?	1	2	3	4	5
SC2.	Did you have trouble eating, for example, cutting food or swallowing?	1	2	3	4	5
SC4.	Did you have trouble getting dressed, for example, putting on socks or shoes, buttoning buttons, or zipping?	1	2	3	4	5
SC5.	Did you have trouble taking a bath or shower?	1	2	3	4	5
SC8.	Did you have trouble using the toilet?	1	2	3	4	5
V1.	Did you have trouble seeing the television well enough to enjoy a show?	1	2	3	4	5
V2.	Did you have trouble reaching for things because of poor eyesight?	1	2	3	4	5
V3.	Did you have trouble seeing things off to one side?	1	2	3	4	5
L2.	Did you have trouble speaking, for example, get stuck, stutter, stammer, or slur your words?	1	2	3	4	5
L3.	Did you have trouble speaking clearly enough to use the telephone?	1	2	3	4	5

DURING THE PAST WEEK:

		COULDN'T DO IT AT ALL	A LOT OF TROUBLE	SOME TROUBLE	A LITTLE TROUBLE	NO TROUBLE AT ALL
L5.	Did other people have trouble understanding what you said?	1	2	3	4	5
L6.	Did you have trouble finding the word you wanted to say?	1	2	3	4	5
L7.	Did you need to repeat yourself so others could understand you?	1	2	3	4	5
M1.	Did you have trouble walking? (If you can't walk, circle 1 and go to question M7)	1	2	3	4	5
M4.	Did you lose your balance when bending over or reaching for something?	1	2	3	4	5
M6.	Did you have trouble climbing stairs?	1	2	3	4	5
M7.	Did you have trouble with needing to stop and rest when walking or using a wheelchair?	1	2	3	4	5
SR5.	I didn't see as many of my friends as I would like.	1	2	3	4	5
SR6.	I had sex less often than I would like.	1	2	3	4	5
SR7.	My physical condition interfered with my social life.	1	2	3	4	5

(*continued*)

TABLE 39.3 Stroke-Specific Quality of Life Scale (*continued*)

DURING THE PAST WEEK:

		STRONGLY AGREE	MODERATELY AGREE	NEITHER AGREE NOR DISAGREE	MODERATELY DISAGREE	STRONGLY DISAGREE
MD6.	I felt withdrawn from other people.	1	2	3	4	5
MD7.	I had little confidence in myself.	1	2	3	4	5
MD8.	I was not interested in food.	1	2	3	4	5
E2.	I felt tired most of the time.	1	2	3	4	5
E3.	I had to stop and rest often during the day.	1	2	3	4	5
E4.	I was too tired to do what I wanted to do.	1	2	3	4	5

Now, we would like to ask how you feel you are doing today in some general areas compared to how you were before your stroke. Put an "X" in the box to show whether each area is a lot worse, a little worse, or the same as before your stroke. Please remember to compare how you are doing today with how you were before your stroke happened.

	A LOT WORSE THAN BEFORE MY STROKE	SOMEWHAT WORSE THAN BEFORE MY STROKE	A LITTLE WORSE THAN BEFORE MY STROKE	THE SAME AS BEFORE MY STROKE
1. E. My energy level is . . .				
2. L. My speech is . . .				
3. M. My walking is . . .				
4. V. My vision is . . .				
5. UE. The use of my arms or hands is . . .				
6. T. My thinking is . . .				
7. MD. My mood is . . .				
8. P. My personality is . . .				
9. W. I do my jobs at home or at work.				
10. SC. I can take care of myself.				
11. FR. I do things for my family.				
12. SR. I do things for my friends.				
13. Overall, my quality of life is . . .				

SS-QOL also demonstrated excellent internal consistency in all domains (Cronbach alpha range 0.79–0.96) (54). No test–retest or inter-rater reliabilities are available. The responsiveness was evaluated on patients one and three months after an ischemic stroke. Most of the domains were shown to have moderate responsiveness (standardized effect sizes greater than 0.4) (52)

One advantage of SS-QOL is that it is a comprehensive measure of stroke. For example, it assesses language function, which has been ignored by most functional assessments. Because SS-QOL is a condition-specific quality-of-life measure, it is related more to the overall health-related quality of life in stroke patients than generic QOL measures (55). However, the scoring procedure can be confusing, as one domain may use two response set keys. The Likert response scale for each key is inconsistent with others, that is, in one scale, 5 may indicate "no help needed" or may indicate "strongly disagree." Consequently, the domain sum score may be difficult to interpret. In addition, this is a lengthy questionnaire and, therefore, might be inefficient to use in some settings. SS-QOL was validated mainly using direct self-reports of patients with ischemic stroke, although validation in patients with aneurysmal subarachnoid hemorrhage has been reported (56). Caution is needed in applying it to different populations or if proxies are used.

Stroke Adapted Sickness Impact Profile

The Stroke Adapted Sickness Impact Profile (SA-SIP30) is adapted from the 136-item SIP to measure quality of life after stroke (57). The scale eliminates the disadvantage of length in the SIP by excluding irrelevant and unreliable items. It is an evaluative instrument and covers body structures and functions, activities, and participation in the ICF.

Administration is via a structured interview with the patient. The SA-SIP30 includes 30 yes/no items in eight domains: body care and movement, ambulation, mobility,

household management, social interaction, communication, emotional behavior, and alertness behavior (57). The first four domains assess a physical dimension, and the other four assess a psychosocial dimension. Items are weighted for scoring with a lower score indicating a more desirable outcome. Time to complete the questionnaire is less than 30 minutes.

Validity was compared with the 136-item SIP ($\gamma_s = 0.96$), as well as with the BI ($\gamma_s = 0.50$) and the Rankin Scale ($\gamma_s = 0.68$) (57). The internal consistency was moderate to good ($\alpha > 0.68$) (58). No test–retest and inter-rater reliabilities were specifically reported for the SA-SIP30. Responsiveness was assessed on patients at 6 and 12 months and showed moderate effect sizes (effect size = 0.6) (58,59).

SA-SIP30 is a time-efficient quality-of-life measure for stroke patients. However, the scale has few psychosocial items and has a tendency to measure physical functioning rather than health-related quality of life (60). The scale has not been validated in patients with cognitive or language impairments or with proxy reporting.

Stroke Impact Scale

The SIS was developed from the perspective and input of stroke patients, caregivers, and health professionals with stroke expertise (61). It is a comprehensive evaluative instrument that tries to capture the heterogeneous consequences after a stroke. It covers all three conceptual domains in the ICF (Table 39.4).

It is a self-report measure administered through a structured interview with a patient and includes 59 items in 8 domains: strength, hand function, ADLs/IADLs, mobility, communication, emotion, memory and thinking, and social participation. SIS scoring uses a five-point Likert scale, with a higher score indicating higher function. Time to complete is approximately 15 to 20 minutes. If the patient has trouble following a three-step command because of cognitive impairment or aphasia, a proxy can be used to complete the interview (62). The instrument can also be administered via telephone interview and mail survey, which increases the feasibility for use to follow up functional recovery in a community setting (63).

Validity was assessed through correlations with established measures (61). The correlation coefficients are from 0.82 to 0.84 for items in the mobility and ADLs/IADLs domains. The correlation coefficients are from 0.44 to 0.58 for items in the memory and communication domains. The correlation coefficient is 0.70 for items in the participation domain. The internal consistencies of the eight domains range from 0.7 to 0.92 (ICCs) (61). Rasch analysis also demonstrated that most items in each domain are unidimensional, and five misfit items identified by the analysis were dropped from the latest version of SIS (62). The sensitivity

TABLE 39.4 Stroke Impact Scale (Version 3.0)

The purpose of this questionnaire is to evaluate how stroke has impacted your health and life. We want to know from your point of view how stroke has affected you. We will ask you questions about impairments and disabilities caused by your stroke, as well as how stroke has affected your quality of life. Finally, we will ask you to rate how much you think you have recovered from your stroke. These questions are about the physical problems that may have occurred as a result of your stroke.

1. IN THE PAST WEEK, HOW WOULD YOU RATE THE STRENGTH OF YOUR . . .	A LOT OF STRENGTH	QUITE A BIT OF STRENGTH	SOME STRENGTH	A LITTLE STRENGTH	NO STRENGTH AT ALL
a. Arm that was most affected by your stroke?	5	4	3	2	1
b. Grip of your hand that was most affected by your stroke?	5	4	3	2	1
c. Leg that was most affected by your stroke?	5	4	3	2	1
d. Foot/ankle that was most affected by your stroke?	5	4	3	2	1

These questions are about your memory and thinking.

2. IN THE PAST WEEK, HOW DIFFICULT WAS IT FOR YOU TO . . .	NOT DIFFICULT AT ALL	A LITTLE DIFFICULT	SOMEWHAT DIFFICULT	VERY DIFFICULT	EXTREMELY DIFFICULT
a. Remember things that people just told you?	5	4	3	2	1
b. Remember things that happened the day before?	5	4	3	2	1
c. Remember to do things (keep scheduled appointments or take medication)?	5	4	3	2	1
d. Remember the day of the week?	5	4	3	2	1
e. Concentrate?	5	4	3	2	1
f. Think quickly?	5	4	3	2	1
g. Solve everyday problems?	5	4	3	2	1

These questions are about how you feel, about changes in your mood, and about your ability to control your emotions since your stroke.

(*continued*)

TABLE 39.4 Stroke Impact Scale (Version 3.0) (*continued*)

3. IN THE PAST WEEK, HOW OFTEN DID YOU . . .	NONE OF THE TIME	A LITTLE OF THE TIME	SOME OF THE TIME	MOST OF THE TIME	ALL OF THE TIME
a. Feel sad?	5	4	3	2	1
b. Feel that there is nobody you are close to?	5	4	3	2	1
c. Feel that you are a burden to others?	5	4	3	2	1
d. Feel that you have nothing to look forward to?	5	4	3	2	1
e. Blame yourself for mistakes that you made?	5	4	3	2	1
f. Enjoy things as much as ever?	5	4	3	2	1
g. Feel quite nervous?	5	4	3	2	1
h. Feel that life is worth living?	5	4	3	2	1
i. Smile and laugh at least once a day?	5	4	3	2	1

The following questions are about your ability to communicate with other people, as well as your ability to understand what you read and what you hear in a conversation.

4. IN THE PAST WEEK, HOW DIFFICULT WAS IT TO . . .	NOT DIFFICULT AT ALL	A LITTLE DIFFICULT	SOMEWHAT DIFFICULT	VERY DIFFICULT	EXTREMELY DIFFICULT
a. Say the name of someone who was in front of you?	5	4	3	2	1
b. Understand what was being said to you in a conversation?	5	4	3	2	1
c. Reply to questions?	5	4	3	2	1
d. Correctly name objects?	5	4	3	2	1
e. Participate in a conversation with a group of people?	5	4	3	2	1
f. Have a conversation on the telephone?	5	4	3	2	1
g. Call another person on the telephone, including selecting the correct phone number and dialing?	5	4	3	2	1

The following questions ask about activities you might do during a typical day.

5. IN THE PAST TWO WEEKS, HOW DIFFICULT WAS IT TO . . .	NOT DIFFICULT AT ALL	A LITTLE DIFFICULT	SOMEWHAT DIFFICULT	VERY DIFFICULT	COULD NOT DO AT ALL
a. Cut your food with a knife and fork?	5	4	3	2	1
b. Dress the top part of your body?	5	4	3	2	1
c. Bathe yourself?	5	4	3	2	1
d. Clip your toenails?	5	4	3	2	1
e. Get to the toilet on time?	5	4	3	2	1
f. Control your bladder (not have an accident)?	5	4	3	2	1
g. Control your bowels (not have an accident)?	5	4	3	2	1
h. Do light household tasks/chores (dust, make a bed, take out garbage, and do the dishes)?	5	4	3	2	1
i. Go shopping?	5	4	3	2	1
j. Do heavy household chores (vacuum, laundry, or yard work)?	5	4	3	2	1

The following questions are about your ability to be mobile at home and in the community.

6. IN THE PAST TWO WEEKS, HOW DIFFICULT WAS IT TO . . .	NOT DIFFICULT AT ALL	A LITTLE DIFFICULT	SOMEWHAT DIFFICULT	VERY DIFFICULT	COULD NOT DO AT ALL
a. Climb one flight of stairs?	5	4	3	2	1
b. Climb several flights of stairs?	5	4	3	2	1
c. Get in and out of a car?	5	4	3	2	1

(*continued*)

TABLE 39.4 Stroke Impact Scale (Version 3.0) (*continued*)

7. IN THE PAST TWO WEEKS, HOW DIFFICULT WAS IT TO USE YOUR HAND THAT WAS MOST AFFECTED BY YOUR STROKE TO . . .	NOT DIFFICULT AT ALL	A LITTLE DIFFICULT	SOMEWHAT DIFFICULT	VERY DIFFICULT	COULD NOT DO AT ALL
a. Carry heavy objects (a bag of groceries)?	5	4	3	2	1
b. Turn a doorknob?	5	4	3	2	1
c. Open a can or jar?	5	4	3	2	1
d. Tie a shoelace?	5	4	3	2	1
e. Pick up a dime?	5	4	3	2	1

The following questions are about how stroke has affected your ability to participate in the activities that you usually do, things that are meaningful to you and help you to find purpose in life.

8. DURING THE PAST FOUR WEEKS, HOW MUCH OF THE TIME HAVE YOU BEEN LIMITED IN . . .	NONE OF THE TIME	A LITTLE OF THE TIME	SOME OF THE TIME	MOST OF THE TIME	ALL OF THE TIME
a. Your work (paid, voluntary, or other)	5	4	3	2	1
b. Your social activities?	5	4	3	2	1
c. Quiet recreation (crafts, reading)?	5	4	3	2	1
d. Active recreation (sports, outings, travel)?	5	4	3	2	1
e. Your role as a family member and/or friend?	5	4	3	2	1
f. Your participation in spiritual or religious activities?	5	4	3	2	1
g. Your ability to control your life as you wish?	5	4	3	2	1
h. Your ability to help others?	5	4	3	2	1

9. STROKE RECOVERY

On a scale of 0 to 100, with 100 representing full recovery and 0 representing no recovery, how much have you recovered from your stroke?

_____ 100 Full Recovery
_____ 90
_____ 80
_____ 70
_____ 60
_____ 50
_____ 40
_____ 30
_____ 20
_____ 10
_____.

to change of the SIS depends on the patient's stage of stroke severity. The scale has been shown to detect change from 1 to 3 months and 1 to 6 months for minor and moderate stroke ($t > 1.73$), and from 3 to 6 months for people with moderate stroke who have higher functioning ($t > 2.14$) (61).

The SIS has demonstrated good test–retest reliability through telephone interview (ICCs range from 0.75–0.95) and mail survey mode (ICCs range from 0.68–0.98) in a sample of veterans (63). SIS has demonstrated a moderate level of agreement between the proxy and patient (ICCs range from 0.50–0.83), especially in the domains that are related to physical function (strength, hand function, ADLs/IADLs, and mobility) (64). These four domains can be combined as one physical domain score. A short version (SIS-16), in which items are selected from these four domains, has demonstrated less ceiling effect for patients with mild stroke than the BI (65).

To our knowledge, SIS is the first stroke-specific instrument validated in a large and diverse group of stroke survivors, including ischemic and hemorrhagic stroke, from multiple clinical sites in the United States and Canada. Test content is comprehensive, and the scale can differentiate among patients with various functional states because of its broad range of item difficulty (62). The scale can be widely applied because it has been validated for use by mail or telephone and when

a proxy respondent is required. Another advantage is that the short version of SIS-16 can be an alternative to traditional ADL scales.

Research Frontiers: Future Directions for Functional Assessment

The Precision Versus Feasibility Dilemma

As the review of instruments in the earlier text demonstrates, we have greatly improved the breadth of functional status measurement used in the stroke field and the broader health care arena (66,67). However, even those functional outcome instruments with excellent breadth still have problems of inadequate depth of measurement (68). Thus, although we now have the capability to quantify many different functional dimensions, most instruments are relatively crude and imprecise, which particularly restricts their utility as evaluative instruments designed to monitor clinically relevant change in function in the clinic, quality improvement, and/or research. Those instruments that do provide more depth of measurement along with breadth are quite lengthy and are thus impractical to use in most settings and for most applications.

Contemporary test development techniques, relatively new to the health care arena, provide the field with innovative means of solving this measurement dilemma and open the way to more responsive instruments to monitor change in function. Although these newer measurement techniques have yet to be applied to the development of a stroke-specific functional status instrument, this is an active area of research.

Contemporary Methods to Improve Functional Assessment

We believe two contemporary measurement techniques—item response theory (IRT) and computer-adaptive testing (CAT)—have the ability to overcome many limitations in traditional functional status instruments and have the potential to transform how functional assessment is done within rehabilitation. Although these advances have been used in educational testing for many decades, they have only begun to be applied to functional outcome assessment in rehabilitation and other arenas of health care in the past decade.

Item Response Theory Techniques

IRT methods examine the associations between individuals' response to a series of items designed to measure a specific concept such as functional status (69). Data collected from samples of rehabilitation patients are fit statistically to an underlying IRT model that best explains the covariance among item responses (70,71). IRT measurement models are a class of statistical procedures used to develop measurement scales. The measurement scales are comprised of items with a known relationship between item responses and positions on an underlying functional domain, called an *item characteristic curve*. The form of the relationships is typically nonlinear. Using this approach, probabilities of patients scoring a particular response on an item at various functional ability levels can be modeled. Persons with more functional ability have higher probabilities of responding positively to functional items than persons with lower functional abilities. These probability estimates are used to determine the individual's most likely position along the functional dimension. When assumptions of a particular IRT model are met, estimates of a person's functional ability do not strictly depend on a particular fixed set of items. This scaling feature allows one to compare persons along a functional outcome dimension even if they have not completed the identical set of functional items. Because items and functional outcome scores are defined on the same scale, items can be optimally selected to provide good estimates of each domain of function at any level of the scale. This feature of IRT creates important flexibility in administering tests in a dynamic and tailored approach for each individual. See Hambleton (1989) for a more detailed explanation of IRT methods (72).

IRT is currently being applied in rehabilitation to develop new measures, improve existing measures, investigate group differences in item and scale functioning, equate different instruments, and, as we highlight, develop efficient test applications, such as CATs.

To apply IRT to functional outcome assessment, an appropriate item pool of functional tasks or activities must be assembled. An *item pool* is a collection of outcome items that represent a range of levels of a particular outcome domain. Item pools used in IRT analyses are developed by equating outcome items from different sources so they can be meaningfully compared on a common underlying scale. IRT methods open the door to understanding the linkages among items used to assess a common functional outcome domain and, in this way, serve as the psychometric foundation underlying CAT (73–75).

The quality of life in neurological disorders instrument, known as Neuro-QOL, was recently created in a major initiative sponsored by the National Institute of Neurological Disorders and Stroke. This is the first comprehensive measurement system for health-related quality of life (HRQoL) that has focused on people with neurological disorders and uses modern IRT-based methods to create CATs and short forms that are brief enough to be used in a variety of settings (76). Although this instrument is not stroke-specific, in that it was developed for people who have one of many major neurological conditions, throughout the development process the input of stroke expert clinicians and stroke survivors and their caregivers was obtained, and the instrument has been tested in people with stroke. The Neuro-QOL has developed 14 generic item banks and 8 targeted scales to assess HRQoL in 5 adult and 2 pediatric conditions. The development of the Neuro-QOL is ongoing, and the content of the instrument is expected to evolve to include more health domains. The instrument content is freely available at the Neuro-QOL website: http://www.neuroqol.org.

CAT Methodology

CAT programs use a simple form of artificial intelligence that selects questions tailored to the test-taker, and thereby shortens or lengthens the test to achieve the level of precision desired

by a user. Functional status CAT applications rely on extensive item pools constructed for each outcome area. They contain items that consistently scale along each functional domain from low to high proficiency and include rules guiding starting, stopping, and scoring procedures. CAT methodology uses a computer interface for the patient/clinician report that is tailored to a patient's unique functional ability level. The basic notion of a CAT test is to mimic what an experienced clinician does. A clinician learns most when he or she directs questions at the patient's approximate level of proficiency. Administering functional items that represent tasks that are either too easy or too hard for the patient provides little information. In contrast to traditional, fixed-form functional tests that ask the same questions of everyone, regardless of how the respondent answers, CAT instruments, like a skilled clinician, tailor their assessment by asking only the most informative questions based on a person's response to previous questions.

A CAT is programmed to first present an item from the midrange of an IRT-defined item pool and then direct subsequent functional items to the level based on the patient's (or clinician's) previous responses without asking unnecessary questions. The selection of an item in the midrange is arbitrary, and the CAT can be set to select an initial item based on other information entered about the patient, such as age, diagnosis, or severity of his or her condition. By having comprehensive item banks available in each functional outcome domain of interest, the selection of additional items after the initial one can be based on responses to the previous items. This allows for fewer items to be administered while gaining precise information regarding an individual's placement along an outcome continuum.

We will illustrate how the CAT works using a functional activity scale developed in our research group (77). In this functional activity scale, we assume that the midpoint of the scale is 50, and this serves as the initial (default) score estimate prior to CAT administration. For this example, we used data collected in a prospective rehabilitation outcome study (78). We set the CAT precision stopping rule as a 95% CI less than 3.0. The case is an individual who suffered a stroke and is now receiving rehabilitation therapy in a community-based outpatient center.

The initial item administered is, "How much difficulty do you have coming to sit at the side of a bed?" A response of "a little difficulty" yields a score estimate of 38.2 with a large confidence interval.

A second question is administered, based on the estimate from the first response, "How much difficulty do you have carrying a suitcase?" The person responds, "No difficulty." A new score estimate is then calculated (44.4 ± 9.2), and the CAT program checks to see if the stop rule has been satisfied. Because the stop rule in this case is a confidence interval of less than 5, a third item is administered.

To the third item, "How much difficulty do you have running to catch a bus?" the person responds, "A little difficulty." A new score estimate is calculated (44 ± 6). The stop rule has not yet been satisfied, so a fourth item is administered.

The item, "How much difficulty do you have doing heavy housework?," is given to the person, and the answer is "a little difficulty," with a new score estimate of 44.2 ± 3. Because this meets the stop rule, no additional items are administered, and a final score estimate based on four items is 44.2 with a confidence interval of ±3. In this case, the four items administered were able to reproduce closely the score of 43.8 that was obtained by the administration of all 101 items in the full item pool. The number of items administered can be increased to achieve the desired level of precision.

Though intuitively appealing on its surface, to be truly innovative and useful in rehabilitation, functional status CATs must be shown to meet several standards for acceptability for clinical and research applications. These include:

1. Acceptable score accuracy in comparison to the entire item pool
2. Adequate score precision for group and individual assessments
3. Sufficient content breadth for application across a wide array of care settings
4. Adequate responsiveness for monitoring clinically relevant change
5. Feasibility with respect to user burden and administration cost for widespread use. This is an active area of research investigation within rehabilitation.

SUMMARY

Functional assessment is now an essential part of stroke research and clinical practice. The selection of the most appropriate instrument is a complex process that requires careful consideration. Health professionals, researchers, and others who utilize functional assessments must carefully evaluate the existing instruments to determine which one is most appropriate to meet their needs. The field of functional assessment has progressed so that there are now many stroke-specific functional assessments to choose from (Table 39.5). Potential users should consider the scope of the instrument, the purpose for which it has been developed, the administration and scaling methods used, and the psychometric properties of the instrument, as well as its feasibility in a particular context.

Even though the breadth of content in functional status instruments used in the stroke field and the broader health care arena has improved in recent decades, existing instruments still have problems with the balance between feasibility and breadth as well as depth of coverage. Fortunately, new methodologies such as IRT and CAT provide a way to overcome these problems. These methods have already been applied to the Neuro-QOL instrument, which has been developed for people with neurological problems and validated in people with stroke. It is anticipated that these methods will be applied to more stroke-specific measures in the future and yield further improvements in our ability to accurately and efficiently measure functional status in a wide range of people following a stroke.

Predictive Factors for Recovery

Robert W. Teasell and Norhayati Hussein

Stroke often results in significant neurologic deficits leading to loss of function or independence, the consequences of which can be devastating to both patients and families. Fortunately, patients demonstrate significant recovery following stroke, although the degree to which individuals recover after stroke is highly variable. Most stroke recovery occurs during the first three to six months following a stroke (1–3). The course of recovery decelerates as a function of time and is generally a predictable phenomenon.

Even though a number of processes have been identified as contributing to neurologic recovery following a stroke, the role of each is not completely understood. Recovery from stroke has long been attributed to the resolution of edema and return of circulation within the ischemic penumbra, prompting skeptics to speculate that rehabilitation has limited influence on stroke recovery (4). However, it is now well recognized that recovery can be a prolonged process, extending well past the resolution period of acute physiological and structural changes occurring as a result of the stroke. Results from animal and clinical studies have shown that the cerebral cortex undergoes functional and structural reorganization for weeks and months following a stroke, with compensatory changes extending up to six months in more severe strokes (5). Physiological factors that account for stroke recovery include resolution of poststroke edema, reperfusion of the ischemic penumbra, resolution of diaschisis, and cortical reorganization in response to learning and rehabilitation training.

NEUROPHYSIOLOGICAL FACTORS IN STROKE RECOVERY

Resolution of Poststroke Edema

In the early period following a stroke, edema surrounding the ischemic or infarcted area may disrupt local neuronal functioning. A portion of the early recovery following a stroke may be attributable to resolution of edema (6) (Figure 40.1). As the edema subsides, neurons that have become inactive but remain structurally intact begin to function again. This process takes place relatively early in the course of recovery; however, it can extend for as long as eight weeks after stroke (7). Greater edema is associated with cerebral hemorrhage, which may take longer to subside and may partially explain why patients with hemorrhagic strokes tend to enter rehabilitation later than those with ischemic strokes and yet achieve similar outcomes by the time of discharge (8).

Reperfusion of the Ischemic Penumbra

A focal ischemic lesion of the brain consists of a core area of infarcted tissue, caused by loss of arterial perfusion, that is surrounded by a region of reduced blood flow or perfusion, known as the *ischemic penumbra* (9,10) (Figure 40.2). The penumbra is at risk for infarction, but is still salvageable. Reperfusion of this area early on following a stroke permits ischemic and nonfunctioning, but still viable, neurons to regain function with subsequent clinical recovery.

Resolution of Diaschisis

Diaschisis is a reversible state of low reactivity or depressed function as a consequence of a sudden interruption or loss of excitation in regions of the brain remote from, but connected to, the site of cerebral damage. Nudo et al. (11) noted that diaschisis occurs early after injury and is an inhibition or suppression of the surrounding cortex or distant areas of cortex with a connection to the damaged area (11). This reversibility may be partially a consequence of resolution of edema, which may account for a portion of the spontaneous recovery. Neuronal function may return following the resolution of diaschisis, particularly as the affected area of the brain demonstrates recovery and connections are restored.

Cortical Reorganization

Rehabilitation helps to facilitate cortical reorganization, an important contributor to the recovery process and one that is influenced by rehabilitation. Neuroplasticity following a

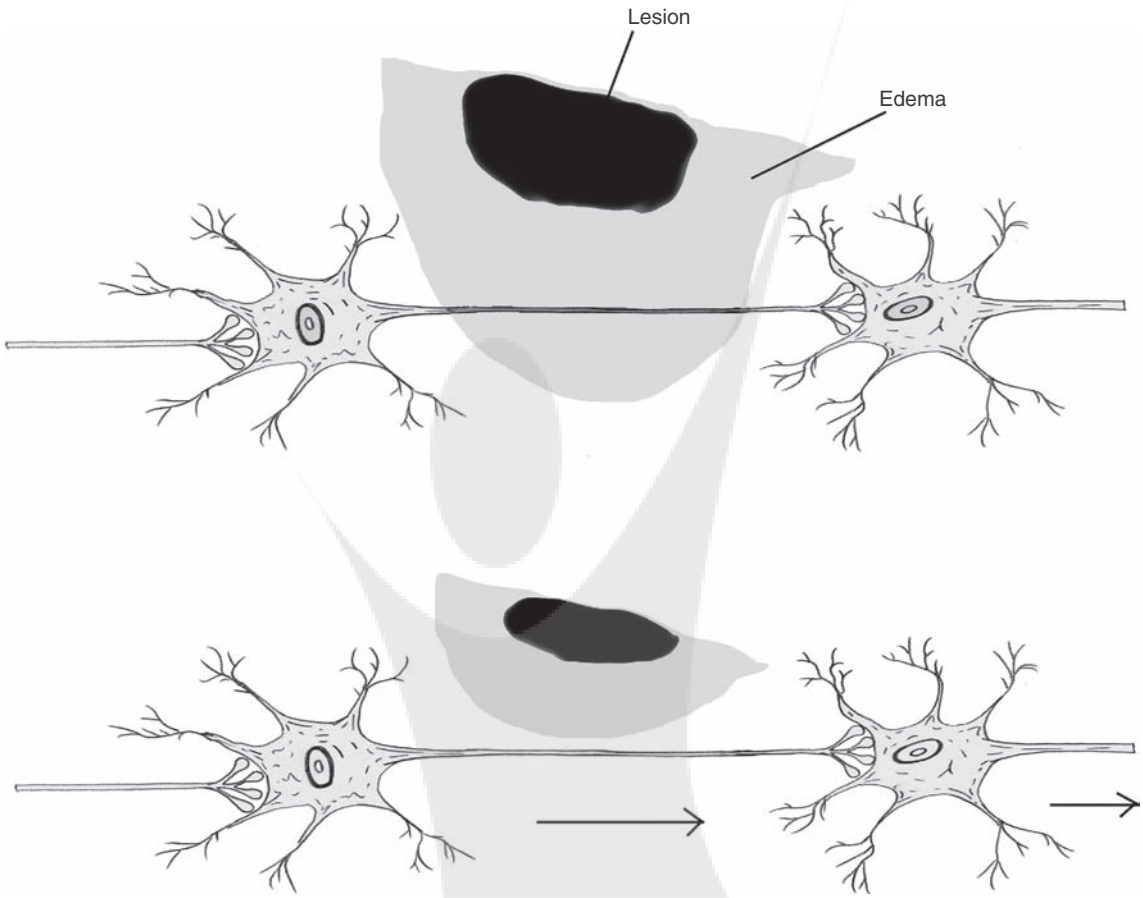

FIGURE 40.1 Resolution of poststroke edema.

stroke, after damage to the motor cortex, is based on three main concepts (12):

1. In normal (nonstroke) brains, acquisition of skilled movements is associated with predictable functional changes within the motor cortex.
2. Injury to the motor cortex from stroke results in functional changes in the remaining cortical tissue.
3. After a cortical stroke, these two observations interact so that reacquisition of motor skills is associated with functional neurologic reorganization occurring in the undamaged cortex (12).

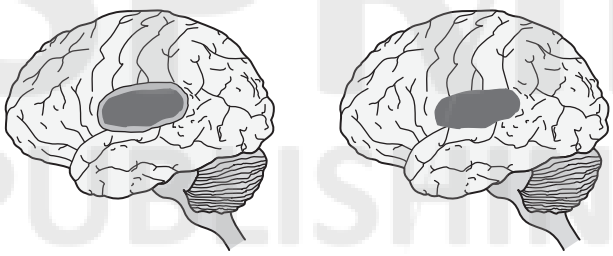

FIGURE 40.2 Reperfusion of ischemic penumbra.

Neuroplasticity, or cortical reorganization, is an important underlying rationale for poststroke rehabilitation, although the degree to which it accounts for functional recovery continues to be a source of debate.

IMPORTANCE OF PREDICTING STROKE RECOVERY

Accurate prediction of stroke recovery, or its potential, will greatly assist in the planning of rehabilitation interventions. Prediction and prognostication allow the setting of practical rehabilitation goals as well as appropriate discharge planning. Accurate prognostication will assist in providing accurate planning information to patients and caregivers, thus allowing realistic adjustments to recovery expectations. Accurate prognostication also leads to appropriate triaging, ensuring that suitable patients receive timely and appropriate rehabilitation. With accurate triaging, functional goals are more likely to be met, which in turn will improve the overall efficiency and effectiveness of the rehabilitation process. This is especially important given the increasing necessity to maximize limited health care resources.

Stroke recovery is influenced by a myriad of factors. Predictors reported in the literature include stroke

severity, age, gender, unilateral spatial neglect (USN), depression, cognitive impairment, dysphasia and bladder incontinence (13–15). It is worth noting that the initial severity of stroke and age of the stroke patient are the two most consistently reported and strongest predictive factors of stroke recovery (Table 40.1).

For the purpose of discussion, predictive factors for stroke recovery can be divided into intrinsic and extrinsic factors. Intrinsic factors are specific stroke survivors' attributes (age, gender, comorbidities) and the characteristics of the stroke (size, site, laterality, first-ever versus recurrent, stroke type, and associated impairment(s)). Extrinsic factors that help predict the course of stroke recovery largely revolve around the provision of rehabilitation services or social supports. This encompasses the concepts of time from stroke onset to the initiation of rehabilitation, therapy intensity, and task specificity as well as the setting of rehabilitation delivery (e.g., stroke units). In addition, the external social support that an individual receives (e.g., family support) may also influence recovery.

INTRINSIC PREDICTIVE FACTORS

Patient Characteristics

Age

Animal Studies. The impact of age on stroke and recovery in animals is not entirely clear. Shapira et al. (16) examined the effects of age on the development of ischemic injury in rats and discovered that young rats were affected more by the stroke than old rats, with more pronounced neurologic impairments and poorer performance in a water maze task. However, the duration of motor impairment after brain lesion appears to increase with age (16,17). The regenerative response of neurons and glial cells, although largely preserved with age, appears to be delayed or occurs at a diminished rate the older the animal (18,19). Reactive neuronal synaptogenesis declines, sprouting responses are less robust, and synaptic replacement rates diminish as age increases (19,20).

Clinical Studies. In humans, age has long been thought to limit poststroke neurologic recovery. Evidence suggests that, compared with older patients, younger patients recover at a faster rate and more completely (21,22). When compared with older stroke survivors, younger stroke survivors—defined as persons less than 65 years old—tend to have a better chance of regaining independence in activities of daily living (ADLs) and returning home at discharge (23). Herman et al. (24) reported that, when compared to those stroke survivors over 85 years of age, odds of successful discharge home, although dependent on many factors other than stroke recovery, were 18 times greater if the stroke survivor was under 65 (24). The effect of age on recovery was demonstrated even within a cohort of younger stroke survivors. Bogousslavsky and Pierre (25) reported that, following first-ever ischemic stroke, the prognosis of stroke survivors between the ages of 16 to 30 was better than that of stroke survivors aged 31 to 45 years. Nakayama et al. (26) reported that although older stroke survivors achieved the same degree of neurologic recovery as younger stroke survivors, the functional gains were lower. It was suggested that elderly stroke survivors had fewer compensatory abilities than younger stroke survivors with comparable neurologic impairments (26).

In a study on 43,163 subjects prospectively enrolled in the Austrian Stroke Unit Registry, Knoflach et al. (27) demonstrated that increasing age is a highly significant negative predictor of good functional outcome three months after ischemic stroke, independent of stroke severity, etiology, sex, risk factors, and stroke complications. The regression-adjusted probability of good outcome was highest in the age group 18 to 35 years and gradually declined by 3.1% to 4.2% per decade until age 75, with a steep drop thereafter (27).

Even though younger age has been associated with improved recovery, the results from several studies challenge the concept that age necessarily limits recovery. Kugler et al. (28) studied the effect of patient age on early stroke recovery and found that relative improvement decreased significantly with increasing age. Stroke survivors younger than 55 years of age achieved 67% of the maximum possible improvement, compared with only 50% for patients above 55 years (28). They also found that age had a significant, but relatively small, impact on the speed of recovery; younger stroke survivors demonstrated slightly faster functional recovery. Bagg et al. (29) found that even though age was a significant predictor of motor and total functional independence measure (FIM) scores at discharge, age alone accounted for only 3% of the variance in a multivariable model (30) and at most 1.3% of the variation in functional outcome after adjustments for other factors including admission FIM. The authors concluded that although age had a significant impact, it was a

poor predictor of individual functional recovery and could not be regarded as a limiting factor in the rehabilitation of stroke survivors (29).

Age appears to affect functional recovery more for severe strokes. Younger stroke survivors fare significantly better than older stroke survivors if they have low functional status upon admission, but not necessarily if both belong to a high-functioning group (31). Using the admission functional independence measure (AFIM) score as a proxy for stroke severity, Black-Schaffer and Winston (31) examined the relationship of advancing age to functional outcome, which included FIM gain, length of stay (LOS), LOS efficiency (defined as change in FIM/day of hospital stay), and the percentage discharged home. To control for the influence of AFIM score, the samples were divided into three groups: AFIM less than 40, AFIM 40–80, and AFIM greater than 80. Analysis was made based on 5 age groups: less than 55, 55–64, 65–74, 75–84, and more than 85 years old. Overall analysis showed that increasing age was related to decreasing total FIM change, LOS efficiency, and the likelihood of home discharge. When results were analyzed based on the AFIM groups, striking results were seen in the lowest functional group (AFIM <40). In this group, FIM gain, LOS efficiency, and rate of home discharge were significantly greatest in the youngest age group and declined as age increased. In those with AFIM less than 40, the oldest group, aged more than 85, improved at only half the rate (LOS efficiency = 0.44) of those aged less than 55 (LOS efficiency = 0.85). In the less functionally impaired group (AFIM >80), there was no relationship between increasing age and any outcome variables. Results were mixed in the moderately functional group (AFIM 40–80). The authors concluded that for subjects with severe strokes as measured by lower functional admission scores, younger stroke survivors generally do better than older stroke survivors. For patients at a high functional level, age does not affect the degree of improvement (31).

Gender

An earlier review by Jongbloed reported that gender was not a predictor of stroke recovery (13). However, in later studies, gender has been reported to have an impact on functional recovery after stroke. Compared to men, women stroke survivors have lower functional recovery at three months after discharge from rehabilitation (32,33) and at six months after stroke (34,35). Data from the Registry of the Canadian Stroke Network showed that at 6 months, when compared to men, women experienced a less favorable outcome as measured by the Stroke Impact Scale-16; they had longer lengths of stay and higher rates of institutional care (34). Data from China's National Stroke Registry also yielded similar findings, as researchers reporting that women demonstrated a significantly higher dependency rate at 12 months when compared to men (36).

A combined hospital-based registry from a number of centers in seven European countries also highlighted the role of gender in stroke recovery (32). After controlling for baseline and clinical factors, female sex proved to be a significant predictor of disability and handicap at three months after stroke (32). Similar findings were obtained from the Michigan state stroke registry, which reported that female stroke survivors had lower functional recovery and poorer quality of life three months after discharge; differences were not explained by the females' greater age of onset or other demographic and clinical characteristics (33).

Comorbidities

Greater medical complexity contributes to the severity of functional impairment following stroke and may impede recovery. Comorbidities may affect the outcome of stroke rehabilitation through a number of mechanisms, either by affecting response or participation in rehabilitation (36). In general, the presence of multiple comorbid diagnoses or increased comorbid burden is associated with decreased functional status, both at admission to and discharge from rehabilitation (37–39). Individuals with more than one comorbid diagnosis may experience less functional gain and more incomplete recovery than individuals with no comorbid burden. In a study of 1,020 adult rehabilitation patients, Stineman and colleagues (40) determined that the odds of full functional recovery decreased as the number of comorbid medical conditions increased (40). Similarly, within populations of individuals with stroke, increasing comorbid burden has been associated with reduced gain in functional ability over the course of rehabilitation as well as decreased rehabilitation efficiency (14,41). Furthermore, among community-dwelling stroke survivors, comorbid burden has been identified as a significant predictor of functional outcome (40) and has been associated with an increased risk of physical decline and new problems in ADLs (42).

Comorbidity indexes have been used in stroke outcome studies to adjust for patients' comorbid conditions. The Charlson Comorbidity Index, adjusted for ischemic stroke, has been validated for use in stroke outcome studies (43,44). Studies utilizing the Charlson Comorbidity Index have shown that higher comorbidities are associated with poorer stroke outcomes (43,45–47). Logistic regression adjusting for initial stroke severity showed that those patients with a high Charlson Comorbidity Index had a 36% increased chance of having a poor outcome at discharge, with every 1-point increase in the index resulting in a 15% increase in the odds of a poor outcome (43). Multivariate analyses have found that coronary heart disease and diabetes (45,46), as well as atrial fibrillation (46), were associated with poorer outcome as reflected by modified Rankin Score at three to four months after stroke. In a long-term population-based study, diabetes mellitus was also noted to be a significant negative predictor of functional outcome over a course of five years (48).

There is an association between age and comorbid burden such that elderly individuals tend to experience an increasing number of comorbidities (38,39). Hence, the presence of multiple comorbidities is not uncommon in the stroke population (42,49). Rigler et al. (42) reported that, in a sample of community-dwelling stroke survivors, only 6% were free from comorbid conditions, whereas more than 40% had three or more comorbid conditions (42). Even though comorbid burden may be an important modifier in the prediction

of future functional status, it appears not to be as important as either age or initial/baseline functional status (42,49).

Stroke Characteristics

Lesion Size and Site

The cerebral cortex undergoes functional and structural reorganization for weeks and months following injury, with compensatory changes extending up to six months in more severe strokes (8). Animals with induced small strokes experienced functional and structural recovery occurring spontaneously for weeks to months after stroke (50,51). Underlying neural changes appear to be related to surrounding intact brain regions taking over the lost function. Animals with larger lesions show much less return of function, and the function that returns may take weeks or months to stabilize (52,53). Compensatory movements may play an important role here, with activation and reorganization occurring in more distant cortical areas (53). Kolb suggested that the differences between recovery from small and larger strokes are related to the mechanisms of neural recovery (53). For smaller strokes, the mode of recovery is most likely related to changes in the remaining intact motor cortex, whereas for larger lesions, changes in related, but more distant, cortical regions facilitate compensatory behavior that improves with practice (53).

Lesion volume is believed to be an important parameter reflecting the extent of the pathological condition, and thus may serve as a predictor of the severity of neurological impairments such as paresis and functional outcomes such as ADL dependency after a stroke (55). Lesion volume, whether assessed during initial hours of symptom onset by diffusion-weighted imaging or assessed at a later time point by T2 or FLAIR, was noted to be an important predictor of outcome after ischemic stroke (56).

However, different stroke locations lead to different deficits and may confound the relationship between lesion volume and outcome (55–57). Even small lesions, particularly within the subcortical white matter and brainstem, may produce a disproportionate degree of impairment (56,57). Deep white-matter lesions involving major tracts can produce greater clinical deficits than superficial cortical lesions with a comparable volume. The site of stroke must be considered, as it will impact the outcome regardless of size (56,57).

Laterality of Lesion

Right-sided hemispheric strokes have been associated with a poorer functional outcome, as determined by the Barthel index (BI), when compared to a left-sided stroke (48). Lesion site has also been shown to influence FIM change: patients with bilateral and right-sided strokes do worse than patients with left-sided strokes (14). Right hemispheric stroke survivors also had lower FIM efficiency scores than left-sided stroke survivors (14). Right-sided lesions are associated with potentially more disabling cognitive disorders, such as USN and visuospatial perceptual disorders, which likely accounts for the difference (14).

Occurrence: First-Ever Stroke Versus Recurrent Stroke

A previous stroke has been identified as a significant adverse predictor of functional recovery in patients with stroke (13,58). Subjects with ischemic stroke enrolled in the Management of Atherothrombosis with Clopidogrel in High Risk Patients (MATCH) study underwent a long-term prospective assessment of modified Rankin Scale (mRS) score at baseline, 1, 3, 6, 12, and 18 months. The authors studied the evolution of the proportion of stroke survivors switching from functionally dependent (defined as mRS score 3–5) to functionally independent (defined as mRS score of 0–2). The rate of functional recovery was greatest within the first 6 months but continued in some patients for up to 18 months. At 18 months, stroke survivors who had a first-ever ischemic stroke demonstrated a greater rate of recovery compared to those with a previous history of ischemic stroke (58).

The Copenhagen Stroke Study on stroke recurrence showed that the mortality rate for subjects with recurrent stroke was almost double that compared to subjects with first-ever stroke (59). Upon completion of rehabilitation, the Scandinavian Stroke Scale (SSS) was administered to reflect neurologic recovery, whereas the BI was used to reflect functional recovery. Among the stroke survivors, both neurologic and functional outcomes and the speed of recovery were almost similar (59). When compared to stroke survivors with ipsilateral recurrence, stroke survivors with recurrence contralateral to their first stroke had significantly more severe functional disability after completion of rehabilitation despite having comparable neurologic recovery. The discrepancy in functional recovery implies that there is decreased ability to compensate using the contralateral hemisphere in stroke survivors with contralateral stroke recurrence (59).

Stroke Type

Approximately 10% to 15% of all strokes are the result of an intracerebral hemorrhage (ICH) (60,61). Paolucci et al. (60) matched hemorrhagic and ischemic stroke patients on the basis of initial stroke severity (same Canadian Neurological Scale [CNS]), baseline disability (same BI) score, age, sex, and time interval between stroke onset to rehabilitation admission. A trend toward better BI at discharge was observed in hemorrhagic compared with ischemic etiology. In addition, there was a bigger proportion of high responders of BI (defined as patients whose BI score was higher than the mean BI score) in the hemorrhagic compared to the ischemic group. The probability of achieving higher therapeutic response on the BI was 2.5 times more in the hemorrhagic compared to the ischemic group (60). The authors attributed these greater gains in hemorrhagic strokes to better neurological recovery associated with resolving brain compression (60).

Kelly et al. (61) demonstrated that stroke survivors with ICH made significant greater recovery than those with cerebral infarction. Upon admission to rehabilitation, total

admission FIM was, on average, lower in stroke survivors with ICH when compared to those with ischemic stroke. However, there was no significant difference in total discharge FIM score between the two groups (61). During rehabilitation stay, stroke survivors with ICH significantly gained more FIM points compared to those with ischemic stroke. When stratified by initial severity, stroke survivors with ICH who had the most severe strokes had greater functional improvement than those with cerebral infarction of similar severity (61). Katrak et al. (62) reported on a prospectively maintained database of all stroke survivors admitted to a rehabilitation unit during a 9.5-year period; 718 consecutive stroke admissions (589 ischemic, 129 hemorrhagic strokes) were included in the study. Outcome measures (FIM gain, FIM efficiency, Motor Assessment Scale change), gait velocity, and discharge destination were compared between the two groups. Stroke survivors with ICH were more severely disabled on admission but by discharge there was no difference in the mean FIM scores between groups. However, the ICH group made significantly greater gains on their FIM scores, leading to a higher FIM efficiency in hemorrhagic compared to ischemic strokes. After adjusting for admission FIM, LOS, age, and days from stroke onset to rehabilitation admission, it was found that stroke survivors with ICH obtained a better functional outcome than those with ischemic stroke (62).

Jørgensen et al. (63) found that stroke type (ischemic vs. hemorrhagic) did not influence mortality, the time course of neurologic recovery, neurologic outcome, or the time course of recovery from disability (63). Poorer outcome among stroke survivors with ICH was found to be a consequence of greater initial stroke severity (63).

Stroke Severity

The most important predictor of stroke recovery is initial stroke severity as determined by clinically based scales. As a general rule, the severity of the initial deficit following stroke is inversely proportional to the prognosis for recovery (2,3). Numerous scales have been used to denote the degree of stroke severity, both for global and for impairment-specific contexts. Examples of scales commonly used to reflect global severity are the SSS (2,3,50), National Institute of Health Stroke Scale (NIHSS) (48), CNS (33), and admission FIM (14). Examples of impairment-specific scales used are the Motricity Index and the Fugl-Meyer Assessment for sensorimotor impairment after stroke (64,65).

Global Stroke Severity

In the Copenhagen Stroke Study, stroke severity was reported using the Scandinavian Neurological Stroke Scale (SSS), which evaluates the degree of neurological impairment. The time to maximal neurological recovery was achieved sooner among those who had a milder severity stroke (66): 95% of stroke survivors with mild strokes reached their maximal neurologic recovery within 6 weeks. For stroke survivors with moderate, severe, and very severe strokes, 95% of the group had achieved their maximal recovery within 10, 13, and 15 weeks respectively (66). Maximal neurologic recovery occurred, on average, two weeks earlier than marginal functional recovery (2,3). Among surviving stroke survivors, the best neurologic recovery occurred within 4.5 weeks in 80% of the stroke survivors, whereas best ADL function was achieved by 6 weeks. For 95% of the patients, best neurologic recovery was reached by 11 weeks and best ADL function within 12.5 weeks (2,3). The specific timeline for neurologic and functional disability recovery is presented in Tables 40.2 and 40.3.

Subscales of global severity scores have also been reported to be strong outcome predictors. A systematic review by Veerbek et al. (67) found that the severity of neurological deficits based on upper-limb subscores of the NIHSS and CNS were found to be a strong predictor of better ADL outcome beyond three months after stroke (67). Based on the motor subscale of SSS, Jørgensen et al. (2) reported that the best walking function was reached within 4 weeks for stroke survivors with mild paresis of the affected lower extremity, 6 weeks for those with moderate paresis, and 11 weeks for those with severe paralysis (2).

Impairment-Specific Severity

Motor Impairment. Motor impairment has been identified as a predictor of discharge outcome including mobility and ADLs (41,68,69). Recovery of the upper limb is a major concern for many stroke survivors. A systematic review and

meta-analysis by Coupar et al. (70) demonstrated that the most important predictive factor of upper-limb recovery following stroke was the initial severity of upper-limb motor impairment and upper-limb function. In addition, motor- and somatosensory-evoked potentials (neurophysiologic measures of corticospinal and spinothalamic tracts) were also consistently identified as being strongly associated with upper-limb recovery following stroke (70). Muscle strength of the paretic upper limb, including shoulder abduction, elbow flexion, and finger extension as measured by the Motricity Index, as well as two-point discrimination, were noted to be the best predictors of dextrous hand function recovery at six months (71).

In a prospective study by Smania et al. (72), three outcome measures (Nine Hole Peg Test, Fugl-Meyer Arm subtest, Motricity Index) evaluating upper-limb function were assessed at 7, 14, 30, 90, and 180 days after stroke. Four potential predictors of recovery, which included active finger extension, shoulder abduction, shoulder shrug, and hand movement scale, were assessed. Active finger extension was found to be a strong predictor of short-, medium-, and long-term poststroke recovery (72). Houwink et al. (73) found that patients with minimal shoulder abduction and upper motor control of the paretic limb upon admission to rehabilitation had a reasonably good chance of regaining some hand capacity, whereas patients without proximal arm control had a poor prognosis for regaining hand capacity (73).

Recent studies have focused on determining if outcome after stroke can be accurately predicted in the early phase, while a patient is still in a hospital acute stroke unit, using clinical parameters (63,64). As part of the early prediction of outcome after stroke (EPOS) study, Nijland et al. (63) attempted to determine if upper limb function using the Arm Reach Action Test (ARAT) at 6 months after stroke can be predicted using clinical parameters within 72 hours after stroke onset. The results demonstrated that stroke survivors with some finger extension and shoulder abduction on day 2 after stroke onset had a 98% probability of achieving some degree of dexterity at 6 months, in contrast to only 25% of those who did not show similar voluntary motor control. In addition, 60% of stroke survivors with finger extension within 72 hours had regained full recovery of upper-limb function according to ARAT score at 6 months. This suggests that the functional recovery of the hemiplegic arm at 6 months can be predicted within 72 hours after stroke onset using 2 simple bedside examinations, namely active finger extension and shoulder abduction (63).

In the EPOS study, Verbeek et al. (64) attempted to predict the likelihood of regaining independent gait in nonambulant stroke survivors within 72 hours of stroke onset. They found that nonambulant patients who regained sitting balance and some voluntary movement of the hip, knee, and/or ankle within the first 72 hours after stroke had about a 98% chance of regaining independent gait within 6 months (64). In contrast, those who were unable to sit independently for 30 seconds and could not contract the paretic lower limb within the first 72 hours after stroke had a 27% probability of achieving independent gait (64).

Trunk balance and severity of motor impairment have also been identified as significant predictors of ambulatory outcome (74,75). Verheyden et al. (75) examined the predictive ability of the trunk impairment scale (TIS) and its static sitting balance, dynamic sitting balance, and coordination subscales to predict the Barthel Score at six months after stroke. Participants were first assessed upon admission to rehabilitation (median time since stroke onset of 20 days) and at 6 months. The best predictors of BI score at six months were the total TIS and static sitting balance subscale score on admission (75).

Mood Disorders. Poststroke depression (PSD) is a frequent consequence of stroke, with reported frequency ranging from 20% to 65%, depending on the selection of stroke survivors and time elapsed after stroke. In general, depression identified acutely or within the first three months following stroke has an adverse effect on both functional status and physical recovery in both the short (76–78) and long term (76,79,80). Pohjaasvaara et al. (76) evaluated the effect of depression at 3 months on functional outcome at 15 months following stroke. Results showed that stroke survivors with depression (Beck's Depression Inventory score ≥10) and major depression (*DSM-III-R* major depressive disorders, bipolar disorders with depressed episodes, organic depressive disorder and *DSM-IV* dementia with depressive mood) demonstrated

higher dependence on the BI score and poorer functional outcome (Rankin Scale > II) at 15 months after stroke when compared to nondepressed stroke survivors (76). In a logistic regression analysis, depression at 3 months correlated with poor functional outcome (Rankin Scale > II) at 15 months, with an odds ratio of 2.5 (76). In this study, depression was an independent and powerful predictor of poor long-term functional outcome after stroke (76).

However, the presence of depression does not preclude recovery, and over the course of rehabilitation, stroke survivors with depression may experience significant improvements, although functional ability may remain at a lower level despite rehabilitation interventions (81,82). Physical impairment and poststroke depression appear to interact with each other, and each influences the recovery of the other. Reports on the contribution of physical impairments to the development of poststroke depression vary from a low 5% to 15% (83) to a high of 48% (84). Van de Port et al. (85) published the results of a prospective cohort study, which demonstrated that mobility decline was experienced by 21% of participants between 1 and 3 years after stroke (85). Significant predictors of this decline in mobility status were level of activity, cognitive problems, fatigue, and depression. Given that the relationship between depression and physical impairment may be reciprocal, depression may contribute to deteriorations in mobility that may, in turn, contribute to increased feelings of depression. Because depression is a treatable condition that affects both function and functional recovery, it should be taken into account in the evaluation and treatment of all stroke survivors (77). Early recognition and treatment of depression may optimize rehabilitation potential and reduce significant human and financial costs associated with poststroke functional impairment (77).

Anxiety also can occur following a stroke. Follow-up findings of the Collaborative Evaluation of Rehabilitation in Stroke across Europe (CERISE) project showed that approximately 40% of the subjects initially classified as being anxious or depressed remained so at 6-month follow-up. The severity of anxiety and depression increased significantly between six months and five years (86). Hama et al. (87,88) highlighted that neuropsychiatric consequences after a stroke can also include apathy, defined as reduced motivation or lack of initiative. Depression and apathy often coexist. The apathetic state after a stroke may prevent stroke survivors from engaging in rehabilitation programs, resulting in delayed physical and social recovery (87,88). In a study designed to examine the effect of depression or apathy on functional recovery after stroke, Hama et al. (87) found that when compared to depression, apathy was more frequently associated with poorer functional abilities and more likely to interact with the recovery process (87).

Cognition. It has been suggested that higher-order cognitive abilities, such as abstract thinking, judgment, short-term verbal memory, comprehension, and orientation, are important predictors of the stroke survivor's functional status at discharge (89–91). Reduced cognition has been associated with a decreased ability to perform ADLs, with poorer physical functioning at discharge and a greater likelihood of mortality within one year of discharge (91–97). Zinn et al. (98) reported fewer discharges home among stroke patients with cognitive impairment than among cognitively intact patients (98).

Although the presence of cognitive impairment may be associated with decreased ADL function, it has been demonstrated that it is not a significant predictor of ADL function at six months after stroke (98). Instrumental ADL (IADL) function may be more severely impacted by the presence of cognitive impairment. At six months after stroke, the presence of cognitive impairment was associated with and predictive of decreased IADL function (98). Similarly, Mok et al. (99) determined that higher levels of cognitive impairment after stroke were associated with greater deficits in IADL function and greater levels of prestroke cognitive decline (99). Identified predictors of IADL performance were stroke severity, executive dysfunction, age, and prestroke cognitive decline (94).

Early poststroke cognition approximately 2 to 3 weeks after hospital admission was found to be a significant and independent predictor of functional outcome at 13 months as determined by the mRS (100). Within the domain of cognition, executive function appears to be the most robust cognitive predictor of poor functional recovery after stroke. Stroke survivors with executive dysfunction had a seven-fold greater likelihood of remaining functionally dependent at one year (101).

Aphasia has also been reported as a predictor of both functional and social outcomes after stroke (102). Compared to stroke survivors without aphasia, those with aphasia had lower motor FIM and cognitive FIM scores both upon admission to rehabilitation and at discharge. FIM effectiveness (defined as proportion of potential improvement achieved during rehabilitation) for both motor and cognitive scores was also poorer in patients with aphasia (102). Multivariate regression analysis demonstrated aphasia to be a predictor of the final score of the motor and cognitive FIM and discharge destination (102).

USN has been highlighted specifically as an important and independent predictor of poor functional recovery after stroke (103). The presence of USN has been shown to affect functional recovery and has been consistently associated with slower functional progress during rehabilitation, lower motor FIM efficiency scores, longer LOS, and reduced ADL and mobility performance (103–108). Monaco et al. (109) examined the relationship between the severity of USN and the functional recovery in ADLs after a right hemispheric stroke. USN severity was assessed at a median of 19 days after stroke using the Behavioral Inattention Test (BIT). Both sections of the BIT, the conventional section (BITC) and the unconventional/behavioral section (BITB), were administered and analyzed separately. BITC consists of six written subtests, and BITB consists of nine behavioral-task subtests. After adjusting for potential confounders, significant positive associations were noted between both sections of BIT scores

and FIM scores, FIM efficiency, and FIM effectiveness. Overall, the USN emerged as a factor that negatively impacted functional recovery and contributed to an unfavorable overall rehabilitation outcome (109).

EXTRINSIC PREDICTIVE FACTORS FOR STROKE RECOVERY

The manner in which rehabilitation is provided may also predict functional recovery after a stroke. The important components of rehabilitation are timing to rehabilitation, therapy intensity, task specificity, and the rehabilitation setting. In addition, level of social support may also affect the overall outcome.

Service Delivery

Timing to Rehabilitation

Previous evidence suggests that the brain is not only able to reorganize but is, in fact, primed to do so early on after a stroke (52,110,111). Animal studies have demonstrated that if therapy is delayed for several weeks after stroke, dendritic arborization is markedly reduced. The concept of a detrimental effect with rehabilitation delay was best shown through the animal work of Biernaskie et al. (112). After small strokes were induced in rats, they were subjected to 5 weeks of rehabilitation (consisting of exposure to an enriched environment) beginning at days 5, 14, and 30 after stroke. A group of control rats received no rehabilitation and were placed in social housing. Rats receiving early (day 5) rehabilitation showed marked improvement in neurologic recovery. Rats beginning rehabilitation at day 14 showed moderate improvement, whereas rats starting rehabilitation at day 30 showed no greater improvement than the control animals. In addition, enriched rehabilitation provided very early after stroke (at day 5) resulted in an increased number of dendritic branches and greater complexity of layer V neurons when compared to those rats receiving rehabilitation at day 30 and to those exposed to social housing only (112). The authors concluded that the poststroke brain was more responsive to rehabilitation early in the poststroke period and that responsiveness declined linearly with time, to the point of being not effective when delayed (beginning at day 30 in rats), The clinical implications of this finding are apparent; rehabilitation will have the greatest impact during that early time window when the brain is primed for behavior-dependent changes or cortical reorganization (112).

Several clinical studies have supported the association between early admission to rehabilitation and improved functional outcomes and/or decreased length of rehabilitation hospital stay (113–116). Paolucci et al. (115) suggested that early initiation of rehabilitation after stroke may be a relevant prognostic factor of functional outcome (115). This is supported by reports based on both American (117,118) and Canadian (113) data, which suggest that early admission to rehabilitation, regardless of initial severity of disability, is associated with greater functional gain and shorter lengths of stay.

Date on moderate or severe strokes from the Post-Stroke Rehabilitation Outcome Project (PSROP) database, showed that the time of onset of stroke symptoms to rehabilitation admission was a significant predictor of total and motor FIM at discharge (117). Earlier initiation of rehabilitation was associated with better functional outcome, as reflected in higher total, motor, mobility, and ADL discharge FIM scores after controlling for confounding variables (118). The severely impaired group demonstrated the strongest relationship between early rehabilitation and improved functional outcome (118). Earlier rehabilitation admission was also associated with shorter LOS (118).

The impact of timing to rehabilitation on overall functional outcome was not limited to patients transferred from acute care to rehabilitation. A positive impact was also observed on severe strokes in the stroke intensive care unit (ICU) setting. Hu et al. (119) examined the effect of timing of initiation of rehabilitation in a stroke ICU with a multidisciplinary stroke care team. The stroke ICU patients in general have more neurological deficits (NIHSS >10), stroke in evolution, or unstable medical conditions requiring intensive care. For acute patients admitted to the stroke ICU, early initiation of rehabilitation predicted better functional outcome. After adjusting for stroke severity and age, patients who started earlier rehabilitation had higher BI scores at discharge. Commencing rehabilitation 1 day earlier in the stroke ICU resulted in an increase of the BI score by 0.65 points (119).

In tandem with the importance of early initiation of rehabilitation, there has been increasing interest in very early mobilization (VEM) after a stroke (120–124). VEM has been defined as any intervention delivered with the aim of reducing the time from stroke onset to first mobilization (first out-of-bed episode) and increasing the amount of out-of-bed physical activity (120). The AVERT (A Very Early Rehabilitation Trial) is a large multicentered trial emphasizing on VEM in stroke rehabilitation (121). The trial consists of three phases: Phase I involves collection of baseline data on current practice, Phase II is a trial protocol regarding feasibility and safety of VEM, and Phase III focuses on efficacy and cost-effectiveness of VEM (121–124). In AVERT II, safety and outcome of commencing VEM were studied in comparison to standard care (SC) (122). In the VEM group, mobilization was initiated within 24 hours of stroke symptom onset and continued daily for the first 14 days after stroke or until discharge, whichever was sooner (122–124).

Results in AVERT II trial showed that there was no significant difference in the number of deaths between groups (122). After adjusting for age, baseline NIHSS score, and premorbid mRS score, the odds of experiencing a good outcome were significantly higher at 12 months for the VEM group (122). AVERT II trials also demonstrated that no significant differences in complications were encountered at 3 months for either the VEM or the control groups (123). In addition, patients in the very early and intensive mobilization group

returned to walking significantly earlier than those on standard stroke unit care controls, with a median of 3.5 days (VEM) versus 7.0 days in standard control (124). Multivariable regression demonstrated that exposure to very early and intensive mobilization was independently associated with good functional outcome on the BI at 3 months and on the Rivermead Motor Assessment at 3 and 12 months (124).

Therapy Intensity

Animal and clinical studies have demonstrated that training or inpatient rehabilitation increases cortical representation with subsequent functional recovery, whereas lack of rehabilitation or training decreases cortical representation and delays recovery. Animals exposed to enriched environments after stroke have improved functional outcomes when compared with animals exposed to nonenriched environments (125). Socialization alone can improve stroke recovery in animals, with the mediating factor appearing to be increased activity. In animal studies, the key factors promoting neurologic recovery include increased activity and a complex and stimulating environment. Therefore, it follows that, if training and stimulation lead to increased cortical reorganization, neurologic recovery, and functional improvements, then more intensive therapy is likely to result in a greater degree of recovery and improved functional outcomes (125).

The intensity of rehabilitation therapies is often cited as an important factor associated with both specialized stroke rehabilitation and improved functional outcome. Evidences suggest that increased intensity of therapy is beneficial (127,128). Langhorne et al. (126) examined the effects of differing intensities of physical therapy and showed significant improvements in ADL and function, and reduction of impairments was seen with higher intensities of treatment (126). Kwakkel et al. (127) evaluated the benefits of augmented physical therapy, which involved assessments on various interventions including occupational (upper extremity), physiotherapy (lower extremity), leisure therapy, home care, and sensorimotor training (127). Augmented therapy was associated with statistically significant treatment effects for the outcomes of ADL and walking speed, although not for upper-extremity therapy assessed using the ARAT (127). A 16-hour increase in therapy time during the first 6 months following stroke was associated with a favorable outcome (127). Veerbek et al. (128) studied outcomes specifically related to gait and gait-related activities, with results suggesting that augmented therapy produces small to moderate effects in walking ability, walking speed, and extended ADLs (128). Wang et al. demonstrated that stroke survivors who received a total therapy time less than three hours per day had significantly lower total functional gain than those who received more than three hours (129). The daily treatment time of physical therapy, occupational therapy, and speech and language therapy was also significantly associated with corresponding subscale functional gains.

The amount of exercise in the first week after a stroke has been reported to be able to predict walking speed and unassisted walking (130). In a prospective cohort study, Scrivener et al. (130) examined the predictor variables of walking speed and unassisted walking in 191 stroke survivors with an average modified Rankin Score of 4.29 (SD 0.8). During the first week of admission, the number of exercise repetitions achieved ranged from 0 to 5,522 (median = 703). Multivariate analysis showed that a higher dose of lower-limb exercise repetitions in the first week predicted a faster walking velocity (130). In addition, the completion of more repetitions was associated with a quicker recovery of unassisted walking. Participants who completed the median number of repetitions (703 or more) achieved unassisted walking after a median of 9 days of therapy as compared to 30 days for those who did not reach 703 repetitions (130).

The total amount of time that a stroke survivor spends engaged in rehabilitation activities can vary considerably between units, institutions, and countries (131,132). De Wit et al. (132) observed differences in the amount of time patients spent in rehabilitation activities among four centers in four European countries (Belgium, UK, Switzerland, and Germany) (132). Patients from Germany spent a larger percentage of the day in therapy time (23.4%), whereas those from the United Kingdom spent the least (10.1%). Therapy time ranged from one hour per day in the United Kingdom to about three hours per day in Switzerland (132). A subsequent follow-up analysis to determine degree of recovery noted that motor and functional recovery was better in the German and Swiss centers, compared to the UK center, suggesting that higher therapy intensity is beneficial for recovery (132).

Despite the positive effects, reviews have found that intensity of therapy is only weakly correlated with improved functional outcome (133–137). A review by Teasell et al. (134) found evidence that greater intensity of physiotherapy and occupational therapy resulted in improved functional outcomes, although the overall beneficial effect was modest and not maintained over time (134). Chen et al. (135) examined the relationship between intensity of therapy and functional gains and found that, even though admission function, LOS, and therapy intensity collectively contributed to greater functional gains, LOS and therapy intensity did not always predict those gains (135). The effect of intensity on functional outcome showed weak evidence of dose–response relationship (136) and limited support in favor of greater intensity therapy (137). Page (138) argues that intensity of therapy has been overemphasized and that less intense (30–45 min/day) task-specific training regimens with the more affected limb can produce cortical reorganization and correlative, meaningful functional improvements (138).

Task Specificity

Task-specific practice to relearn a motor skill is considered to be a critical variable enhancing plastic changes in neural circuits (139). Repeated, task-specific practice during motor skill acquisition has been shown to increase dendritic growth,

synaptic strength and number, and/or neuronal activity in brain or spinal circuits, creating long-lasting alterations in motor performance (125). Repetitive task training involves active motor sequences performed repetitively within a single training session, aimed towards a specific functional goal (141). Repetitive task training therefore combines the elements of intensity and task-specificity in a more functional relevance approach (141).

Intensive rehabilitation paradigms that focus on participation in specific tasks in the early poststroke period may improve locomotor recovery more than traditional techniques (139). Gait training over ground or on treadmill with or without body weight support (BWS) has been shown to elicit significant improvements in meaningful clinical outcome measures such as gait speed, timed distance, balance, gait efficiency, peak treadmill speed, and peak metabolic capacity in patients at least four months after stroke (139). However, data from the Locomotor Experience Applied Post Stroke (LEAPS) study indicates that treadmill training with BWS was not superior to home-based physical therapy in improving walking, although both groups improved (140). In a systematic review by Langhorne (141), repetitive task training seemed to be beneficial for mobility during rising to stand. Cochrane systematic review and meta-analysis on repetitive task training showed that repetitive task training resulted in modest improvements across a range of lower-limb outcome measures but not of upper-limb measures (142).

Rehabilitation Setting

Interdisciplinary specialized stroke rehabilitation units are associated with better outcomes when compared to conventional multidisciplinary care. The benefit has been attributed, in part, to the provision of higher intensities of stroke rehabilitation therapies delivered by individual clinicians specializing in stroke care and working more as a team. Even with baseline similarities between groups, Kalra et al. (143) demonstrated that subjects who received care on a stroke unit two weeks following an acute stroke had higher median BI discharge scores, which were achieved in a shorter length of time, compared with patients who were rehabilitated on a general ward (143). The rate of change of median Barthel scores was higher among stroke unit patients with a gain of 2.2 points/week compared with 0.9 points/week (143). The Stroke Unit Trialists' Collaboration showed that stroke patients who receive organized inpatient care in a stroke unit are more likely to be alive, independent, and living at home one year after the stroke (144). The benefits were most apparent on units based in dedicated wards. In addition, there was no indication that organized stroke unit care resulted in longer hospital stay (144). Chan et al. demonstrated that at six months after stroke, stroke survivors who were admitted to an inpatient rehabilitation facility (IRF) during their course of rehabilitation had functional scores on the activity measure for post-acute care (AM-PAC) that were at least eight points higher (twice the minimally detectable change) than those who went to a nursing facility skilled in all three domains and in two of three functional domains compared with those who received home health/outpatient care, after controlling for age, functional status at acute care discharge, and total hours of rehabilitation (145).

Social Support

Family function and support have an influence on stroke outcomes, in that high levels of social support have been associated with faster and more extensive recovery of functional status after stroke (146,147). Glass et al. (147) noted significant differences in functional status based on degree of social support. Stroke survivors receiving high levels of support recover more rapidly and to a greater extent, even when the initial severity is relatively high (147). These authors concluded that social support may be an important prognostic factor in recovery from stroke and predict a more functional favorable outcome (147).

Jørgensen et al. (15) also highlighted that in a cohort of subjects with the most severe strokes from the Copenhagen Stroke Study trial, the existence of a spouse at home increased the relative chance of a good outcome by threefold independent of age, sex, stroke severity, and other factors. This was thought to reflect the importance of a good social network on outcomes in general (15). Bhogal et al. (148) reported moderate evidence that improved social support as an intervention improved outcomes. This has been confirmed by multiple nonrandomized studies that have looked at the association between social support and improved outcomes. Despite a lack of randomized trials, the evidence as a whole linking social support to improved outcomes is quite impressive. Emotional support, in particular, is correlated with better functional outcomes, although the impact may not be noticeable in the acute phase of the stroke (148).

SUMMARY

A stroke can be a devastating event, leaving the stroke survivor with impairments and disabilities that threaten his or her independence. Stroke survivors recover to varying degrees, with the extent of recovery dependent upon various intrinsic and extrinsic factors. The two most important intrinsic factors affecting stroke recovery are stroke severity and the age of the stroke survivor. Lesion volume and site, stroke type, stroke recurrence, medical comorbidities, mood disorders, and cognitive deficits can also influence recovery and outcome. In addition, extrinsic factors comprising rehabilitation service delivery and social support may alter the recovery process. Our increasing understanding of factors that contribute to cortical reorganization, gleaned through the animal model, including complex stimulating environments and high activity levels, have corollaries in the clinical realm. These include early admission to rehabilitation, intensity of therapies, and task-specific therapies, all of which have been associated with better recovery and outcome. Clearly, focused and intensive rehabilitation is essential to ensure maximal stroke recovery.

Stroke Services: A Global Perspective

Peter Langhorne and Anthony George Rudd

GLOBAL BURDEN OF STROKE

Stroke is recognized as being a global problem. In high-income countries, it is the third most common cause of death after coronary heart disease and cancer and one of the most important causes of severe disability (1,2). There is a common misconception that stroke is predominantly a disease of high-income countries. However, a broader estimate of the global burden of disease (3) suggests that the top three causes of death globally are ischemic heart disease (7.2 million deaths), stroke (5.5 million), and lower respiratory diseases (3.9 million), out of a total of 56 million deaths. On a worldwide basis, the leading causes of disability-adjusted life years (DALY) are those that affect predominantly younger patients, such as perinatal conditions (7.1% of global DALY), lower respiratory infections (6.7%), and diarrheal diseases (4.7%). Ischemic heart disease and stroke rank sixth and seventh, respectively, as causes of global disease burden (3).

Despite a prolonged investment in efforts to identify effective drug therapies, we still lack a medical therapy that significantly lessens the burden of stroke across an unselected population. Acute treatment with aspirin can reduce death and disability to a modest extent (approximately one extra independent survivor per 100 patients treated) (4). Thrombolysis with tissue plasminogen activator is more potent, but is applicable to only a minority of patients (5). Therefore, for the foreseeable future, the greatest hope for reducing the burden of stroke will depend upon prevention measures and effective systems for managing stroke patients from acute care through rehabilitation (5).

Governments, in particular those responsible for providing health care, are increasingly aware of the impact that stroke has on the health of the population and the cost to the community. Stroke patients account for about 5% of all Health Service costs in the United Kingdom (6). Studies from other countries (e.g., Sweden, the United States, Canada, the Netherlands, and Japan) suggest that the financial burden may be even greater than in the United Kingdom, possibly because of greater health service expenditure (7–14). Furthermore, demographic changes are likely to cause increasing mortality and morbidity, particularly in the developing world (15,16).

This chapter focuses on the organization of services for people who have had a stroke. We concentrate on care in the hospital, but we also mention the early postdischarge period. The discussion emphasizes models of care targeted at a broad range of stroke patients rather than at those with specific problems (e.g., aphasia). It largely reflects models of care in the United Kingdom and other European countries but also mentions other regions, particularly Australia and Canada.

FACTORS INFLUENCING STROKE SERVICES

The overall aim of stroke services should be to deliver the care required by stroke patients and their families in the most efficient, effective, equitable, timely, and humane manner possible. These services may not always be exclusively stroke-specific; parts may be embedded in general (internal) medicine, geriatric medicine, neurology, or rehabilitation medicine services.

In an ideal world, our decisions about the delivery of stroke services would always be informed by robust evidence from randomized trials, and priority would be given to those aspects of care that have been proven to be effective. However, we must recognize that carrying out randomized trials of complex interventions such as stroke services is challenging (17). At present, relatively few clinical trials are available, especially in rehabilitation and recovery, and these trials can be difficult to interpret and generalize.

Several factors other than evidence of effectiveness or cost-effectiveness may shape stroke-service delivery and constrain the options available to clinicians and service planners. These include the following:

1. Local health care culture and economy. The existing approach to providing health care, and the way it is funded or reimbursed, will influence the way services are delivered. Developing a stroke service in the United States or Germany presents different challenges from doing so in Scandinavia or the United Kingdom.
2. Needs of different patient groups. Stroke presents a complex challenge to service planners, in that most patients require a common basic service, although a smaller number (for instance, those eligible for hyperacute interventions) may require more specialized services.

TABLE 41.1 Objectives and Common Service Solutions for Managing Patients With Stroke

OBJECTIVES	PROPOSED SERVICE OPTIONS
Specific acute medical and surgical treatment	Acute or comprehensive stroke units; stroke centers
Identification and assessment of patient problems	Acute or comprehensive stroke units
Secondary prevention of further vascular events	Acute or comprehensive stroke units
General care, including interventions to resolve problems (includes many aspects of rehabilitation)	Comprehensive or rehabilitation stroke units
Terminal care for patients who are unlikely to survive	Stroke units
Hospital discharge and reintegration into the community	Early supported discharge services; discharge planning
Continuing or long-term care for severely disabled patients	Therapy-based rehabilitation services; stroke liaison worker services; day hospital services
Follow-up to detect and manage late-onset problems	Chronic disease management; outpatient clinics

See Table 41.4 for some definitions of terms.

3. Views of patients and families. One of the common complaints from patients and caregivers is the discontinuity of services they receive (18,19), resulting in fragmentation of care and dissatisfaction with services.
4. Resources available. It is relatively easier to organize or reorganize a stroke service if the basic levels of staffing and investigation services are already available. For this reason, much of our discussion will be relevant mainly to well-resourced services in high-income countries. However, we recognize that there is an urgent need to develop affordable health care solutions for low- and middle-income countries.

EVIDENCE BASE FOR STROKE SERVICES

Before outlining the pattern of stroke services in different regions, and the evidence base underpinning them, we should provide some service terms and descriptions.

Comprehensive Stroke Service

We have used the term *comprehensive stroke service* to mean a stroke service that covers most of the needs of patients with stroke and is integrated in a way that provides a continuous patient journey—a "seamless service" (Table 41.1).

Organized Inpatient (Stroke-Unit) Care

Throughout most European countries (and, indeed, further afield), there is now widespread acceptance that stroke services in hospitals should be organized within stroke units (20,21). Much of the evidence comes from a systematic review of clinical trials that compared the outcomes for stroke patients cared for in a specialist stroke unit with the outcomes of those cared for in general wards. Patients managed in stroke units are more likely to survive, return home, and regain independence (Table 41.2). The units included in the systematic review were run by geriatricians, neurologists,

TABLE 41.2 Summary of Patient Outcomes in the Stroke-Unit Trials

	STROKE UNIT	CONVENTIONAL CARE	APPROXIMATE NUMBER OF OUTCOMES PER 100 ADMITTED
Home (independent)	44%	38%	5 (1, 8)
Home (dependent)	16%	16%	0 (–2, 3)
Institutional care	18%	20%	–2 (–5, 0)
Dead	22%	26%	–3 (–6, –1)

This table shows the proportion (%) of patients with various outcomes at the end of scheduled follow-up (median one year) in the randomized trials of stroke-unit care versus conventional care.
The absolute risk difference is the proportion of outcomes achieved (+) or avoided (–) with stroke-unit care. The next column is the number of outcomes achieved (+) or avoided (–) for every 100 patients cared for in a stroke unit, assuming the absolute risk of an outcome in the population is similar to that in the trials. These figures are based on data from 31 trials (6,900 patients).

Source: From Ref. (21). Stroke Unit Trialists' Collaboration. Organised inpatient (stroke unit) care for stroke. *Cochrane Database Syst Rev.* 2007;(4):CD000197.

general (internal) physicians, and rehabilitationists. Patients with mild, moderate, and severe strokes and of all age groups appear likely to benefit from stroke-unit care (20,21).

Although comprehensive stroke-unit care is a complex and multifaceted intervention, the key components are reasonably well described (22) and include all of the following (Table 41.3):

- Ward base—effective stroke units have usually been based in a distinct ward with dedicated nursing staff.
- Specialist staffing—they have been staffed with medical, nursing, and therapy staff with a specialist interest and expertise in stroke and/or rehabilitation.
- Multidisciplinary teamwork—they have always included good multidisciplinary communication (defined as a formal meeting of all staff at least once per week to plan the management of individual patients).
- Education and training—they have included programs of education and training for staff and provision of information for patients and caregivers.

Several consistent features of the process of care in stroke units have also been described (20,22). These typically do not depend on high-technology facilities, but include a systematic approach to care (Table 41.3) that incorporates the following:

- Careful assessment and monitoring of medical, nursing, and therapy needs
- Early active management, incorporating management of food and fluids, control of pyrexia, hypoxia, hyperglycemia, early mobilization, careful positioning and handling, and avoidance of urinary catheterization
- Ongoing multidisciplinary rehabilitation, with early goal setting, early involvement of caregivers in rehabilitation, and provision of information to patients and caregivers. This also includes early planning of discharge needs.

Many of these processes of care will come as no surprise to those experienced in stroke care, but audit studies raise concerns that many are not routinely provided (23).

Beyond describing the basic components of stroke-unit care, it is difficult to determine whether the effectiveness of the stroke units is a result of the total package of care or of particular components. Although the basic principles of stroke-unit care are reasonably well described, they have been delivered in a variety of ways, and the term *stroke unit* means different things to different people. Thus, it is important to define our terms (see Table 41.4).

TABLE 41.3 Characteristics of Comprehensive Stroke-Unit Care

Structure
- Geographically discrete ward
- Multidisciplinary staffing (nursing, medical, physiotherapy, occupational therapy, speech therapy, social work)
- Medical staff with specialist interest in stroke and rehabilitation
- Nursing staff with specialist interest in stroke and rehabilitation

Coordination of care
- Regular multidisciplinary team meetings (formal meeting of all staff once weekly, informal meetings 2–3 times per week)
- Close linking of nursing and multidisciplinary team care
- Educational programs for staff

Assessment and monitoring
- Rapid admission to stroke unit
- Medical history and examination
- Standard routine investigations (biochemistry, hematology, ECG, CT scanning)
- Further selective investigations (carotid Doppler ultrasound, echocardiogram, MRI scanning)
- Nursing assessments (vital signs, general care needs, swallow test, fluid balance, pressure areas, neurologic monitoring)
- Therapy assessments of impairments and disability

Early management
- Careful management of fluids/food
- Pyrexia management, paracetamol for pyrexia, antibiotic for suspected infection
- Hypoxia management; oxygen if hypoxia, drowsiness, or cardiorespiratory disease
- Glycemic management, insulin for hyperglycemia
- Careful positioning and handling
- Pressure-area care
- Avoidance of urinary catheterization if possible
- Early mobilization: up to sit, stand, and walk as soon as possible

Ongoing multidisciplinary rehabilitation
- Early goal setting
- Early involvement of caregivers in rehabilitation
- Provision of information to patients and caregivers

Discharge planning
- Early assessment of discharge needs
- Discharge plan involving patients and caregivers

Acute Stroke Unit

Acute refers to the policy of rapid admission of the stroke patient to the stroke unit. In some regions such as North America and Germany (and increasingly in the United Kingdom), there has been a pattern of admitting stroke patients to ward areas with facilities for intensive monitoring of physiological functions (cardiac, respiratory, and neurologic). Interventions are introduced to correct these abnormalities (e.g., raised intracranial pressure, systemic hypertension). Broadly speaking, two approaches have been described:

- Intensive care units, which can offer all monitoring (including intracranial monitoring) and life-support options (e.g., respiratory support).
- "Semi-intensive" units are similar to coronary-care units, where monitoring and intervention focus on physiological variables but not life support. More recently, these have also been termed *hyperacute stroke units*.

There have been three small clinical trials of semi-intensive units that have reported rather inconclusive findings.

Comprehensive Stroke Units

Perhaps the most successfully implemented model has been the comprehensive stroke unit, which admits patients for acute care and then provides at least a few weeks of reha-

TABLE 41.4 Classification of Different Forms of Organized Inpatient (Stroke-Unit) Care

TYPE	PHILOSOPHY OF CARE	PATIENT GROUP	MDT BASE	TIMING OF ADMISSION	TIMING OF DISCHARGE	TYPE OF CARE
Acute (intensive) stroke unit	Acute	Stroke	Ward	Acute (hours)	Early (3–7 days)	Acute medical and nursing care (with high staffing levels)
Acute (semi-intensive) stroke unit	Acute	Stroke	Ward	Acute (hours)	Early (3–7 days)	Acute medical and nursing care. Monitoring and management of physiological variables
Comprehensive stroke unit	Acute care and multidisciplinary rehabilitation	Stroke	Ward	Acute (hours)	Later (days–weeks); some referral to specialist rehabilitation	Acute medical and nursing care. Nonintensive management of physiological variables. Early active multidisciplinary rehabilitation
Rehabilitation stroke unit	Multidisciplinary rehabilitation	Stroke	Ward	Delayed (days)	Later (weeks)	Multidisciplinary rehabilitation
Mixed rehabilitation unit	Multidisciplinary rehabilitation	Stroke and other disabling illness	Ward	Early (hours–days)	Later (weeks)	Multidisciplinary rehabilitation
Mobile stroke team	Acute care and/or multidisciplinary rehabilitation	Stroke	Mobile (no ward) base	Early (hours–days)	Later (weeks)	Acute medical care and/or multidisciplinary rehabilitation. No specialist nursing input

This table summarizes, in broad terms, the characteristics of different types of stroke unit.
Abbreviation: MDT, multidisciplinary team.

bilitation. This approach, which is widespread in Norway and Sweden, is supported by several clinical trials included in the systematic review and results from a national stroke register in Sweden (24). A major advantage of this approach is that rehabilitation can start on the day of the stroke. In practice, although these units provide good care to most patients, it is common to refer some patients with ongoing, complex rehabilitation needs to other rehabilitation services.

Rehabilitation Stroke Units

Several trials have indicated benefit from rehabilitation units that admit patients a few days after stroke onset and continue rehabilitation for several weeks. These trials have inevitably examined a more select patient group, with patients who are stable enough for that environment and have ongoing rehabilitation needs (21).

Some trials also explored the impact of organizing stroke care within generic rehabilitation services (e.g., geriatric medicine or neurologic rehabilitation services); patients achieve better outcomes in mixed rehabilitation units than in general wards (21). Comparisons with stroke-specific units indicate a trend toward better outcomes in stroke-specific units, but the data are limited.

Mobile Stroke Teams

Overall, the trials in the meta-analysis indicated that a stroke team working across several general wards may improve aspects of the processes of care (e.g., access to specialist assessments) but cannot achieve patient outcomes as good as those of a team based in a stroke unit (25,26).

Transfer From Hospital to Community

One of the main areas of concern to patients, and perhaps even more so to caregivers, is the organization (or rather the lack of organization) of hospital discharge (18,19). A number of approaches have been attempted to reduce the stress of the transition from hospital to home:

- Providing adequate information and training to the caregivers while the patient is in the hospital; for example, inviting the caregivers to therapy sessions and involving them in the patient's care on the unit. However, trials of information provision and patient education do not provide clear evidence to guide practice.
- Programs for training caregivers to manage their new role have been tested in one moderately large randomized trial (27). This involved stroke-unit staff training caregivers about stroke and in practical caring skills. This approach was initially reported effective but not confirmed in a larger cluster randomized trial (28). However, most clinical guideline groups still recommend providing information and training for carers.
- Predischarge home visits with the patient and one or more members of the team to ensure that the home environment is tailored to the patient's needs. Although this is a well-established procedure in many centers, we could not identify any published clinical trials of such policies.
- Predischarge case conferences to allow the patient and caregiver to meet with the hospital-based team and any professionals who are to be involved in their care in the community, including clear guidelines about who to contact in the event of problems. Once again, this is a well-established approach for which we could not identify any clinical trials.

Early Supported Discharge Services

Early supported discharge (ESD) services aim to accelerate discharge home from the hospital but provide more continuity of rehabilitation in the home setting. To date, 14 randomized trials have tested this approach to care in a variety of settings around the world (29,30). Most were centered around a small, multidisciplinary team of physiotherapy, occupational therapy, nursing, and assistant staff—with input from medical, speech and language therapy, and social work professionals. These teams were either hospital based (and went out to the patient's home) or community based (and came into the hospital to recruit patients). All incorporated regular multidisciplinary team meetings to plan patient care. A typical pathway of care (30) is shown in Table 41.5. Typically, these services can reduce hospital stay by about one week and provide input in the patient's home for up to three months, but this has been shorter with handover to other community services (30).

Even when compared with high-quality care in a hospital-based stroke unit, an ESD team could not only accelerate the discharge procedure (with an average reduction in length of stay of eight days), but also could result in the patient having a greater chance of remaining at home and regaining independence. Overall, for every 100 patients randomized to early supported discharge services, an extra four remained at home and/or were independent at

TABLE 41.5 Typical Care Pathway in an Early Supported Discharge Service

- Early identification of eligible patients in hospital
- Early assessment by a "key worker" from the ESD team (an individual who supervises the care of the patient)
- Assessment of home needs through a home visit (with or without the patient present)
- Identification of recovery goals with the patient and caregivers
- Discharge home with very early input (within 24 hours) by members of the ESD team
- Continuing rehabilitation in the home setting (up to five days per week if necessary)
- Negotiated withdrawal of the team as recovery goals are achieved
- Multidisciplinary review of the patient's progress
- Planned discharge from the service with later follow-up and review

6 to 12 months after the stroke. Good results were most likely with a well-resourced, coordinated multidisciplinary supported discharge team and with patients who had mild to moderate stroke severity (30). There is a suggestion that such services may not work as well in more dispersed rural populations (31), but this requires confirmation. Overall, ESD services may be relevant to about half the stroke patients admitted to hospitals (30).

Economic analyses (29) indicate that the additional costs of community rehabilitation are more than outweighed by the savings in hospital bed days. In addition to the "harder" outcomes mentioned earlier, it is also noteworthy that patients and caregivers allocated to ESD services were more likely to report satisfaction with their services. Early supported discharge services appear to be an important component of a truly comprehensive stroke service and should particularly target patients with mild to moderately severe strokes.

Continuing Rehabilitation and Reintegration Into Normal Life

Even when stroke patients have received good care in hospital and around the discharge period, they may still have difficulty maintaining independence and reintegrating into normal life. At this stage of the patient's journey, services are often quite variable and may be completely nonexistent (32). This probably reflects the diversity of approaches in different countries, but also limits the evidence base indicating that effective interventions can really improve recovery. In general, two broad approaches have been tested in clinical trials:

- Therapy-based rehabilitation services (provided by physiotherapy, occupational therapy, or multidisciplinary staff and primarily aiming to increase activities in daily living). In practice, this might include a range of task-related interventions aiming to improve mobility, activities of daily living (ADLs), or specific tasks such as dressing. In a systematic review (33) of therapy-based rehabilitation services, therapy-based rehabilitation (when compared with no routine intervention) helped prevent stroke patients from deteriorating in their ability to carry out ADLs, and improved ADL scores. Therefore, even relatively late (several months) after stroke onset, patients may gain from input from a therapist. Less clear is the absolute benefit likely to be achieved and the cost-effectiveness of these services.
- Stroke liaison-worker services provided by stroke nurses, family support workers, or specialist social workers primarily aim to improve participation in normal living and quality of life (34). In practice, these have included a mix of interventions, which could deliver a program of rehabilitation or respond to identified problems. These services often involve approaching patients and families during hospital admission, when staff can provide information and education about stroke. Assistance is also available for input after discharge, particularly to identify problems or unmet needs and to develop customized solutions. At least 15 randomized trials have tested this type of service in the United Kingdom, Australia, the United States, and the Netherlands. Their impact on patient outcomes is modest (34), but some aspects do appear to be valued by patients and caregivers.

STROKE SERVICES IN DIFFERENT REGIONS

Having outlined some general principles, background research, and different approaches to providing stroke care, we can discuss in more detail the delivery of stroke services in various parts of the world, particularly in Europe.

The subsequent discussion is, of course, very general, and there will inevitably be many local exceptions. However, we aim to indicate the different approaches that have been adopted in different parts of the world (Table 41.6). For each section, we try to briefly mention the local health care economy, those medical specialties largely providing stroke-unit care, the types of stroke-unit care and coverage available (including issues of equity of access), and access to other services. Finally, we try to mention evidence of successful implementation of service components.

Scandinavia (Norway, Sweden, Denmark, Finland)

The Scandinavian countries have mature social democratic economies with largely publicly funded health services (24,35). The main medical specialties managing stroke in Norway, Sweden, and Denmark tend to have been general (internal) medicine and geriatric medicine, although neurologists also play an important role, particularly in Finland. The most common stroke-unit model has been the comprehensive stroke unit, which was developed and pioneered in Norway and Sweden, although more acute systems of care have evolved, particularly in Finland (36).

Recent surveys suggest that most hospitals (more than 90%) have stroke units, and the majority of patients (70%–80%) obtain access to stroke units during their hospital stay.

Evidence of successful service implementation comes from studies of the Swedish (24) and Finnish (36) stroke registries, which aimed to register all admitted stroke patients and follow them up after discharge from hospital. These publications indicate that admission to a hospital with a stroke unit is an independent predictor of good outcome such that stroke-unit admission is associated with fewer deaths and more patients returning home.

Scandinavian countries have also pioneered the development and evaluation of early supported discharge services (29). Such services are becoming more widespread, but current figures are unclear.

United Kingdom (England, Scotland, Wales, Northern Ireland)

The United Kingdom also has a largely publicly funded health service (23,37–39). Traditionally, stroke care has been provided in departments of geriatric medicine and

TABLE 41.6 Summary of Predominant Service Patterns in Different Regions

	SCANDINAVIA	UNITED KINGDOM	CONTINENTAL EUROPE	MEDITERRANEAN	AUSTRALIA AND NEW ZEALAND	CANADA	DEVELOPING WORLD
Health care economy	Public health services	Public health services	Mixed health economies	Mixed health economies	Mixed	Mixed	Variety
Specialties providing stroke-unit care	General medicine, geriatric medicine, neurology	Geriatric medicine, general medicine	Neurology, rehabilitation medicine	Neurology, general (internal) medicine	Neurology, rehabilitation medicine	Neurology, rehabilitation medicine	Variety
Type of stroke-unit care and coverage	Comprehensive stroke-unit model	Rehabilitation (and comprehensive) units	Acute and rehabilitation units	Acute and rehabilitation units	Acute and rehabilitation units	Acute and rehabilitation units	Very limited access
Equity of access to stroke units	Most hospitals (> 90%) have stroke units, and most patients get access (70%–80%)	More than 90% of hospitals have stroke unit (80% of patients gain access)	Less than 50% access at last surveys	Variable access (10%–20%) in PROSIT register in Italy	Incomplete SU access Australia and New Zealand	Incomplete SU access	Very few stroke units established (usually in private hospitals)
Evidence of successful implementation of stroke units	Swedish RIKS—Stroke and Finnish register show effective implementation	National sentinel audit showed improved outcome with admission to stroke unit	Registries show some effective implementation (but also inequities of access)	PROSIT register (Italy) suggests that effective implementation is possible	Reports indicate improved outcomes with stroke-unit care	Register indicates improved outcome with SU care	Limited information available
Services after hospital discharge	Some early supported discharge services	Increasing community rehabilitation services	Variable	Limited	Variable	Variable	Very limited access

Abbreviation: SU, stroke unit.

general (internal) medicine (40), and stroke units have tended to evolve from rehabilitation services. Some specialist rehabilitation services (e.g., for younger adults) are provided by rehabilitation medicine physicians.

Relatively little attention was paid to stroke in the United Kingdom until the publication of the King's Fund Consensus Conference (1988). This highlighted the many deficiencies in the services provided for stroke patients (19). Since then, stroke has moved up in the political agenda. These changes have led to a substantial interest in stroke in general, and in stroke services in particular. Over the past few years, an increasing amount of research has been implemented to determine the best and most cost-effective ways of providing care for stroke patients.

In the most recent audits of services in England and Wales (38), 100% of hospitals reported having a stroke unit, and more than 80% of patients gained access to a unit during their admission. In earlier research with the National Sentinel Audit (23), admission to a stroke unit was an independent predictor of better survival, with an odds ratio of death of 0.75 among those admitted to a stroke unit. Recent data from Scotland show similar patterns (40,41).

Supported discharge services provided by community teams are becoming more widely available, with up to 66% of hospitals in the United Kingdom having access to early supported discharge in the latest national audit (38,40).

West Continental Europe (France, Germany, Austria, Switzerland, the Netherlands)

This group of countries tends to have mixed health care economies with a mixture of public funding and private insurance (42–45). Traditionally, the acute phase of stroke care tends to be provided in neurology services (and sometimes geriatric medicine services for older stroke patients), with rehabilitation medicine providing the main rehabilitation services. In neurology departments, acute units (intensive care or semi-intensive care units) appear to predominate. After the acute illness, rehabilitation services tend to be provided in rehabilitation stroke units. Some publications (46) have suggested incomplete access for stroke patients in Germany, but this appears to vary from region to region.

Studies of stroke-unit registries (45) suggest effective implementation but also some reduction in access for older patients.

Mediterranean Europe (Spain, Portugal, Italy, Greece)

This group of countries also has mixed health care economies, with a mixture of public funding and insurance (47,48). Once again, the acute management of stroke frequently occurs in departments of neurology and sometimes general (internal) medicine. In many neurology departments, acute semi-intensive units have been adopted, as well as rehabilitation services based in rehabilitation units. Studies from Italy (48) suggest variable access to stroke-unit care, but improved outcomes where implementation has taken place (49).

Eastern Europe (Poland, the Czech Republic, Hungary, Russia, Baltic States)

Many of these countries have undergone a rapid economic transition, with health services moving from a publicly funded model to a more mixed economy (50,51). Traditionally, stroke services have often been provided in departments of neurology. Organized (stroke-unit) care has been developed in Poland and Hungary (50,51) but appears less well established in other areas. Postdischarge services appear to be quite variable (52).

Australia and New Zealand

The structures of health care in Australia and New Zealand originally developed from a United Kingdom model of service. However, in recent years, both countries have developed a more mixed health care economy.

Much of acute stroke care in Australia is carried out in departments of neurology, with more of a mixed picture in New Zealand. Rehabilitation is frequently provided by rehabilitation medicine specialists or in departments of geriatric medicine. In Australia, there have been concerns about the limited provision of stroke-unit care, and several promising initiatives have been implemented in Australia to develop stroke units in both acute settings and rehabilitation units (53). A recent report from New Zealand (54) indicated limited access to stroke-unit care.

Canada

The Canadian health care economy is based on a national health insurance system. Traditional stroke care has been provided by a range of specialties, predominantly neurology, rehabilitation medicine, and general (internal) medicine. Stroke-unit care has been available in an increasing number of hospitals (55), and is linked to better outcomes. A variety of postdischarge services exist, which appear variable in nature.

Low- and Middle-Income Countries (Especially Africa, Asia, South America)

It is recognized that low- and middle-income countries have some of the highest stroke mortality rates, accounting for two-thirds of stroke deaths worldwide (3). There appears to be a lack of organized stroke-unit care and rehabilitation services in these nations (56), although there is some evidence that stroke units may be effective in these less well-resourced settings (57). Some excellent services do exist, but frequently with poor access for the majority of the population. The authors concluded that there is a need to develop basic organized stroke-unit care in low- and middle-income countries (57).

CONCLUSIONS AND CHALLENGES

The challenges facing high-income countries clearly differ from those of low- and middle-income regions. Scandinavian countries appear to be facing the challenge of maintaining established standards through clinical guidelines and national quality registries. In the United Kingdom, there has been strategic investment to improve acute services and a widening of access to services. In western continental Europe, issues have been raised around the cost and the equity of access to services, and we have seen an expansion of stroke-unit care and may see the adoption of a less-intensive model of acute stroke care. In the Mediterranean region, there has been underdevelopment of specialist stroke services, and it is expected that strategic investment may be required. In low- and middle-income countries, the major challenge is determining how to provide stroke services that are effective, affordable, tailored to local needs, and available to the majority of people who need such services.

Research Frontiers

The value of the stroke-unit model of care is clearly demonstrated. Future studies should explore the impact of different components of the stroke-unit "package" (e.g., early mobilization). In particular, we need to identify simple, widely applicable inventions that could be applied in low-resource settings in low- and middle-income countries. Effective ways of improving discharge procedures, reintegrating to normal life, and relieving caregiver burden also require identification.

Postacute Rehabilitation Care and Patient Triage

Anne Deutsch and M. Elizabeth Sandel

Health care delivery in the United States involves a patchwork of private and public (government) insurance and financing with service delivery that is provided by a mix of for-profit, not-for-profit, and government-owned entities. Following the acute care hospital stay in the United States, patients with stroke may continue to receive rehabilitation services from one or more postacute care (PAC) providers, which includes inpatient rehabilitation facilities (IRFs), skilled nursing facilities (SNFs), home health agencies (HHAs), long-term care hospitals (LTCHs), and outpatient therapy providers. This chapter describes the structure and trends of PAC in the United States and includes an overview of each of these types of providers, including the provider definition and characteristics, the provider payment system, and, where available, patient characteristics and quality data. Clinical and nonclinical (e.g., insurance) factors associated with PAC utilization are described, and the chapter ends by discussing current issues facing PAC providers and efforts to reform the delivery of health care services in the United States.

PAC PROVIDERS

Following the implementation of the acute care prospective payment system (PPS) in 1983, acute care lengths of stays (LOS) decreased and PAC utilization increased (1,2). The number of PAC providers increased dramatically in response to shorter acute care stays. Between 1985 and 1996, the number of IRFs increased from 454 to 1031; the number of SNFs increased from 6725 to 14,548; the number of HHAs rose from 5983 to 9808; and the number of LTCHs increased from 86 to 183 (3,4). As shown in Figure 42.1, Medicare payments to these four types of PAC providers continue to grow and were estimated to be $63.5 billion in 2011 (4). Although each type of PAC provider generally offers a unique mix of services from physicians, nurses, therapists, and other clinicians, there is overlap of some or all services across IRFs, SNFs, HHAs, LTCHs, and outpatient therapy providers.

Inpatient Rehabilitation Facilities

IRFs, including both distinct-part units within acute care hospitals and freestanding rehabilitation hospitals, provide intensive (i.e., 3 hours of therapy at least 5 days a week or an average of at least 15 hours per week) interdisciplinary therapy services, including physical, occupational, and speech therapy, rehabilitation nursing, and close medical supervision to patients recovering from a major injury, illness, or surgery. Patients admitted to IRFs must be able to tolerate and benefit from three hours of therapy from physical therapy (PT), occupational therapy (OT), speech–language pathology (SLP) or prosthetics/orthotics services (5).

There were approximately 359,000 Medicare beneficiary IRF stays in 2010, and total Medicare payments that year were $6.32 billion (4). There are approximately 1,179 IRFs (2010), of which 80% are units and 20% are freestanding facilities. About one-quarter of IRFs are for-profit entities, whereas 62% are not-for-profit and 13% are government owned. Most (83%) IRFs are located in urban settings and 17% are in rural locations (4).

After the Medicare program determined that IRFs would not be included in the acute care diagnosis-related group payment system, a set of criteria was developed to define an IRF. One criterion that has been used by the Medicare program to define an IRF is the current "60% rule" (for many years this was the "75% rule"). The 60% rule requires that at least 60% of a facility's patients have one of thirteen specified medical conditions that typically require an intensive rehabilitation program (6). Stroke is listed as one of the thirteen conditions and is now the most common primary impairment condition for patients admitted to an IRF (4). Many patients with stroke who are admitted to IRFs are 65 years of age or older, and thus Medicare, the federal insurance program for the elderly and disabled, accounts for approximately 69% of payments for IRF care (7).

Since 2010, the Medicare program has required documentation in the medical record that the decision to admit the patient was reasonable and necessary (8). Documentation includes a preadmission screening, postadmission physician evaluation, individualized plan of care, physician orders, and the IRF patient assessment instrument (IRF-PAI). Medicare's criteria for an IRF admission to be considered reasonable and necessary are: multiple therapy disciplines, intensive level of rehabilitation services, the ability to participate in an intensive therapy program, physician supervision, and an interdisciplinary team approach to care. Measurable, practical

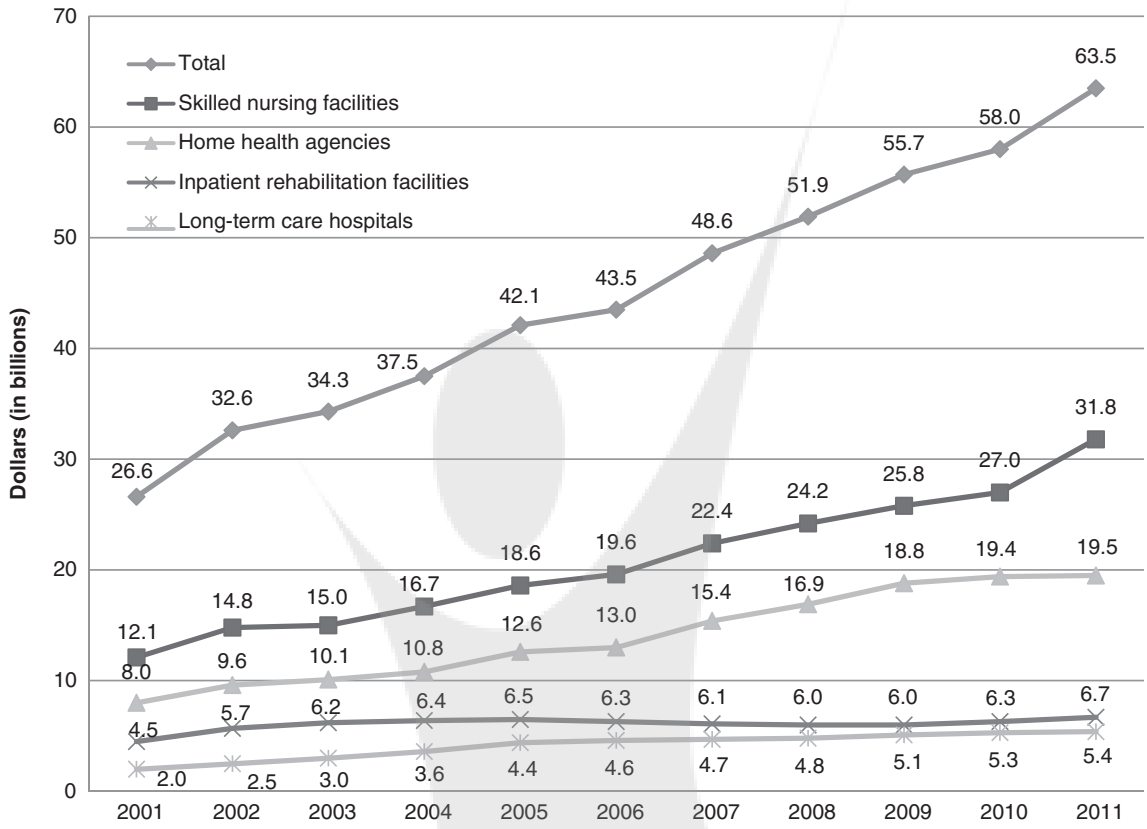

FIGURE 42.1 Medicare postacute care spending, 2001–2011.

Source: From Refs. (3,4).

improvement in the patient's functional status is expected within a predetermined and reasonable period of time, and for most patients, the goal of IRF care is the patient's safe return home or to a community-based setting (8).

Medicare has paid IRFs under a PPS since 2002 (9). The IRF PPS provides facilities with a predetermined per-discharge payment for each Medicare fee-for-service patient based on the patient's clinical condition, with adjustments for facility-specific factors. Under the IRF PPS, each patient is assigned into one of 92 case-mix groups (CMGs), of which 10 are for patients with stroke, based on data reported on the IRF-PAI. A patient's CMG assignment is based on the primary impairment, admission motor and cognitive functional status, and age. Additional adjustments are made based on the presence of certain comorbidities. Five of the CMGs are for patients with stays of three days or fewer (short-stay outliers) and patients who die. A transfer rule adjusts payments for patients who are transferred to another facility and have a length of stay that is less than the mean stay for patients with the same CMG/comorbidity tier group (10).

The Medicare payment is calculated based on the CMG/comorbidity group; each has a relative weight that reflects the average costliness of patients in that group relative to the average IRF Medicare patient. A base payment amount, which is updated each year, is multiplied by the CMG/comorbidity (case mix) relative weight and the labor portion (70% in 2012) is adjusted with the facility wage index. Additional adjustments are made for rural IRFs, the share of low-income patients, teaching status, and high-cost outliers (10).

Medicare began an IRF Quality Reporting Program in 2012, with two quality metrics: (a) National Health Safety Network (NHSN) Catheter Associated Urinary Tract Infection Outcome Measure, and (b) percentage of patients with new or worsened pressure ulcers (11). Failure to submit required quality data for these two quality metrics will result in a 2% point reduction to the annual increase factor for payments made for discharges occurring during the next federal fiscal year (fiscal year 2014 for October to December 2012 data) (8). The IRF Quality Reporting Program is expected to evolve in the future to include additional quality metrics and public reporting of quality metric data for each IRF.

Patient data from IRFs have been submitted to national databases, which provide national-level statistics on patient characteristics and IRF hospitalization stay information as well as patient outcomes. Over time, patients with stroke have been admitted to IRFs sooner after the stroke, the rehabilitation stays have been shorter, and a lower proportion

of patients were discharged home from the IRF (12,13). Between 1990 and 2008, the mean onset time decreased from 22.0 days to 10.6 days. Admission functional status, as measured by Total FIM® score (score range 18–126, with higher score indicating more independence), decreased from 62.1 in 1990 to 55.1 in 2008. In 1990, the average IRF LOS for patients with stroke was 32.0 days. By 2002, with the introduction of the IRF PPS, the average IRF LOS was 19.6, and in 2008, it was 16.5 days. Discharge functional status, as measured by Total FIM® score, decreased from 87.0 in 1990 to 79.8 in 2008. The percent of patients discharged to the community decreased from 76% in 1990 to 70% in 2008, as more patients are transferred back to acute care (10% in 2008) and to other PAC providers (7.5% in 2008) (12,13).

Skilled Nursing Facilities

SNFs, the most numerous of the PAC providers, are certified by the Centers for Medicare and Medicaid Services to provide skilled nursing and therapy services. SNFs provide varying levels of physical, occupational, and speech therapy services; sufficient staff to provide 24-hour nursing services; and a physician who supervises patient care and is available 24 hours a day on an emergency basis. The patient must be seen by a physician at least once every 30 days during the first 90 days after admission, and then at least once every 60 days thereafter. In addition, respiratory therapy, dietary, pharmaceutical, dental, and medical social services are available (5).

Following the implementation of acute care PPS in the 1980s, some SNFs began providing more therapy services and admitted patients with greater needs for therapy, nursing, physician, and other services, and some referred to their programs as "subacute rehabilitation" (14). *Subacute care* is not formally recognized by the CMS, and the term has been used to describe many different types of programs. One description of *subacute rehabilitation* is: "A level of rehabilitative care designed to meet the needs of patients who medically and physically are too frail to participate in the rigors of a conventional inpatient physical rehabilitation program (i.e., 3 hours or more of daily therapy). Subacute rehabilitation also may be appropriate for patients who do not require intense multiple therapies but may have medical comorbidities and complicating factors that require the medical supervision of a physiatrist, geriatrician, or internist. Physicians usually visit patients in subacute rehabilitation two or three times per week, based on medical necessity" (15, p. 60).

There are approximately 15,207 SNFs (2010 data), of which 94% are freestanding nursing homes and 6% are units colocated in acute care hospitals or rehabilitation hospitals. Freestanding nursing homes often provide SNF services and long-term care services. Most SNFs (70%) are for-profit entities, 25% are not-for-profit entities, and 5% are government owned; 30% are situated in a rural location. Medicare payments to SNFs in 2010 totaled $27 billion (4).

Medicare beneficiaries must have a hospital stay of 3 or more days in the 30 days prior to the SNF stay to be eligible for covered SNF services. The Medicare SNF benefit covers skilled nursing care, rehabilitation services, and other goods and services up to 100 days per episode of illness, if the patient meets established criteria (5,16).

Since 1998, Medicare has paid SNFs under a per diem PPS, which covers all operating and capital costs, with certain high-cost, low-probability ancillary services paid separately. PPS payments are determined based on a patient's clinical and utilization data with adjustments for facility-level factors (16). The patient classification system for reimbursement under the SNF-PPS is the resource utilization groups (RUGs IV), and clinical data are from the patient assessment instrument called the Minimum Data Set (MDS) 3.0. Patients are assigned into one of the sixty-six RUGs (i.e., payment groups) based on the number of minutes of therapy (physical, occupational, or speech) that the patient received or will receive, an activities of daily living index based on the patient's ability to perform four activities (eating, toileting, bed mobility, and transferring), the need for certain services (e.g., specialized feeding, respiratory therapy), and the presence of certain conditions (e.g., pneumonia, dehydration). Facility-level adjustments are made for rural locations and geographic differences in labor costs (16).

Although there is no required minimum amount of therapy for patients in SNFs, when patients receive more therapy, Medicare payments are higher under the SNF PPS. Therefore, several studies have examined the amount and intensity of therapy provided to SNF patients and whether a higher intensity of therapy is associated with better patient outcomes. For example, Wodchis et al. (17) found that the amount of rehabilitation therapy was associated with a higher likelihood of patients being discharged to the community, and the relation between "dose" and outcome was strongest for patients for whom discharge to the community was uncertain or not expected. Jette et al. (18) found that higher-intensity PT and OT was associated with greater odds of improving at least one stage of mobility and self-care function for patients with stroke. Higher OT intensity and higher SLP intensity were associated with greater odds of improving by at least one stage of social cognition function. Higher SLP intensity was associated with greater odds of improving by at least one stage of mobility function.

The Medicare program has been reporting quality metric data and other information about nursing homes, including short-stay residents, on its website (www.medicare.gov/NursingHomeCompare) for several years. The current set of quality metrics includes a mix of outcome measures and process measures: (a) the percentage of short-stay residents who self-report moderate to severe pain; (b) the percentage of short-stay residents with pressure ulcers that are new or worsened; (c) the percentage of short-stay residents assessed and given, appropriately, the seasonal influenza vaccine; (d) the percentage of short-stay residents assessed and given, when appropriate, the pneumococcal vaccine; and (e) the percentage of short-stay residents who are newly administered antipsychotic medications. Additional information about facilities provided on the site includes health

inspection results and complaints, nursing home staffing (number of registered nurses, licensed practical or vocational nurses, physical therapists, and nursing assistants), and penalties levied against the nursing home. Five-star quality ratings on the website provide a summary rating that considers health inspections, quality metrics, and hours of care provided per resident by staff performing nursing care tasks.

Home Health Agencies

HHAs provide therapy, skilled nursing services, and other services to patients in their homes. Medicare beneficiaries eligible for medical services at home are generally restricted to their home (i.e., homebound) and need skilled care, either nursing care or therapy, on a part-time or intermittent basis (5). In 2011, Medicare implemented a requirement for a face-to-face encounter prior to the certification of the patient's eligibility for Medicare home health care. The certifying physician, the physician in the acute or PAC provider, or a nonphysician practitioner must have a face-to-face encounter with the patient no more than 90 days prior to the start of care or within 30 days after the start of care (5).

There are 11,815 HHAs (2010), and the average number of home health visits per user was 36.2. Approximately 3.4 million Medicare beneficiaries used HHA services in 2010, and total Medicare payments that year were $19.6 billion (4).

The CMS has been paying HHAs under a PPS since 2000. The PPS predetermined payment rate for each 60-day HHA episode is determined based on the admission assessment and service use with adjustments for geographic wages based on the patient's location, high-cost outliers, and nonroutine medical supplies (e.g., wound care products) (19). If fewer than 5 visits occur during the 60-day episode (short-stay outlier), the payment is determined per visit and per visit type instead of by the episode payment method. Patients with 5 or more visits during an episode are assigned into one of 153 Home Health Resource Groups (HHRGs) based on clinical, functional status, and service utilization data reported on the patient assessment instrument called the Outcome and Assessment Instrument (OASIS) data set. The clinical data include the primary home care diagnosis, intravenous/infusion or parenteral/enteral therapy, vision limitation, wound or lesion, multiple pressure ulcers, most problematic pressure ulcer stage, stasis ulcer status, surgical wound status, shortness of breath, bowel incontinence, and injectable drug use; these data are used to assign a patient into a low, moderate, or high clinical score group. The functional status data include dressing, bathing, toileting, transferring, and locomotion and are grouped into low, moderate, and high functional groups. Service utilization data includes the number of therapy visits and the episode's timing in a sequence of episodes (19).

The Medicare payment is calculated based on the HHRG relative weight that reflects the average costliness of patients in that HHRG relative to the average home health Medicare patient. A base payment amount is adjusted for the HHRG group (case mix) and the labor portion (77% in 2012) is adjusted with the wage index. A 3% add-on payment is provided for providers in rural locations for services provided from April 2010 through 2015 (19).

HHAs have many quality metrics that are publicly reported on the Home Health Compare website (http://medicare.gov/homehealthcompare) including: (a) how often the home health team began patient care in a timely manner; (b) how often the home health team taught patients (or their family caregivers) about their drugs; (c) how often patients got better at taking their drugs correctly by mouth; (d) how often the home health team checked patients' risk of falling; (e) how often the home health team checked patients for depression; (f) how often the home health team checked patients for pain; (g) how often the home health team treated their patients' pain; (h) how often patients had less pain when moving around; (i) how often the home health team checked patients for the risk of developing pressure sores; (j) how often the home health team included treatments to prevent pressure sores in the plan of care; (k) how often the home health team took doctor-ordered action to prevent pressure sores; (l) how often patients got better at walking or moving around; (m) how often patients got better at getting in and out of bed; (n) how often patients got better at bathing; (o) how often patients receiving home health care needed any urgent, unplanned care in the hospital emergency room without being admitted to the hospital; and (p) how often home health patients had to be admitted to the hospital. Other quality metrics focus on assessing whether patients received an influenza vaccine and a pneumococcal vaccine, treatment of heart failure symptoms for patients with heart failure, improvement in breathing for patients with breathing problems, wound improvement or healing after an operation, and foot care for individuals with diabetes.

Long-Term Care Hospitals

LTCHs are certified as hospitals and provide medical, nursing, respiratory therapy, PT, OT, and SLP services to patients with clinically complex problems who need hospital-level care for an extended period of time. Many LTCH patients are considered critically ill; common medical issues include ventilator dependence and multiorgan failure (5). LTCHs have the highest average nurse staffing hours per patient day among PAC providers, often have respiratory therapy services 24 hours a day and 7 days a week, and physicians have daily contact with LTCH patients. Medicare defines LTCHs as hospitals that have an average LOS of 25 days or longer (5). Several proposals have been put forth to redefine LTCHs based on patients' clinical characteristics, but there has not been agreement on a definition.

Medicare is the payer for approximately two-thirds of LTCH care. The number of LTCHs has grown from 86 in 1985 (3) to 406 in 2007 (4), and this rapid growth of LTCHs led to a moratorium in 2007 that is due to expire in 2017. Many of the newer LTCHs are located within acute care hospitals, and are considered a "hospital within a hospital" with their own administration and medical, nursing, and therapy staff. More

than two-thirds (75.9%) of LTCHs are for-profit entities, 19.2% are not-for-profit entities, and 4.9% are government-owned. Most (61.7%) are freestanding hospitals and 93.4% are situated in an urban location. In 2010, approximately 118,300 Medicare beneficiaries had almost 134,700 LTCH stays costing Medicare $5.3 billion (5).

Medicare implemented a per-discharge LTCH PPS in 2002, which covers all operating and capital costs, with the exception of certain high-cost ancillary services, which are paid separately (20). The patient classification system for the LTCH PPS is the Medicare severity long-term care diagnosis related groups (MS-LTC-DRGs). Data from the hospital bill (e.g., diagnosis, procedures, patient characteristics) are used to assign each patient into one of the MS-LTC-DRGs (payment groups). The MS-LTC-DRGs are the same groupings used in the acute care inpatient PPS, but the LTCH relative weights for each group are different from the acute care weights. The relative weight assigned to each MS-LTC-DRG reflects the average costliness of patients in that group relative to the average LTCH Medicare patient. A base payment amount, which is updated each year, is multiplied by the MS-LTC-DRG (case mix) relative weight. Payments are adjusted for short-stay and high-cost outliers, indirect medical education, and geographic differences in labor costs. A transfer policy discourages transfers between an LTCH and a colocated acute care hospital and transfers to colocated SNFs, IRFs, and psychiatric facilities. A "25% rule" reduces payments for LTCHs that exceed the established percentage thresholds for patients admitted from certain referring hospitals during a cost-reporting period. Less strict thresholds are applied to LTCHs located within hospitals and satellites in rural areas or in urban areas where the facility is the only LTCH and there is a dominant acute care hospital (5,20).

Medicare began an LTCH Quality Reporting Program in 2012, with three quality metrics: (a) NHSN CAUTI Outcome Measure; (b) percent of patients with new or worsened pressure ulcers; and (c) NHSN Central Line-Associated Bloodstream Infection Outcome Measure. Failure to submit required quality data for these three quality metrics will result in a 2% point reduction to the annual increase factor for payments made for discharges occurring during the next federal fiscal year (fiscal year 2014 for 2012 data) (21). Beginning in 2014, data collection begins for two additional measures: (a) the percent of patients who were assessed and appropriately given the seasonal influenza vaccine and (b) influenza vaccination coverage among health care personnel (21). With the implementation of the LTCH Quality Reporting Program, LTCHs began collecting standardized clinical assessment data on a patient assessment instrument called the LTCH CARE data set. The LTCH Quality Reporting Program is expected to evolve to include additional quality metrics and public reporting of quality metric data for each LTCH.

Outpatient Therapy Services

Outpatient therapy services include PT, OT, and SLP services and are provided in a variety of settings: private practices, hospital outpatient departments, outpatient rehabilitation facilities, comprehensive outpatient rehabilitation facilities (CORFs), and, in some circumstances, at home. For Medicare fee-for-service beneficiaries, Part B of Medicare pays for outpatient services as well as therapy services for individuals who are nursing facility residents in nursing homes. Medicare covers outpatient therapy services if they are provided by a skilled professional, are appropriate and effective for the patient's condition, and are reasonable in terms of frequency and duration.

Medicare pays for outpatient therapy based on fees established in the physician fee schedule and services are classified and reported using the Healthcare Common Procedure Coding System. Payments are based on relative weights called *relative value units* (22). There are annual spending limits, referred to as *therapy caps*, on Medicare payments for outpatient therapy services. One spending limit applies to PT and SLP services and a separate limit applies to OT services. If additional services are considered reasonable and medically necessary, an exemption from the therapy caps may be requested. Research examining outpatient therapy alternatives is underway. Medicare spending on outpatient therapy services was approximately $5.7 billion in 2011, with almost three-quarters of therapy services attributed to PT (22).

UTILIZATION OF PAC SERVICES

Utilization of PAC services increased when acute care LOS decreased. The acute care LOS for patients with stroke decreased dramatically between 1989 and 1999, but not in the 10 years thereafter. The average length of stay was 10.2 days in 1989, 5.4 days in 1999, and 5.3 days in 2009 (23). Patients in the acute hospital with disabling strokes may be discharged to institutional settings or home, depending on a variety of factors such as severity of stroke; care needs (including need for continued hospitalization in a rehabilitation hospital setting); coexisting medical conditions; payment systems; availability of beds and caregivers; options within the geographic area; provider, patient, and family preferences; or cultural factors.

Population-based studies have documented significant differences in the percentages of patients who are discharged to each of the different types of PAC providers. An analysis of 2006 Medicare claims data showed that among patients who were assigned to the Medicare severity diagnosis related groups intracranial hemorrhage or cerebral infarction, with comorbidities or without complications in acute care, 75.0% used PAC services. Of these patients, 37.0 were discharged to an IRF, 36.8% were discharged to an SNF, 17.3% were discharged to home with HHA services, 7.7% used outpatient services, and 1.2% were discharged to an LTCH (24). Studies have shown significant geographic variation in PAC utilization, however. One study found that IRF, SNF, and HHA care among Medicare stroke patients varied from 82.1% in Washington state to 59.1% in Oklahoma (25). In a more recent Medicare study, IRF utilization ranged from a high of

57% in Massachusetts to a low of 34% in Alaska; as IRF and SNF utilization tend to vary proportionally, the ratio of IRF to all inpatient care received across states varied from 22% in Connecticut to 59% in Nevada (26).

Patient characteristics that may play a role in decisions about PAC care include age, severity of stroke, burden of care, comorbid conditions requiring physician decision making or nursing care, and cognitive and physical capacity to participate in a therapeutic program of activity and exercise. Many studies have found that older patients are more likely to go to an SNF than an IRF (25–31). In one study, stroke patients treated in IRFs were more functionally independent on admission, had better cognitive function, and were more likely to have caregivers (32); however, in a recent study in another health system, IRF patients were more functionally impaired than patients in other PAC groups (28). Not unexpectedly, studies have found that living alone or being unmarried, widowed, or divorced, or being a woman increased the likelihood of discharge to SNF rather than IRF (32,33). Patients being discharged to home after an acute care stay tend to have shorter stays in the acute hospital and be less impaired at the time of acute care discharge (32,34).

Race and ethnicity may be a determinant of discharge destination or care trajectories for stroke patients, likely because of cofactors such as stroke severity, socioeconomic status, or availability of caregivers. Black patients, and those with low incomes, experience more severe strokes and a worse "trajectory of functional recovery" in the first year after the stroke (35–37). A Medicare sample analysis from 297 hospitals in 5 states showed more black patients than white patients receiving PT and OT services, but black patients had more motor deficits (36). A Los Angeles study of community-dwelling patients with stroke and other diagnoses found that minority populations, patients with less education, and the oldest patients were significantly less likely to use PT and OT outpatient services (38). Results of both a Maryland study and a California study suggested that black patients experiencing a stroke were more likely than white patients to go to an IRF (39,40). In the same California study, Asian patients were more likely to go to IRF as well (33). Hispanics and Asian populations have a greater incidence of hemorrhagic stroke, and hemorrhagic strokes are associated with greater degrees of functional impairment than ischemic strokes (40), and thus patients with these conditions may be more likely to go to an IRF (33). A study of stroke patients in the Veterans Administration system, however, found no racial differences in IRF care (41). Patient characteristics may not explain all of this variance, and cultural factors such as the availability of caregivers are a possible unstudied cofactor (33,42).

Different health service markets are likely drivers of some of these variations (43,44). Distance to IRF or SNF facilities in a geographic area also influence utilization and create variation in care (33,42). As SNFs are represented in greater numbers than IRFs in most areas of the country, the likelihood of patients going to an SNF is proportionally greater when geographic factors influence decisions. Choice of provider may be influenced by both provider and patient/family choices owing to these factors. One study found that SNF utilization increased as SNF bed availability increased (27). In the same study, 50% of stroke patients received care in an acute hospital with an SNF distinct-part unit, and nearly 38% received care in one with an IRF distinct-part unit. Having either type of unit increased the likelihood of patients being treated in that unit.

Payment systems also influence discharge destinations following acute care. Payment systems for PAC have undergone dramatic changes over the past few decades. The change to PPSs for PAC providers has had a major impact on utilization (45,46). For example, after PPS implementation in SNFs and HHAs in 2001, there was a 46% decrease in HHA utilization (number of episodes), whereas SNF care episodes increased by 28%, and those involving LTCH, IRF, or psychiatric inpatient care increased by 33%; episodes of SNF care followed by HHA care decreased by 13%; and those involving other trajectories increased by 17% (47). Another study of patients with stroke and other diagnoses showed substantial increases in the use of IRFs when the SNF PPS was being instituted (48). Copayment systems, more prevalent over the last decade, have also influenced patient and provider choices. One study found that patients with a second source of health insurance in addition to Medicare were more likely to use SNFs than HHAs (49).

The specialty of the physician may influence decisions about PAC selection. One study found that neurologists were more likely to discharge patients to IRFs (21.9%) as compared to internists (16%) or family practice physicians (13%). Conversely, family practice physicians and internists were more likely to discharge patients to SNFs (39.6% and 33.1%), compared with neurologists (22.2%) (50).

Triage of stroke patients from the acute care hospital to a PAC provider usually occurs with input from clinicians, patients, and families. Beginning in the 1980s, stroke guidelines have been developed by organizations and health systems in the United States and abroad that include decision-making criteria and care delivery processes (51–53), including care transitions and interdisciplinary care (54). The Joint Commission certification process for stroke centers also includes a requirement for assessment for rehabilitation (55). CARF, formerly known as the Commission on Accreditation of Rehabilitation Facilities, developed stroke program accreditation standards that include information for decision making about rehabilitation following discharge from an IRF (56).

Variation in utilization of PAC services by stroke patients is still incompletely explained. One study found that half to two-thirds of practice variation in utilization of rehabilitation services could not be explained by differences in patient characteristics and market conditions (43). As further changes in health care delivery systems take place, undoubtedly more changes in PAC utilization will also occur. Reimbursement for episodes of care rather than reimbursement based on each care setting, for example, will further drive changes in how care is delivered over time for patients with

stroke (57). Both in the United States and abroad, stroke care is being organized across the care continuum (58).

TRACKING OUTCOMES ACROSS PROVIDERS OF CARE

A number of studies have tracked functional outcomes of patients with a history of stroke over many months and even years. In a Framingham study several decades ago, researchers found that "significant recovery" occurred primarily during the first three months, with marginal gains made after that time point. In a Danish study, patients were assessed at the end of the rehabilitation program and then at six months. The researchers concluded that a reliable prognosis is possible by 12 weeks of stroke onset. Best ADL function was reached, for example, within 8.5 weeks for mild strokes and within 20 weeks for patients with severe strokes. In an Italian study, postdischarge outpatient rehabilitation, performed on 46.5% of the sample, was significantly and positively associated with functional improvement and absence of functional worsening in the year following discharge from the rehabilitation hospital. Age greater than or equal to 65 years and hemi-neglect were predictors of functional worsening at follow-up. In an Australian study, two-thirds had good functional outcome, 22.5% had cognitive impairment indicative of dementia, 20% had had a recurrent stroke, 15% were institutionalized, and almost 30% had symptoms suggesting depression at 5 years after stroke.

Transfers from one PAC provider to another have increased with the implementation of the PAC PPSs and reduced length of PAC stays. Most patients with moderate to severe strokes are treated by multiple providers over the months following a stroke. An analysis of all Medicare patients (all diagnoses) showed that among patients who were discharged from an acute care hospital to an IRF, only 12.3% did not use additional PAC services in the episode. More than a quarter (27.3) completed the episode with HHA care, 16.9% went from acute care to an IRF to outpatient, and 0.2% used LTCH services after the acute and IRF stay (59). In a recent study of stroke patients in an integrated health system, patients were followed for six months from one provider to the next. The most common pathways for patients whose first PAC provider was an SNF or IRF also included HHA and outpatient services, and some patients had PAC in every type of provider (HHA, outpatient, IRF, and SNF) (28,34).

The increase in utilization of multiple PAC providers makes utilization and outcome research difficult. The PAC PPSs and the quality reporting programs have been largely developed for each type of provider. Each type of provider collects clinical data, and much of the data covers similar concepts, but data are collected using different assessment items. Therefore, functional status data from the different PAC providers cannot be compared directly. This provider-based framework does not encourage or incentivize collaboration or accountability among providers in care placement decisions or quality measurement. Furthermore, no single provider is accountable for patient outcomes at the end of the episode. Efforts are underway to develop and test a standardized set of clinical items, including functional assessment items, to assess and track patients across the care continuum (28,34,60).

Under the current fee-for-service program, Medicare pays the PPS payment amount for each provider separately, so transferring a patient from one PAC provider to another means each provider receives a payment from the Medicare program. This may encourage utilization of multiple PAC providers, and raises concerns about added costs owing to duplication of services, overuse of services that do not benefit the patient, and poor coordination of services across multiple transitions, including provider-to-provider transitions and provide-to-home transitions.

The Agency for Health Care Policy and Research (AHRQ) defines care transition interventions for stroke in a report that included a systematic review of the literature (61). Although there was limited evidence for a benefit of these interventions in stroke populations (only for early supported discharge), further research using standard definitions was recommended. The categories are outlined in Table 42.1.

As new models of health care delivery evolve with changing incentives and reimbursement models, there will likely be collection of common assessment items and quality metrics within health systems to track outcomes after stroke. The new models of care will require sophisticated and well-defined care transition interventions, and clear roles

TABLE 42.1 Care Transitions Interventions (AHRQ)

Type 1: Predetermined integrated-care pathways, early supported discharge, extended stroke unit services, and rehabilitation coordination with community services, referral for subsequent subspecialty care, and follow-up (if it was part of discharge planning), and education of the patient and family prior to discharge
Type 2: Direct teaching by subspecialty trained nurses
Type 3: Following hospital discharge, community-based support of the patient and family provided through advanced practice nurse care managers, primary and specialty care medical practitioners, and multidisciplinary care teams (including doctors; nurses; social workers; and physical, occupational, and speech therapists), provided in person at the patient's home, by telephone, or at a clinical practice setting and patient and family education at the community level
Type 4: Chronic disease management

and responsibilities for care providers and other administrative staff within these systems (34). Electronic health records (EHRs) present opportunities for decision support and for tracking and measuring outcomes, if they are appropriately designed and staff are trained to utilize them effectively. Three outcome measures that are important to measure within and across the various PAC providers are readmissions to the acute hospital, function, and mortality.

Stroke patients are at high risk for hospital readmissions, and risk-standardized models are required to compare rates across time or across providers of care (62). Acute care hospitals are financially penalized for high readmission rates for patients with selected diagnoses, and stroke is likely to be one of those conditions identified in the future, according to an AHRQ report on the process of transitioning the care of patients from the hospital to the community (61). In the future, the report states, "Better management of patients' care will require management across multiple providers and settings. It will soon be expected that acute-care settings accept the responsibility to manage care transitions and avoid rehospitalizations" (p. 2). The report goes on to state, "These policies will increase the incentives for acute-care hospitals to develop effective transition of care programs and support integrated care. It will be important for health systems to develop and implement sustainable transition of care models in collaboration with primary care, other postacute health care systems (e.g., home health, rehabilitation centers, SNFs), community-based services, and patients and their families" (p. 2). In addition to the acute care readmission efforts, IRFs, SNFs, HHAs, and LTCHs are also expected to have readmission data publically reported and may be financially penalized for higher than expected unplanned readmission rates.

Several studies have examined outcomes for patients with stroke treated in IRFs and SNFs and found that IRF patients tended to have better outcomes at PAC discharge (30,60) or after discharge (31,63). Most recently, in one large population study funded by CMS, IRF patients with nervous system disorders, including stroke, achieved 32% better functional improvement in self-care than SNF patients, whereas HHA and LTCH patients' outcomes were not statistically different from those of SNF patients after controlling for patient acuity. Provider setting was not a significant predictor of change in mobility from admission to discharge in this study (60).

Few studies have measured outcomes in stroke populations across multiple types of PAC providers. In a recent study of patients with stroke who were treated in one integrated health system and followed across care settings over a six-month period, care in an IRF following discharge from the acute hospital was associated with greater functional outcome at six months when compared to SNFs and HHA care after controlling for age, functional status at acute care discharge, and total hours of rehabilitation, even though patients had more severe strokes in the IRF group (28). Studies with larger numbers of subjects will further the work in studying both utilization and outcomes for patients with a history of stroke.

FUTURE DIRECTIONS

Patients with stroke may receive PAC services from an IRF, SNF, HHA, LTCH, or outpatient provider. Increasingly, patients are receiving care in multiple PAC settings. Efforts are underway to move away from the current provider-centric health care delivery system that rewards volume (i.e., PAC-to-PAC transfers) toward a patient-centered system with a value-based purchasing program that includes incentives for quality and safety—measured with both process metrics and outcome metrics. Although the quality initiatives for each type of provider have largely been developed separately, there are efforts to align and harmonize the assessment items and quality metrics across PAC providers. The CMS Innovation Center has several initiatives and demonstrations underway, including the Bundled Payments for Care Improvement efforts and the Accountable Care Organizations initiatives (http://www.innovations.cms.gov/initiatives/index.html). It is not clear which models of care might be implemented beyond initial testing or how these models might evolve over time. It is challenging to identify delivery system reform that aligns incentives for all key stakeholders, including patients, providers, payers, and policy makers. However, there are opportunities to improve care management for patients discharged from acute care hospitals. There is a need for clinical integration between acute and PAC providers and between PAC providers. Key drivers of cross-provider clinical integration should include physicians participating in decision making and overseeing care across multiple services settings, availability of electronic health records and information technology for decision support, and transmission of information (i.e., interoperability) across sites of care (64).

The conclusions of a recent Institute of Medicine (IOM) Report suggest that there will be a much greater focus on PAC given the findings that if there were no variation in PAC spending, variation in Medicare costs would fall by 73% (65).

CONCLUSION

Major changes in PAC have taken place over the past several decades. Changes in the delivery of care and payment systems are occurring rapidly and will likely drive more integration of PAC and possibly result in less variation in care. Common systems of data collection and measurement of patient characteristics, structure, and processes of care, including staffing models, therapeutic interventions, and process and outcome measures, will provide the foundation for comparative effectiveness research in PAC.

Rehabilitation of Children After Stroke

Nico U. F. Dosenbach and Michael J. Noetzel

Over the past two decades, there has been growing recognition of the incidence, severity, functional ramifications, and therefore, rehabilitation needs of pediatric stroke survivors. Although mortality related to stroke in the pediatric population appears to have lessened over the past 20 years (1), cerebrovascular disease remains one of the top 10 causes of death in children (2). Five to ten percent of all pediatric patients who suffer a stroke will expire (3,4), with the highest death rates encountered during the first year of life (2).

Stroke is now a well-recognized cause of chronic morbidity in children that interferes with the normal development of cognitive, gross and fine motor, communication, and psychosocial skills. Disability caused by pediatric stroke and its impact on a child's quality of life endures over a lifetime, typically lasting decades. The economic costs to society of childhood stroke in the acute phase and over the subsequent 5 to 10 years are substantial (5–7). Lifelong economic burden attributable to pediatric stroke on an individual basis is likely equivalent to that of stroke in an adult (6).

As a result, services must be provided over an extended period of time to address the deficits caused by stroke in this young population. Stroke recovery and rehabilitation in the perinatal/childhood population differ significantly from that in the adult population. In children, the profound disruption created by a stroke is often exacerbated secondary to impairment of development, psychological maturation, and, in some instances, physical growth. Although brain injury from a stroke is not progressive, the resultant deficits in neurological function almost always evolve over time commensurate with ongoing maturation of the central nervous system (CNS). Residual neurologic dysfunction is seen in the majority of pediatric stroke survivors. This chapter reviews epidemiology, clinical manifestations and diagnosis, outcomes, and acute management for all classifications of stroke in children, although the primary focus is on the subacute rehabilitation program, neurobiological mechanisms of stroke recovery, and novel therapeutic options to enhance stroke recovery.

Our common goal of improving rehabilitative therapies for young and old stroke patients will be greatly aided by a more profound understanding of the basic mechanisms of stroke recovery (8). Brain reorganization strategies following adult stroke are an important focus of research (9,10) and increasingly are being incorporated into new rehabilitative approaches. For pediatric stroke, a greater understanding of brain recovery should also translate into more meaningful and effective treatments that promote the best possible functional outcomes (11).

CATEGORIES AND EPIDEMIOLOGY OF PEDIATRIC STROKE

Types of Pediatric Stroke

In pediatrics, classification of stroke begins with determining when the event occurs. *Perinatal stroke* is defined as a cerebrovascular event that transpires between 28 weeks of gestation and 28 days of postnatal age. A subtype of perinatal stroke, labeled *presumed perinatal arterial ischemic stroke*, has also been described (12). This refers to infants who appear to be neurologically normal at birth and up through the first few months of life before developing signs of hemiparesis, most commonly in the form of an early hand preference (13); brain imaging studies on these infants demonstrate a prior lesion consistent with a perinatal, typically ischemic, stroke. *Childhood stroke* is defined as a cerebrovascular event that occurs between 29 days and 18 years of age. In addition to age at onset, stroke in the pediatric population can further be subdivided by the type of vascular involvement (arterial and/or sinovenous), the presence (thrombotic) or absence of a clot, and the predominant mechanism of injury (ischemic and/or hemorrhagic), although overlap is considerable. Ischemic stroke is either arterial (AIS) in origin or secondary to cerebral sinovenous thrombosis (CSVT). In AIS, occlusion may be associated with an arteriopathy or thromboembolism; the resultant focal infarction is localized to the vascular distribution of the artery. In contrast, CSVT is defined by thrombosis of the cerebral veins and/or dural venous sinuses. The thrombosis usually produces symptoms but may not result in parenchymal venous infarction; when present, the infarct may be ischemic or hemorrhagic. Over the past 30 to 40 years, the incidence of all forms of pediatric stroke appears to be increasing (14,15).

Pediatric Stroke Epidemiology

Historically, the incidence of all stroke subtypes in the pediatric population was thought to be 2 to 3 per 100,000 children (16,17). Although these findings are consistent with some recent studies (1,18), other data on pediatric stroke suggest a near-doubling from 2.8 to 5.4 per 100,000 in the years 1989–1999 (19). Higher incidence levels have also been reported in a population-based study from Europe (13 per 100,000) (20) and by Lynch (10.7 per 100,000) utilizing a National Hospital Discharge Survey (14). Even taking a conservative approach to the incidence of pediatric stroke (roughly 5–8/100,000 children/year), this figure makes stroke in older infants and children more common than pediatric brain malignancies (14). Despite the relatively large number of publications assessing the incidence rate of pediatric stroke, there remains confusion regarding the relative contributions of ischemic and hemorrhagic stroke to the total number. In some studies, ischemic injury predominates; in others, hemorrhagic stroke is more common; and in a third set, the rates are seemingly equivalent (1,14,16,17,20,21).

The increased frequency with which childhood strokes are being recognized relates predominantly to the development and greater availability of noninvasive and sensitive imaging techniques, most importantly magnetic resonance imaging (MRI). Diagnoses are being made earlier (22–26) and often under circumstances in which stroke previously might not have been a strong diagnostic consideration. Two notable examples are so-called silent cerebral infarcts (SCI) in patients with sickle cell disease (SCD) and perinatal stroke (presumed and overt). Ischemic stroke carries the highest risk in the neonatal period, where an incidence of 1:2500–4000 live births makes it a common cause of brain injury and resultant cerebral palsy. Another important factor contributing to the rise in pediatric stroke recognition is the lowering in mortality that has occurred in a wide spectrum of childhood diseases predisposing to stroke, such as pediatric cancers and congenital heart disease.

PEDIATRIC STROKE PATHOPHYSIOLOGY AND RISK FACTORS

Childhood AIS

It is incumbent upon clinicians to ascertain any and all causes of ischemic brain injury in a timely fashion, so as to inform potentially appropriate interventions (27–29) and predict the risk of stroke recurrence. Important information regarding risk factors for childhood stroke can be found in population-based studies and through large databases, most notably the International Pediatric Stroke Study (IPSS) group (29,30). However, potential etiologies for childhood AIS are numerous and there are frequently multiple risk factors in a single child. Despite thorough investigation, up to one-third of the cases of children with AIS are classified as idiopathic, that is, no cause can be uncovered. Although chronic diseases predispose to childhood AIS, nearly 50% of the cases occur in a previously healthy child (31). However, more than half of the pediatric patients will have two or more risk factors identified if properly evaluated, thus again emphasizing the need for thorough and overlapping assessments (29). The conditions that lead to stroke in adults, such as diabetes, high blood pressure, or atherosclerosis, are uncommon in children (32,33). For the pediatric patient, the variety of risk factors is expansive (34). There are, however, four major categories of risk factors: arteriopathy, SCD and other hematologic disorders, cardiac disease, and prothrombotic disorders (Table 43.1).

TABLE 43.1 Risk Factors for Pediatric Stroke

Childhood Arterial Ischemic Stroke
Arteriopathies—including "transient cerebral arteriopathy," craniocervical dissection, and moyamoya syndrome
Hematological—especially sickle cell disease
Cardiac—including congenital heart disorders (especially those with complex cyanotic anatomy) and catheterization procedures and bypass surgery
Prothrombotic—Factor V Leiden mutations, protein C deficiency, increased lipoprotein(a) levels, prothrombin G20210A mutations, lupus anticoagulant, and antiphospholipid antibodies
Hemorrhagic Stroke
Structural cerebrovascular anomalies—including AVM, vein of Galen malformation, congenital aneurysm, and cavernoma
Sickle cell disease
Tumor
Trauma
Childhood Cerebral Sinovenous Thrombosis (CSVT)
Head and neck infections—especially otitis media, mastoiditis, and sinusitis
Dehydration
Trauma
Prothrombotic—see above
Perinatal Stroke and CSVT
Cardiac disease
Acute systemic illness
Maternal prothrombotic and autoimmune disorders
Neonatal infections
Complications of labor and delivery
Pregnancy as a naturally occurring prothrombotic state

Arteriopathies

Cerebral arteriopathies have emerged as a leading cause of childhood AIS, being present in up to 50% of cases (27,28,30,31,35,36). In addition, these disorders typically result in a worse outcome and have an increased risk of stroke recurrence (22,28,37). Thus, detailed vascular imaging has become an increasingly important tool in the diagnosis of pediatric stroke (28,36,38,39). There are three most commonly identified forms of cerebral arteriopathies in childhood (40). The first is a relative common arteriopathy that occurs in otherwise healthy school-age children. Vascular studies typically

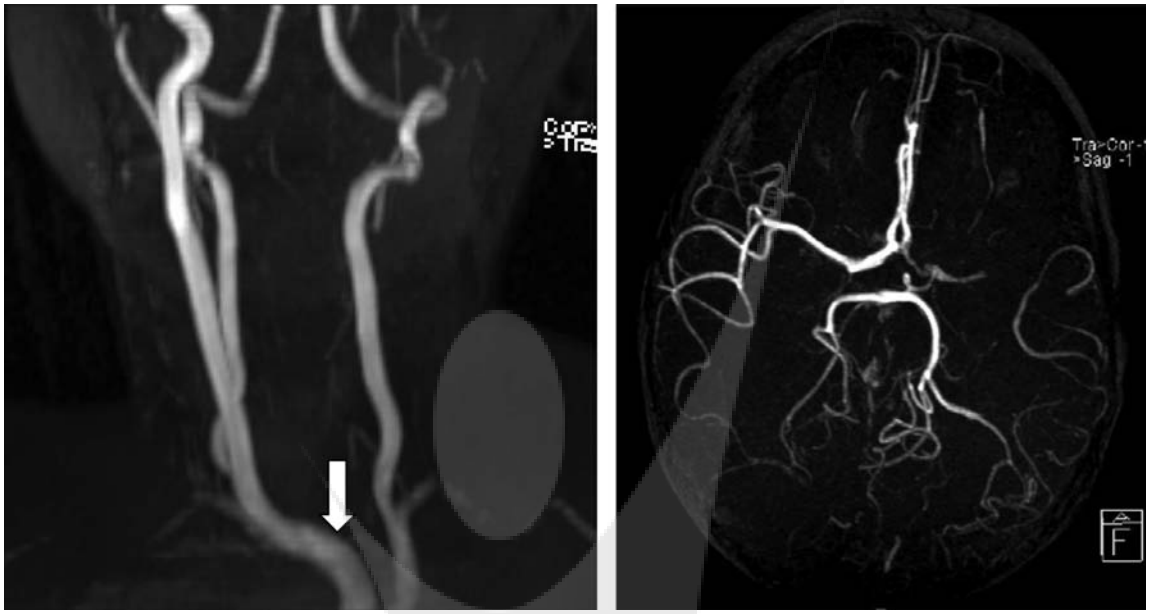

FIGURE 43.1 Occlusion of the left common carotid artery, just after the takeoff from the aortic arch (arrow) caused by a dissection, as seen on conventional angiogram on right and MRA on left.

reveal irregular narrowing or stenosis of an affected vessel wall within the distal internal carotid, proximal middle or anterior cerebral arteries, or some combination thereof. The resultant infarctions are within the lenticulostriate territory, producing unilateral basal ganglia injury. Initial descriptions were classified as "transient cerebral arteriopathy" (TCA) (35,41). It is now recognized that the vast majority are nonprogressive, although early follow-up with serial imaging may reveal increasing vessel narrowing followed by stabilization or lessening of stenosis after two to eight months. The specific etiology of TCA remains uncertain but includes infectious and inflammatory processes. Post- and parainfectious mechanisms have also been evoked in view of the similarity of TCA to postvaricella angiopathy. Indeed, data documenting the role of infection/inflammation in most forms of childhood stroke are accumulating rapidly (42).

The second type of pediatric arteriopathy is craniocervical dissection in either the carotid or posterior vertebrobasilar circulation (Figure 43.1). This dissection causes formation of a subintimal hematoma and represents up to 20% of childhood AIS, most commonly via a mechanism of artery-to-artery thromboembolism (43–45). In the pediatric population, extracranial dissection is three times more frequent than intracranial dissection (45). Dissection often is the result of mechanical distortion of the arterial wall, such as from trauma to the neck, spine, or retropharyngeal area or less overt insults, including exercise, contact sports, and the type of "minor trauma" that occurs on a daily basis in active children (44,45). As symptoms may not be expressed for up to 7 to 10 days following the precipitating event, determining an exact etiology often is a challenge. Finally, some preliminary studies have suggested that inherent differences in connective tissue structure, detectable on skin biopsy (but not physical examination) may predispose to arterial dissection (46,47). Regardless of the cause, a diagnosis of dissection is important, as the risk of recurrent stroke may be 20% or higher (43–45).

Moyamoya syndrome, the final common type of pediatric arteriopathy, is characterized by progressive occlusion typically of the distal internal carotid arteries bilaterally at the circle of Willis, resulting in the evolution of small collateral vessels; the syndrome produces the angiographic picture of a "puff of smoke" (48,49). In the United States, moyamoya as a syndrome is seen more commonly in SCD, trisomy 21, neurofibromatosis type 1, and postradiation vasculopathy, among others (49,50). Genetic causes of moyamoya have also been described, which may explain the prevalence of the idiopathic form in the Asian population (51).

Sickle Cell Disease

SCD is the most common hematological etiology of pediatric stroke. It has been estimated that children with SCD are 200 times more likely to experience an AIS compared to other children without sickle cell. About 12% of the pediatric SCD population will experience a clinically recognized cerebrovascular event, with an average age of onset being 7 to 8 years (52–54). In addition, roughly 25% of children with SCD, but without a history of an overt stroke, will have SCI detected on surveillance MRIs before 6 years of life (55) and up to 37% by age 14 (56). Risk factors for SCI include relatively high systolic blood pressure, low baseline hemoglobin, and male gender (57). Accumulatively, by age 14, almost 50% of SCD children will develop cerebrovascular complications, including vasculopathy/moyamoya, overt strokes, SCIs, or abnormal transcranial Doppler values (56).

Overt strokes are ischemic in roughly 75% and hemorrhagic in 25%, with the latter increasing above age 20 (58). Stroke is responsible for 10% of pediatric deaths in SCD (59).

AIS in SCD is secondary to two major pathophysiologic mechanisms. First, sickling in the small cerebral arteries distally causes thrombosis and occlusion, with resultant multifocal small infarcts typically within the deep white matter (60). In contrast, larger infarcts predominate in cortical areas within a defined vascular distribution or in watershed areas. These strokes often are related to progressive internal carotid vasculopathy consistent with moyamoya. The vasculopathy is hypothesized to be the result of chronic effects of increased carotid blood flow damaging endovascular surfaces, although proinflammatory genetic polymorphisms also may be operant in the evolution of vascular disease (58,61).

Over the last two decades, transcranial Doppler studies have noninvasively detected SCD patients with elevated flow rates (above 200 cm/s) who are therefore at high risk for stroke (62). It is now well accepted that in children with elevated TCD, regular transfusion therapy to lower hemoglobin S by 20% to 30% can significantly reduce (90% reduction) both the initial and recurrent stroke rates (56,62). Unfortunately, the risk of stroke returns following discontinuation of transfusions (63). A similar trial looking at children with SCI in the context of normal TCD values is nearing completion (64).

Cardiac Risk Factors

Abnormalities in cardiac structure and rhythm, ventricular and valvular function, and other factors common to cardiac disease such as altered blood viscosity and flow can generate both extra and intracardiac thrombi that may embolize to the cerebral circulation. Thus, heart disease is another major risk factor for pediatric AIS, present in up to 25% of stroke cases in infancy and childhood (27,31,65). In cases of congenital heart disease, typically the condition will have been recognized well before the stroke occurs. A distribution of ischemic lesions in multiple distinct vascular territories mandates a comprehensive cardiac evaluation, even in cases where another putative risk factor has been identified.

Congenital heart disease, most notably with complex cyanotic anatomy, imposes the greatest risk of stroke, partly because of the necessity for catheterization procedures and surgery with bypass. For example, approximately one child out of every 650 children evaluated with a cardiac catheterization will sustain a stroke (66). In pediatric patients undergoing cardiac surgery, the risk for AIS is 5 to 6 per 1000 (67,68). Surgical interventions, especially the Fontan procedure, significantly elevate the risk of stroke, with estimates for an acute or delayed stroke as high as 20% (69,70). Not all ischemic lesions in children with congenital heart disease cause clinically overt stroke symptoms; in fact, silent infarctions have been identified even in the absence of surgery (71).

Prothrombotic Disorders

Inherited and acquired defects in coagulation, fibrinolysis, and platelet adhesion are the final common risk factors for pediatric AIS, all through the pathological formation of thrombi. The exact role and frequency of thrombophilia in childhood stroke are less clear, because of the large number of disorders potentially involved; the inconsistent laboratory methods utilized; timing of the tests performed; and, most significantly, the sparsity of case-controlled studies available. In addition, many patients with prothrombotic disorders have additional risk factors for stroke (39,72). Nonetheless, coagulation disorders have been documented in 25% to 50% of children with AIS (73–76), with Factor V Leiden mutations causing resistance to factor degradation appearing as one of the stronger associations (39). Based on case-control studies, protein C deficiency, increased lipoprotein(a) levels, prothrombin G20210A mutations, lupus anticoagulant, and antiphospholipid antibodies are each found more commonly in children with AIS (31,75,77,78). Also, stroke has been reported in the context of acquired deficiencies of both protein S and C resulting from antibodies presumably secondary to viral infections such as varicella and bacterial sepsis (74,75,79). The role that platelet abnormalities may play in childhood AIS, though likely important, has not been examined in a critical fashion; more detailed reviews are available (75,76,80).

Pediatric Hemorrhagic Stroke

Initial figures suggest that roughly one-third of pediatric strokes are hemorrhagic when the perinatal population is included (1). In more recent studies, the incidence rates of the two appear comparable, estimated at 1–5/100,000 children/year (15). Risk factor(s) for hemorrhagic stroke can be identified in up to 80% to 90% of the cases. Structural anomalies of the cerebral vasculature, including arteriovenous malformation (AVM), congenital aneurysm, and vein of Galen malformation, collectively account for about 50% of all hemorrhagic strokes in the pediatric population (81–83). Other "ischemic stroke" conditions such as SCD and postinfectious vasculopathies can result in primary hemorrhage. In addition, significant hemorrhagic transformation occurs in more than 50% of CSVT ischemic stroke (84) (Figure 43.2). Intracranial tumors have been documented as the source of brain hemorrhage in roughly 2% to 10% of cases (81–83). Finally, trauma is a frequently observed cause of intracranial and intraparenchymal hemorrhage, whereas hematologic disturbances other than SCD must be considered in any child with intracranial bleeding in the absence of an anatomic disturbance (83).

Most hemorrhagic strokes are supratentorial, with approximately equal involvement of the hemispheres (81,82). Neurological deficits noted at presentation typically reflect impaired function as a result of direct neuronal injury or secondary impairment in cerebral perfusion and alteration in local metabolism. In pediatric survivors of hemorrhagic stroke, outcome generally is better compared to AIS patients, a finding often attributed to the phenomenon of a blood clot displacing neuronal tissue rather than destroying it.

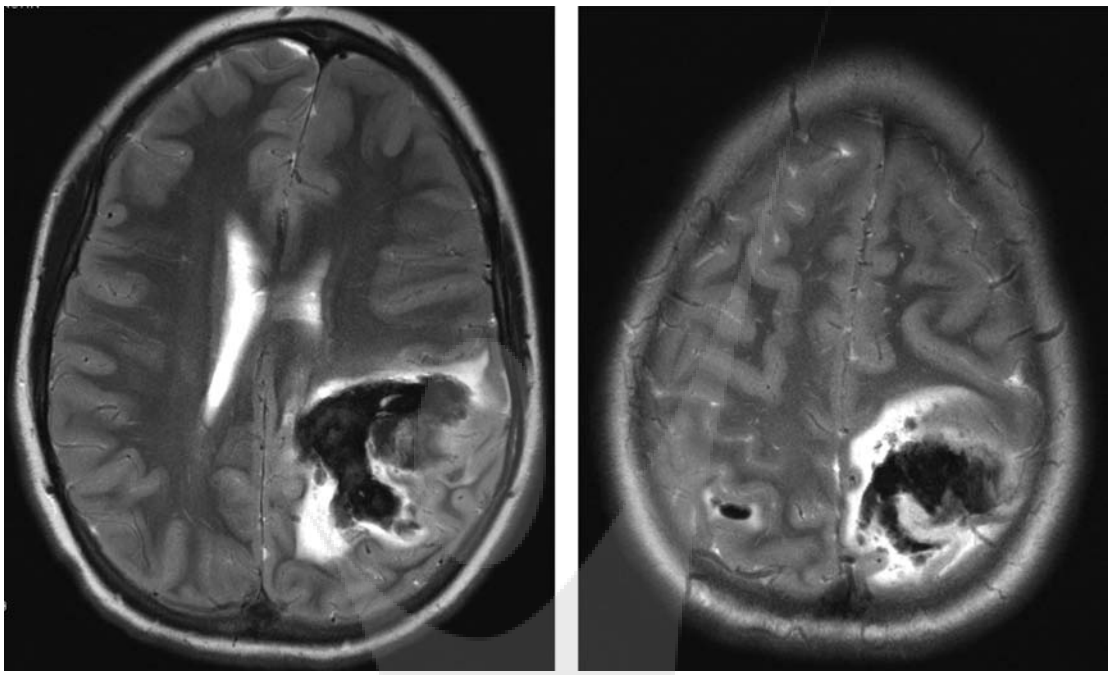

FIGURE 43.2 Noncontrast MRI demonstrating bilateral parietal hemorrhages (left much greater than right) with blood products undergoing evolution. These hemorrhagic strokes occurred in a patient with an acute systemic illness and the cerebral sinovenous thrombosis seen in Figure 43.3.

This same phenomenon also dictates that in contrast to ischemic stroke, treatment of hemorrhage often necessitates neurosurgical intervention caused by the evolution of cerebral edema and risk of herniation.

Cerebral Sinovenous Thrombosis

A recent analysis indicates that CSVT represents about 25% of childhood AIS. An incidence of one in 100,000 pediatric patients per year has been established, with the greatest risk in the neonatal period (85). CSVT includes thrombosis within the cerebral venous system (Figure 43.3), whether symptomatic or not. In contrast to AIS, half of patients will have a thrombus within the cerebral venous system but no visible parenchymal lesions at presentation, and some of these patients will be asymptomatic. In the remaining children, a venous infarction, often hemorrhagic, is observed (85,86) (Figure 43.2).

Risk factors for CSVT typically are multiple and related to age of onset. In the neonatal period (see below), acute systemic events and cardiac disease predominate, whereas in young children dehydration, head and neck infections, and other factors are more common. The latter includes trauma and systemic illness, especially in the older age groups. Otitis media, mastoiditis, sinusitis, and meningitis, which may be present in almost a third of preschool children, should

FIGURE 43.3 Magnetic resonance venogram (MRV) showing venous sinus thrombosis involving almost all of the superior sagittal sinus. The small size of the left transverse and sigmoid sinuses probably is a normal congenital variant.

TABLE 43.2 Differential Diagnosis of Acute Stroke-Like Symptoms

CATEGORY	FEATURES DISTINGUISHING FROM STROKE
Migraine	Complete resolution and shorter duration of symptoms, presence of headache
Seizures	Presence of tonic/clonic or other uncontrolled movements always precedes weakness (in cases of Todd's paralysis)
Cerebellitis	Predominant finding of ataxia in legs and trunk
Syncope	Awareness at onset of impending faint, absence of persistent neurological deficits
Meningitis	Fever, encephalopathy, meningeal signs
ADEM	Encephalopathy, multifocal symptoms and distribution of lesions in brain imaging
Psychogenic	Inconsistent or nonphysiologic findings on exam
Toxin ingestion	Encephalopathy, restricted age (typically between 1–3 years)

always be a consideration in CSVT (84,85,87). Prothrombotic disorders are fairly evenly distributed over the pediatric age range. The frequency with which they are documented is exceedingly variable, ranging from 20% to 80% (84,88,89), but these estimates clearly are in excess of those typically quoted for adult patients. Prothrombotic disorders implicated in childhood CSVT include anticardiolipin antibodies, increased lipoprotein(a) levels, Factor V Leiden mutations, deficiencies of proteins C and S, and antithrombin (84,89,90). Heterozygosity for the factor II G20210A mutation is a recognized risk factor for recurrent CSVT (91).

Perinatal Stroke and CSVT

Newborn strokes occur in 1 out of 4,000 births (14), that is, a stroke rate similar to that of individuals 75 years of age and older. For CSVT in neonates, the incidence is roughly 2 to 3 per 100,000 (90), with both term and premature infants affected. In more than 50% of the neonates, venous infarctions, which are often hemorrhagic, occur and intraventricular hemorrhage is a common feature. Risk factors have been reviewed in the previous three sections but also include maternal prothrombotic and autoimmune disorders, neonatal infections, and complications of labor and delivery (92,93). In particular, some studies have suggested that transplacentally delivered maternal anticardiolipin antibodies and lupus anticoagulant are important risk factors (94). In addition, pregnancy is a naturally occurring prothrombotic state caused by various hemostatic factors. Finally, in the fetus, thrombus development on the fetal side of the placenta can lead to emboli, which gain entrance to the cerebral vasculature via the patent foramen ovale.

CLINICAL MANIFESTATIONS AND DIAGNOSIS OF PEDIATRIC STROKE

In the absence of a known predisposing factor, such as congenital heart disease, SCD, or protein deficiencies in the blood, an initial diagnosis of stroke based on presenting symptoms may be missed or delayed, often beyond 24 hours (23,95–97). Delayed diagnosis typically reflects decreased awareness by the primary care providers and an exceedingly complex and expansive differential diagnosis. The frequency with which seizures occur at the onset of stroke in children may also cloud diagnostic judgment (98). Compared to adults with stroke, pediatric patients have a higher incidence of nonlocalizable symptoms, such as behavioral disturbances and headache, whereas even focal deficits may be hard to elicit in infants or children with premorbid developmental disability. Even recognizing the challenges, in many instances, the acute onset of neurological impairment in a child should be considered a stroke until proven otherwise. Thus, prompt utilization of imaging technology, especially MRI, is often necessary to distinguish stroke from the lengthy list of mimicking conditions (99), the most problematic of which are highlighted in Table 43.2.

DIAGNOSTIC IMAGING

MRI has greatly advanced the diagnosis and management of cerebrovascular disorders in pediatric patients, especially in the early detection of cerebral ischemia through the use of diffusion-weighted images (DWIs) (25,100,101) (Figure 43.4). The radiologic hallmark of acute AIS is restricted diffusion, as evidenced by DWI hyperintensity in combination with overlapping hypointensity on the apparent diffusion coefficient (ADC) map (101). In addition, more advanced MR modalities such as gradient ECHO and susceptibility-weighted studies can demonstrate even minute amounts of blood and thus assist in diagnosing hemorrhagic transformation (102). Most authors recommend that MR angiography (MRA) of intracranial and neck vessels be performed as part of the initial MRI study in children for whom acute AIS is a prominent diagnostic consideration. However, for specific arteriopathies or in cases concerning dissection, conventional angiography (CA) is often indicated (103,104). At the conclusion of the imaging workup, in addition to confirming that an acute vascular event has occurred, the radiological data should

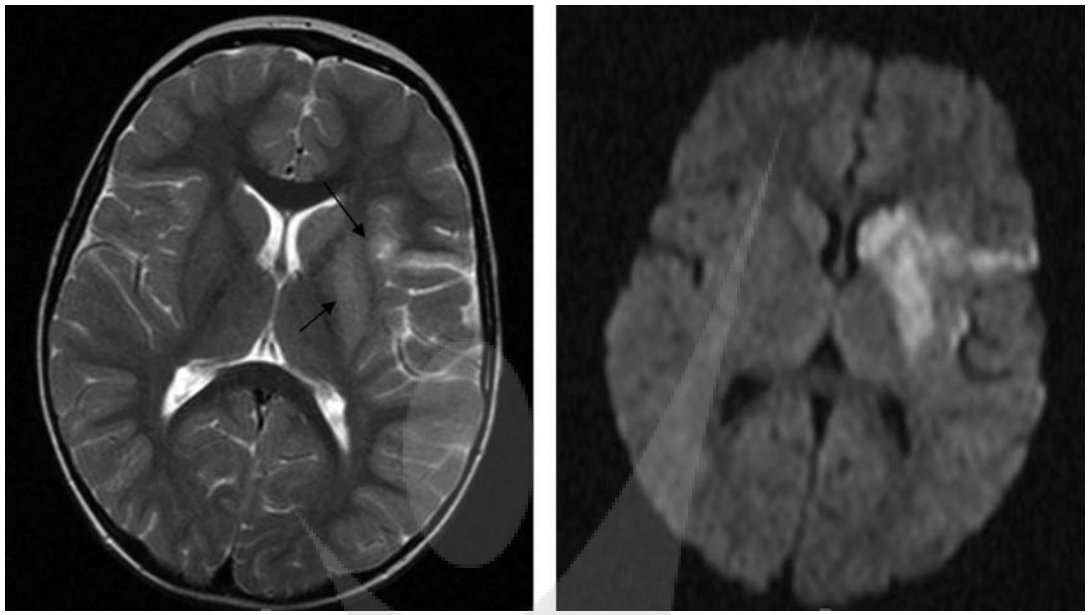

FIGURE 43.4 Left MCA arterial ischemic stroke. Left image demonstrates increased T2 signal in the left basal ganglia, left parietal lobe, and perisylvian region (arrows). These areas demonstrate restricted diffusion consistent with acute infarct, seen on DWI (right).

provide information regarding the extent and location of acute cerebral injury, the patency of major neck and intracranial arteries, and the degree of relative cerebral perfusion.

TREATMENT AND MANAGEMENT

Clinical management of pediatric stroke has evolved significantly over the past 20 years (105,106). Currently, the approach varies depending on the category of stroke and age of the child, but the immediate goal remains the prevention of secondary neuronal injury. Medical stabilization begins with adequate oxygenation, rehydration, seizure control, and management of infection. Treatment modalities can be reviewed based on specific forms of stroke and also the time frame in which intervention is necessary. For example, in cases of SCD, prompt red cell pheresis is indicated. In addition, current treatment of pediatric stroke is informed by three sets of consensus-based guidelines (105,107,108). Generated by expert panels of child neurologists, thrombosis experts, and others experienced in pediatric stroke, these publications attempt to integrate best available evidence with experience to provide practical guidance. These guidelines are predominantly concordant for major treatment recommendations, though they differ in certain areas (109).

Emergent Care

Neuroprotection—All Stroke Subtypes

Neuroprotective strategies have produced disappointing results in adult stroke trials (110). Nonetheless, the underlying basis of neuroprotection is to deliver an appropriate supply of both oxygen and metabolic substrate to ischemic tissues in the penumbra and simultaneously lower cellular metabolic demand. The former can be accomplished by optimizing delivery of oxygen and glucose, managing blood pressure, and maintaining cerebral perfusion. The latter can be assisted by controlling fever, managing infections, and minimizing seizures. This approach can and should be undertaken in all pediatric stroke patients, regardless of age and etiology of stroke (111). Treatment of intracranial hypertension often is essential to ensure adequate cerebral perfusion pressure, especially in cases of CSVT and hemorrhagic stroke. Given these considerations, initial management in an intensive care unit setting often is warranted (112).

Thrombolysis—AIS and CSVT

In cases of an evolving or rapidly progressing AIS, thrombolytic therapy may be a consideration, given that this treatment, typically in the form of tPA, has improved outcomes in adult stroke, with an approximately 15% risk reduction in poor outcome (113). The safety and efficacy of thrombolysis in the pediatric population, however, remain unproven. Studies of its use in children are limited mainly to database compilations (5) and isolated case reports (114,115). The IPSS reported that in 15 children with AIS (out of 680—2%) who were treated with tPA, the outcome was less than encouraging (116). Twelve were left with residual neurological deficits, two died, and only one recovered to normal. In addition, 4 (out of 14) sustained posttPA hemorrhage. The challenges confronting the use of tPA in childhood AIS patients are significant (116). Not surprisingly, the two most commonly quoted consensus-based treatment guidelines have

similar recommendations suggesting that thrombolytics (or mechanical-clot-retrieval therapies) should be carried out only within research protocols designed to address safety issues (13,108). One guideline does not entirely exclude consideration of tPA use in older adolescents with AIS, who otherwise meet standard adult tPA eligibility criteria (13).

Similar concerns regarding safety and efficacy exist for emergent recanalization strategies in childhood-onset CSVT. Endovascular thrombolysis, thrombectomy, or surgical decannulation are suggested only for selected patients with severe CSVT in whom there is no improvement or progressive deterioration, despite an adequate trial of anticoagulation. Thrombolytic agents are not recommended in neonates with either AIS or CSVT (107,108).

Hemorrhagic Stroke

Acute medical management of HS in the pediatric population requires the same "neuroprotective" measures discussed previously. In addition, the potential role of neurosurgical intervention should not be underestimated. In more than half of the reported cases of HS, emergent neurosurgical procedures such as hematoma evacuation and placement of intracranial pressure-monitoring devices have been documented (81–83). Despite this, there are only generic recommendations for treatment of HS delineated in the three pediatric stroke consensus guidelines, such as risk factor evaluation and identification and correction of congenital vascular anomalies. In part, this reflects the need to individualize treatment based on specific patient circumstances. Equally important, however, is the lack of randomized clinical trials on either medical or surgical interventions.

Urgent Care

Antithrombotic Treatment. Management of most pediatric patients with either AIS or CSVT (including neonates) centers on utilization of antithrombic agents, with the targeted site of impact being an intravascular thrombus. The goals of treatment are to prevent early propagation of the initial thrombus, minimize the possibility of re-embolization, inhibit new thrombi from developing, and stimulate prompt recanalization (34). Obviously, these potential benefits have to be weighed against the risk of hemorrhage. Fortunately, the risk of hemorrhagic transformation in childhood AIS does not appear to be appreciably increased by use of anticoagulation (117) and rarely produces additional neurological symptoms. Furthermore, it is clear that in the absence of antithrombotic therapy, the risk of early stroke recurrence is heightened (118). However, there is less compelling evidence regarding choice among the antiplatelet and anticoagulant medications available, given the lack of randomized controlled clinical trials. Based on the three most commonly referenced consensus-based guidelines, a rational approach to treatment of pediatric stroke can be presented (105,107,108). Dosing guidelines for all the agents utilized in the pediatric population and discussed in this chapter are also available (107,108).

Childhood AIS. In the setting of acute childhood AIS (with or without thrombophilia), initial therapy of either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) is recommended when embolic etiologies and/or arterial dissection are being excluded. Once this occurs, daily aspirin prophylaxis should be initiated and maintained for at least one to two years. Recurrence of stroke or the onset of transient ischemic attacks (TIAs) would prompt a switch to clopidogrel or anticoagulant therapy with LMWH versus warfarin or another vitamin K antagonist (VKA); the latter two may also be preferable for long-term anticoagulation in selected hypercoagulable states. In contrast, if the AIS results from either a cardioembolic cause or extracranial dissection, then anticoagulant treatment with either LMWH or a VKA is indicated. Recommended duration of treatment varies considerably between six weeks to six months for dissection, depending on radiologic assessment of degree/extent of stenosis and evidence of recurrent ischemic events. For cardiogenic embolism, treatment is suggested for three months up to one year or until the lesion responsible for the risk has been corrected. In addition, one guideline indicates that in children with extracranial dissection, at some point an antiplatelet agent such as aspirin may be substituted (107). Stroke secondary to vasculopathies other than moyamoya also must be treated differently given the high risk of recurrence. Thus, initial treatment includes UFH or LMWH or aspirin for at least three months. Duration of antithrombotic treatment should be guided by the results of follow-up cerebrovascular imaging. Anticoagulation is not recommended for children with AIS secondary to dissection of an intracranial vessel or in those with subarachnoid hemorrhage from any type of dissection or vasculopathy.

Neonatal AIS. In neonates with AIS and a documented cardioembolic source or severe thrombophilic disorders, anticoagulation should be started with either UFH or LMWH. In the absence of a source, the guidelines recommend only supportive care, although recurrent AIS would prompt either use of an anticoagulant or aspirin therapy (107,108). No recommendations are listed for the duration of therapy.

Childhood CSVT. In patients with CSVT without significant intracranial hemorrhage, initial use of either UFH or LMWH is reasonable followed by at least three to six months of LMWH or a VKA. Continued treatment for an additional three months will be informed either by ongoing symptoms or continued occlusion of the thrombosed vessel. In CSVT with "significant hemorrhage" (not otherwise defined), the Chest guidelines suggest either anticoagulation as described earlier or supportive care and reimaging of the thrombus at five to seven days. Anticoagulation with either UFH or LMWH would then be initiated if thrombus extension is noted, if new-onset symptoms occur, or presumably once the hemorrhage is felt to be stable. Duration of treatment would be for a minimum of three months, with cessation of treatment dictated by the absence of symptoms and recanalization of the thrombosed vessel.

Neonatal CSVT. For CSVT in neonates, the guidelines are more divergent. One suggests that anticoagulation with either LMWH or UFH should be considered only in infants with clinical or radiological evidence of propagating CVST despite supportive therapy (107). The other recommends that for newborns without significant intracranial hemorrhage, initial use of either UFH or LMWH is indicated. If UFH is chosen, at some point LMWH is substituted, with a total therapy duration of between six weeks and three months (108). In newborns with CSVT and "significant hemorrhage" (again not otherwise defined), the Chest guidelines are identical to those described earlier for childhood CSVT, recognizing that duration of treatment may be shorter, as neonates recanalize faster than older children (108).

Moyamoya. Because of the exceedingly high risk of recurrent infarcts in moyamoya (as much as 66%), antiplatelet therapy with aspirin is recommended (107,108). In addition, surgical revascularization should be considered and the patient referred to an appropriate pediatric center (105,107,108). These procedures have been demonstrated to produce improved cerebral perfusion in children with moyamoya with a relatively high degree of success (49). In older children, extracranial blood vessels, such as the superficial temporal artery, can be connected to distal segments of the MCA or other intracranial vessels. For most pediatric patients, indirect procedures such as encephalodural synangiosis (EDAS) and encephalodural myosynangiosis (EDMS) are utilized in which extracranial arteries are approximated to the pial surface. Over the subsequent weeks to months, neovascularization of the previously underperfused cortex transpires (107,119).

Sickle Cell Disease. In children with SCD and acute stroke, prompt red cell pheresis is indicated (105,107,108), regardless of the patient's prior transfusion history. Studies have demonstrated that children who are treated with an exchange transfusion at the time of their first stroke have decreased risk for subsequent strokes compared to children who are treated with either a simple transfusion or no transfusion (120). Automated exchange transfusion (erythrocytapheresis) is preferred; simple transfusion or partial exchange transfusion is acceptable (64). Neuroimaging (MRI) should be obtained as soon as possible, as diagnoses such as central venous thrombosis, reversible posterior leukoencephalopathy (RPLE), and other cerebrovascular abnormalities (such as moyamoya and dissection) can significantly influence management in the acute and subacute phase of care (121). Ideally, utilization of routine TCD studies will minimize the prevalence with which new-onset strokes occur in this population (56). At present the role of hydroxyurea in stroke prevention remains uncertain (122,123), but it should be considered in patients who cannot continue on long-term transfusion (107). Aspirin is a consideration in cases of large vessel vasculopathy, although such an approach has not been studied in a systematic fashion (124). Alternatively, in moyamoya associated with SCD, there is some evidence that revascularization surgery can be of benefit (125). Finally, bone marrow transplantation may be an additional option, even in the absence of randomized controlled trial data (105,107,108).

PEDIATRIC STROKE RECURRENCE RISK AND OUTCOMES

As previously noted, cerebrovascular disease remains one of the major causes of death in the pediatric population, with the highest rates within the first year of life (2). However, advances in medical and surgical care have resulted in a substantial reduction in mortality in all major subtypes of stroke (3). With increasing survival, however, there is a heightened awareness of the substantial neurological morbidity in survivors of neonatal and childhood stroke.

AIS in Childhood

Death occurs in an estimated 3% to 13% of patients with AIS (13,37). Permanent and often moderate to severe neurological disability has been noted in survivors (13,37,126), including motor and cognitive deficits. Epilepsy is a long-term complication observed in 15% to 20% of childhood AIS patients. Infarct location (especially bilateral involvement) and size appear to be major factors in predicting a less favorable outcome. Younger age (most predominantly less than 12 months of age) and the presence of altered consciousness and seizures at onset also have been implicated in more adverse neurological morbidity (37,98,127,128). With respect to epilepsy onset, large cortical infarcts seem to impose the highest risk (129).

The risk of stroke recurrence varies considerably depending on age of patient, cause of stroke, and preventative measures undertaken following the stroke. Recurrence rates have been reported in selected series to range between 10% to 35% (27,65) but may be as high as 50% in the absence of antithrombotic therapy (22). With respect to etiology, arteriopathy (including moyamoya) seems to be the most important predictor of recurrence, perhaps accounting for nearly two-thirds of subsequent strokes (28). Other patients with certain cardiac and prothrombotic disorders also appear to be at a higher risk. For children with arterial dissection, a recurrence rate of 20% or higher has been noted (28,43–45).

AIS in Neonates

Similar challenging neurological outcomes have been documented in perinatal strokes, with motor and cognitive deficits and epilepsy observed in 50% to 75% (14,65,130). Involvement of the basal ganglia and/or internal capsule on imaging studies and certain other vascular classifications strongly predict motor disability and especially severe hemiparesis (12,131,132). Of note, long-term feeding and other sensory motor deficits seem to predominate and outcomes appear worse in preterm neonates (133). Fortunately, mortality in neonatal AIS is low, roughly 3% to 5% (134). Recurrence of stroke is even less common after neonatal AIS

(typically quoted as 2% to 3%) (92,135); when it does occur, prothrombotic risk factors are typically involved, often within a setting of other well-recognized risk factors such as infection, dehydration, and congenital heart disease (135). In addition, recurrent strokes after the age of 1 year are almost never seen.

CSVT in Childhood

Mortality rates in childhood CSVT of 9% to 29% are considerably higher than the rates documented in adult patients, likely a reflection of the severity of underlying or associated disorders such as malignancy and head and neck infection (84,85). Coma at the time of presentation strongly correlates with death. Neurological disability and seizure disorders occur in about one-half of the survivors. Compared with AIS, children with CSVT are more likely to demonstrate cognitive impairment and behavioral disturbances as opposed to motor deficits. In addition, cortical visual impairment and communicating hydrocephalus may occur in up to 30% of children with CSVT (15,87). Predictors for neurological sequelae include seizures or venous infarction at presentation, whereas worsening outcome correlates with deep vessel CSVT and bilateral infarction, often of central gray-matter structures (84,85). Finally, the risk of recurrent cerebral or systemic thrombosis appears comparable to that observed in adults, with a figure of 13% documented in one particularly well-studied population (84).

Hemorrhagic Stroke

Compared with childhood AIS, hemorrhagic stroke has an increased mortality, ranging from 6% to 54%. Mortality appears increased in posterior fossa hemorrhage, consistent with the potential life-threatening consequences of brainstem compression. In contrast, survivors typically demonstrate fewer and less severe disabilities, with roughly 50% to 75% having a good to normal outcome (81). Hemiparesis is seen in about one-third of survivors and epilepsy in 15% to 20%. The most commonly reported neurological disability, however, is cognitive impairment, although this may reflect the greater intensity with which these types of sequelae have been investigated compared to AIS (81). Like mortality, morbidity in hemorrhagic stroke correlates with posterior fossa location, but delay in initiation of intervention and coma at presentation are also predictors of a worse outcome (83,136).

Risk of recurrence in childhood hemorrhagic stroke is roughly equivalent to that noted for AIS in similar-aged pediatric populations, ranging from 10% to 20% depending on the length of follow-up (81,137,138). Although most recurrences transpire within the first six months following initial diagnosis, the incidence of additional hemorrhage continues to rise over time. This is especially true in cases of abnormal vascular development such as AVMs, in which a 2% per year rebleed rate has been documented (137).

ASSESSMENT OF STROKE OUTCOMES IN CHILDREN

In studies of pediatric stroke, the estimates of patients with permanent neurological deficits have ranged from 50% to 90% (98,126,129,139,140). This wide range in deficit estimates demonstrates how difficult it is to assess stroke outcomes in children. As adult stroke assessment scales cannot be transferred to pediatric patients, novel measures of stroke severity (141,142) and outcomes (139,140) specific to children had to be developed. These metrics face the difficult task of evaluating disabilities in a population whose abilities change nonlinearly with age.

Many pediatric neurorehabilitation programs utilize either the Wee-Functional Independence Measure (Wee-FIM) (143) or the Pediatric Evaluation of Disability Inventory (PEDI) (144) to ascertain functional abilities in the domains of mobility, self-care, and cognition/social function (Table 43.3). To a greater or lesser degree, each scale measures impact of stroke via a determination of the burden of care or need for caregiver assistance that must be assumed by a parent or family member following the injury. A more recently developed and validated scale is the Pediatric Stroke Outcome Measure (PSOM), which measures neurological deficit and function across five domains: right and left sensorimotor, language production and comprehension, and cognition/behavior (7,139). Although the PSOM subscale scores demonstrate strong agreement for domain-matched neuropsychology

TABLE 43.3 Comparison of Outcome Measures

OUTCOME MEASURE	AGE RANGE	DESCRIPTION
Wee-Functional Independence Measure (Wee-FIM)	6 months–7 years	Administered by observation or structured questions. Item clusters include self-care, sphincter control, mobility, locomotion, communication, social, and cognition. Ratings of child on a seven-point scale of burden of care.
Pediatric Evaluation of Disability Inventory	6 months–7 years	Rated by informant or by interview. Includes three major content domains: self-care, mobility, social function. Assesses separate measurement dimensions of functional skills, caregiver assistance, and modifications.

test scores, the authors acknowledge that the PSOM likely is biased toward sensory and motor impairments as opposed to cognitive and behavioral deficits (139). Use of these tools enables a program to compare recovery with the national average for pediatric stroke, although improvement within stroke subtypes is harder to ascertain. In addition, the WeeFIM allows one to compute length of stay and expenditure of rehabilitation effort (units of physical therapy, for example) with functional gains. Neurological outcome using the PSOM also has been utilized to correlate cost of stroke care with disability. Not surprisingly, cost during the first year of recovery correlated positively with neurological impairment (7,144). A much more valuable use of these functional outcome measures will be in prospective clinical trials in pediatric stroke, especially those comparing potential benefits of therapeutic interventions.

Many abilities have not yet developed in children at the time of their stroke. Therefore, the full extent of the deficits caused by stroke can remain hidden for years (145,146). For example, the effects of stroke on reading ability can only be assessed once patients have reached the age at which children typically learn to read. More subtle cognitive and behavioral effects of stroke, such as attention deficits or mood disorders, may not be recognized until children are school age or even older. One can think of this as children with strokes "growing into their deficits" (11). Detailed neuropsychological testing in children with strokes suggests that almost all children who suffered strokes show neuropsychological abnormalities at follow-up neuropsychological testing (144,146–148). Because ongoing development can potentially mask deficits for many years in pediatric stroke patients, children who suffered a stroke should ideally be closely followed until adulthood, both for research studies and in routine clinical care.

Studies assessing quality of life in pediatric stroke survivors suggest that cognitive deficits lead to poorer socialization and lower quality of life (149,150). Thus, there have been increasing efforts to utilize standardized assessment tools designed to measure health-related quality of life (HR-QoL) in children and adolescent survivors of stroke. Such measures document more fully how a neurological deficit affects a pediatric patient's ability to live and function within the home, school, and community environments (150). When utilized in conjunction with an impairment measure such as the PSOM, most studies have demonstrated that increasing degrees of neurological deficit strongly predicted diminished well-being and, in older patients, impaired peer-related well-being. In the future, these types of HR-QoL assessments should be incorporated into any study assessing the efficacy and benefit of treatment or rehabilitation strategies in children with stroke. Despite the frequency and severity with which neurological disability occurs in survivors of pediatric stroke, as a general rule the long-term outlook is fairly good. For example, one study documented that children and adolescents with a history of stroke demonstrated fairly good outcomes in terms of transition to adulthood, including high rates of high school graduation and higher education. Thirty-two patients were followed over the course of about 10 years. Study results found that in early adulthood, most individuals were employed (90%) and could drive (76%). As far as general functional status was concerned, mobility outcomes were excellent, although assistive devices and orthotic use were common. Daily living skills, communication, and socialization fell in the moderately low range and were influenced by medical status (151).

MECHANISMS OF STROKE RECOVERY

The common goal of improving rehabilitative therapies for young and old stroke patients will be greatly aided by a better understanding of the basic mechanisms of stroke recovery. As many more adults suffer strokes than children, the vast majority of studies on stroke recovery mechanisms have been performed in adults and equivalent animal models. These studies have elucidated important mechanisms of stroke recovery at all representational levels of the CNS, from molecules to hemispheres. A common finding across this wide range of research approaches has been that stroke recovery mechanisms seem to follow a specific timeline (Figure 43.5).

Immediate Poststroke Period (Less Than Five Days)

Stroke induces acute changes in global brain metabolism and blood flow, as well as causing local inflammation and edema (152). The earliest functional gains in stroke recovery, within the first three to five days after stroke, are at least in part caused by normalization of these transient alterations (153).

Neuroimaging of patients with motor deficits, within the first 72 hours after stroke, showed diminished coupling between primary motor cortex, supplementary motor area, and premotor cortex, when compared to the recovered state (154). Animal studies have shown that surviving neurons in the perilesional zone undergo significant dendrite loss in the first few days after stroke (155). Spontaneous neural activity in the perilesional zone consists mainly of polymorphic delta rhythms for the first 24 hours after stroke (156).

In rodents, initiation of activity programs immediately following stroke increases lesion size (157–160). Increased neural excitability during this immediate poststroke period can be harmful. For example, treatment with $GABA_A$ agonists, which promote tonic GABAergic inhibition, immediately following stroke decreases stroke size (159,161); in contrast, immediate treatment with $GABA_A$ antagonists, which decrease tonic inhibition, increases stroke size (159). Stimulating glutamatergic AMPA receptors, which is important for learning-induced neuroplasticity, immediately after stroke also increases stroke size (160). Based on these types of studies, carried out in rodents, it seems that by five days after stroke, the penumbra adjacent to the infarcted brain tissue is no longer vulnerable to neural overexcitation (159,160,162,163).

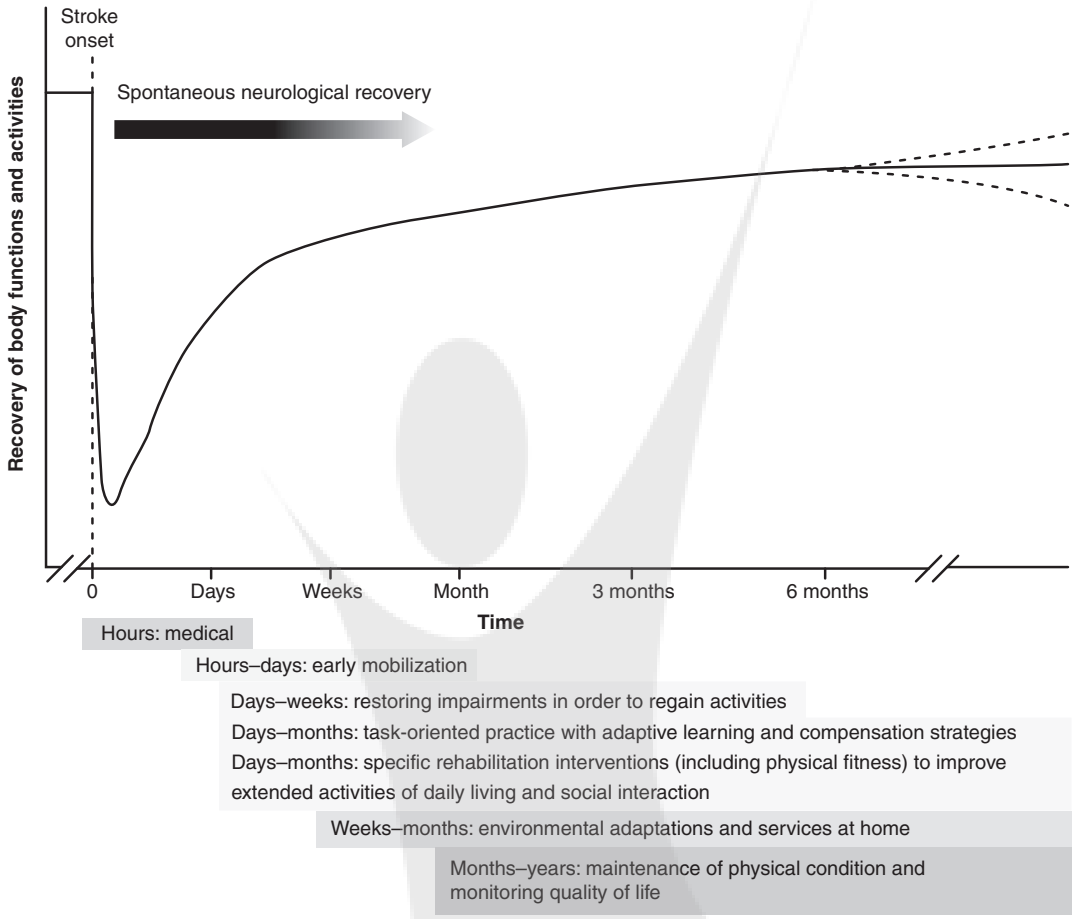

FIGURE 43.5 Proposed pattern of recovery after stroke with timing of recovery

As soon as these acute disturbances subside, the brain initiates complex programs to recover functions previously supported by the now infarcted tissue. Within one to five days following stroke, systems-level, cellular, and molecular mechanisms are initiated that help mediate stroke recovery (156,159,164–171).

Subacute Stroke Recovery (Five Days to Three Months)

In rodent models of stroke, the critical phase for recovery lasts from five days after stroke until about one month (163,165). In adult humans, 95% of the poststroke motor recovery occurs within 3 months, whereas cognitive deficits can recover over a longer period (172). Not surprisingly, the initial severity of the deficits is a fairly good predictor of the eventual outcome (173). The timecourse of recovery in children is similar to that in adults, but on an average, children will show greater overall recovery from stroke deficits than adults (174).

Stroke Recovery at the Systems Level

The human brain is the most complex and computationally powerful system known. It has been shown to contain about 86 billion neurons (175), connected by an estimated 100 trillion synapses (176). Systems neuroscience has subdivided the brain into distinct functional areas based on differences in their cytoarchitectonics, topography, connectivity, and function (177,178). These functional areas are organized into widely distributed networks by massively parallel connections (177). Even though individual brain areas contribute specialized computations, all human behaviors are the emergent property of these distributed networks that include distant parts of cerebral cortex, subcortical structures, and the cerebellum. Abilities such as attention, movement, or executive control are not localized to individual parts of the brain, but rather are supported by widespread networks (179–183).

Functional neuroimaging techniques such as positron emission tomography (PET), functional MRI (fMRI), and functional connectivity MRI (fcMRI), as well as reversible, noninvasive neural stimulation and inactivation methods like transcranial magnetic stimulation (TMS) and transcranial direct current stimulation (tDCS) have enabled researchers to study the functional neuroanatomy of stroke recovery at the level of functional systems and distributed brain networks.

Human Studies. Human neuroimaging studies of strokes that damage parts of the attentional and somatomotor networks have shown that they affect entire functional networks (179,184,185). Stroke alters local activity in distant, but functionally related, brain regions (184) and it changes the functional relationships between brain areas throughout a damaged network (185), including the opposite hemisphere (179). Fortunately, these organizational principles of the brain also point toward clear opportunities for stroke recovery. Redundancies in computational specialization and connectivity enable functional networks to reorganize in search of a new network state that allows the best possible performance given its new resource limitations (181,182).

Functional neuroimaging studies of humans recovering from strokes involving the primary motor cortex have shown more widespread activations throughout the motor system during the initial subacute recovery phase (186). Compared to unaffected controls, recovering stroke patients using the paretic upper extremity initially had greater activations in the contralesional primary motor and premotor cortex, midline supplementary motor areas, and perilesional primary and premotor cortex (187). Over time, the activation patterns of patients who made good functional recoveries became more similar to typical activation patterns, with greater lateralization and activations focused in perilesional areas (188,189) (Figure 43.6). Consistent with these imaging findings, timed inhibition of ipsilesional premotor cortex with TMS degraded motor performance in paretic patients, but not controls (190,191). This finding showed that recovered stroke patients relied on a different functional neuroanatomy to perform the same task.

Across studies, chronic persistence of increased activation in contralesional motor regions has been associated with poorer outcomes (188,192–194). Studies of patients with left neglect following stroke showed similar activation imbalances between the hemispheres that normalized with functional recovery (181,184). Functional neuroimaging and stimulation studies in humans suggest that the negative effects of contralesional activity could be caused by interhemispheric inhibition (IHI), exerted by the contralesional hemisphere onto the lesioned hemisphere, via transcallosal projections (195) (Figure 43.7).

Animal Studies. Studies of sensorimotor stroke in rats using fMRI and optical imaging are congruent with human studies, including correlation with functional recovery, thus lending credibility to rodent models of stroke (168). In addition, more fine-grained intracortical studies have shown that maps representing specific body parts in primary motor and somatosensory cortex in rodents and monkeys can reorganize after limb loss or disuse, as well as stroke (196–200). As predicted, the changes in these cortical maps

were use-dependent (196,197). Although rodent and even monkey brains lack the complexity of the human brain, animal models of stroke recovery have allowed researchers to detail the cellular processes thought to underpin the network-level changes described earlier.

Stroke Recovery at the Neuronal Level

Axonal Sprouting and Dendrite Morphogenesis. An important mechanism by which brains are thought to reorganize functional networks and maps is axonal sprouting (199–201). Rodent and primate stroke recovery models have all documented axonal sprouting correlated with functional recovery (202). In squirrel monkeys, stroke in the hand representation of primary motor cortex induced perilesional axonal remodeling and sprouting of novel axonal connections toward the distant ipsilesional premotor cortex (201). These findings provide a potential cellular mechanism for the increased activation of ipsilesional premotor cortex in humans with strokes affecting primary motor cortex (190,191). Multiple other studies in rodents have documented perilesional axonal sprouting and innervation of novel motor and sensory targets (155,165,170,200). These findings are congruent with the human studies, which have shown that persistent reliance on contralesional regions is a marker of more severe stroke (181,186).

Concurrent with the sprouting of new axons, dendritic spine turnover and synaptogenesis also increase in perilesional cortex (155,203). Moreover, the location of these cellular changes corresponds to areas of somatosensory cortex in which functional maps reorganize following stroke (155,165,203). Synaptogenesis and dendrite reshaping are maximal within a few millimeters of the infarcted region and mainly occur within the first two weeks following stroke (168).

Neuronal Activity Changes. The changes in axonal and dendritic structure during stroke recovery coincide with changes in neuronal activity thought to play an important role in activity-dependent recovery. In rats, one day after stroke, polymorphic delta rhythms (0.2–2.2 Hz) in perilesional cortex, thought to reflect injury, are overtaken by widespread, synchronized, spontaneous, lower-frequency (0.1–0.4 Hz) neural activity (156). These slow rhythms were maximal three days after stroke in perilesional cortex and they were also measured in the contralesional hemisphere. Pharmacological blockade of this slow synchronized neural activity blocked axonal sprouting.

Consistent with human imaging studies and horizontal perilesional axonal sprouting, in vivo imaging experiments in mice have shown that poststroke activations spread more widely into adjacent brain regions, and that these responses lasted three to four times longer than normal responses (155).

Neurogenesis. During stroke recovery, the activity, connectivity, and structure of neurons change in ways that are thought to support functional recovery of stroke deficits. Besides reorganizing the networks of existing neurons, another logical mechanism for stroke recovery at the neuronal level would be neurogenesis, or the generation of new neurons from neural stem cells. In adult brains, neurogenesis has been reported in the hippocampus, the olfactory bulb, and the subventricular zone of the lateral ventricle (170,204). Several studies have suggested that stroke triggers proliferation of neural stem cells and their migration toward the site of the lesion (166,205,206). However, out of these neuronal precursors only a small fraction survives to differentiate into neurons (207). Furthermore, it remains unclear how much neurogenesis contributes toward functional recovery after stroke. It has been proposed that some of the reported correlations between neural stem cell proliferation and improved outcomes may have been mediated by enhanced neural plasticity (170) or enhanced angiogenesis (208). There is currently no clear evidence that newborn neurons can take over the function of infarcted ones to a significant degree.

Stroke Recovery at the Molecular Level

Studies of stroke recovery have started to investigate some of the molecular machinery and signaling cascades that enable recovery at the neuronal and systems level. This research suggests that stroke triggers transcriptional programs that recapture a state of heightened neuroplasticity similar to earlier developmental stages (165). In the periinfarct zone, immediately beyond the glial scar, these transcriptional programs lower levels of growth-inhibitory factors and boost levels of growth-inducing factors (167,209). Many of the molecules differentially modulated during stroke recovery have also been found to be important for learning and memory, suggesting that molecules that enhance learning may also promote stroke recovery (160). For example, brain-derived neurotrophic factor (BDNF) and glutamatergic AMPA receptor signaling, known to be important for the reorganization of cortical maps and spine morphogenesis, are also important for learning-induced plasticity (160,210,211).

Chronic Stroke Phase (Greater Than Three Months)

Most functional recovery from stroke occurs within the first month, but improvements can continue for up to three months, especially in more severely affected patients (212). Among paretic stroke patients, 80% reached their new maximal arm function within 3 weeks, and 95% reached it within 9 weeks (213). In the same study, it was found that 95% of patients with mild aphasia return to their new baseline language ability within 2 weeks, whereas 95% of patients with severe aphasia do so within 12 weeks (214). It has been estimated that as many as 30% of patients with strokes causing cognitive deficits continued to improve beyond 3 months after stroke (215).

Animal studies also suggest a critical period for stroke recovery. Rats made the best functional recovery from a large stroke when they were placed within an enriched rehabilitative environment at five days after stroke (163). When placement within an enriched environment was delayed until 14 days after stroke, benefits were diminished. Waiting until 30 days after stroke abolished the benefits of an enriched environment completely, and there was no difference from

typically housed animals with stroke. Improved functional outcomes in those animals placed in an enriched environment five days after stroke correlated with greater dendritic arborization in perilesional cortex.

PEDIATRIC NEUROREHABILITATION FOR STROKE

The majority of pediatric stroke survivors will demonstrate some degree of neurological impairment. The long-term impact of childhood stroke often is substantial, with residual neurological disability typically including spastic weakness, as well as movement disorders, seizures, speech and language delay, visual impairments, orthopedic deficits, and cognitive and behavioral difficulties. Rehabilitation management of stroke in the pediatric population has been aided by recently developed guidelines emphasizing a multimodal and family-centered approach (105,216). Recent evidence-based practice guidelines for adult stroke rehabilitation are helpful (217). It must be acknowledged, however, that though the benefits of earlier and more intense rehabilitation clearly are documented in adults and buttressed by animal research (10), compelling evidence in childhood stroke is less available.

Principles of Pediatric Rehabilitation

Childhood stroke rehabilitation has several guiding principles based upon the age and developmental level of the patients requiring treatment, as well as the nature of stroke recovery and reorganization mechanisms (Table 43.4) (212,216). The distinguishing principle of pediatric stroke rehabilitation is that assessments of cognitive, motor, and psychosocial deficits and the corresponding therapies must be guided by an understanding of normative development (218). Detailed understanding of the patterns of cognitive development during maturation is especially important in the rehabilitation of infants and children, as these developmental milestones can be incorporated as sequential goals within an individual's therapy program (105). In addition, the manner in which rehabilitation can be provided to a child or adolescent and the patient's ability to engage in therapy may be restricted. This is especially true early in the recovery process of patients who lack the developmental skills necessary to learn complex strategies upon which functional substitution is predicated (216). An understanding of cognitive development allows more accurate prediction of which patients will lack the ability to understand and participate in a meaningful way in their therapy program. A developmental framework also informs the potential long-term effects of cerebral injury in young children. This is most pertinent for areas of the brain subserving functions that normally mature later in childhood and in cases of neonatal and presumed perinatal stroke.

Another principle of pediatric stroke rehabilitation is that the process mandates a coordinated multidisciplinary team working together to develop therapeutic interventions based upon integrated assessments (105). Important considerations of home and school accessibility, psychosocial adaptation to disability, and school reintegration mandate that the team include individuals to address these issues. The rehabilitation process must provide strategies designed to improve functional capabilities as opposed to enacting treatments that merely decrease symptoms.

To accomplish this goal, the team must have a clear understanding of the physical, emotional, cognitive, and social consequences of the child's stroke. The degree, extent, and rate of recovery, which vary considerably among children, are also influenced in a significant manner by the size and location of the infarct and the presence of associated medical conditions (10). In addition, the immature brain's response to stroke is both varied and dynamic (212). Thus, the evolving biological recovery in combination with substitute/alternative cognitive processes and movement patterns necessitates an ongoing program of assessment and reassessment (218). It is anticipated that progress from the baseline condition will be observed as a direct response to the therapeutic interventions. In pediatric stroke, rehabilitation often becomes a spiral management process in which, following an initial evaluation, a treatment program is initiated, which in turn is constantly revised and updated based on successive reassessments.

Finally, and perhaps most importantly, the core principle of family-centered care is recognizing that the child's family is a constant presence in the rehabilitation process, available to provide comfort and reassurance during times of stress (11,105). Practical management decisions must be endorsed by the family and not just by the patient (218). Family members need to be involved in the process of their child's recovery and should be expected to participate in the therapy programs.

2. Treatment strategies initiated as soon as possible following stabilization
3. Therapeutic interventions directed at producing functional improvement
4. Practical management decisions endorsed by patient and family
5. Continual reassessment of child and updating of therapy program
6. Reassessments guided by an understanding of normative developmental maturation

Pediatric Rehabilitation Settings

Rehabilitative therapy can and should be initiated even while the child is still in the intensive care unit or on the inpatient neurology service. This early phase of intervention is designed to limit maladaptive behavioral habits and movement patterns and to prevent or at least minimize complications that can take months to resolve if not properly and promptly addressed, especially prevention of physical

TABLE 43.5 Admission Criteria for a Comprehensive Pediatric Stroke Rehabilitation Program

1. Deficits from stroke require intensive and multidisciplinary rehabilitation care
2. Medically stable
3. Responsive to verbal or visual stimuli, and sufficiently alert to participate in therapy
4. Prestroke physical and cognitive levels indicate potential for recovery of function
5. Stroke condition allows a reasonable expectation for improvement and the potential to achieve clearly identifiable treatment goals within an appropriate time period

deformities such as contractures owing to spasticity and prolonged immobilization (216).

After all medical and surgical issues have been stabilized, a decision has to be rendered regarding how the stroke rehabilitation process should move forward. In some children with stroke, improvements are rapid enough that they can be discharged home from the acute care setting and institution of outpatient therapy or a day treatment program is appropriate. In rare cases, typically involving bilateral hemisphere strokes or brainstem hemorrhage, recovery has been and likely will continue to be very slow. In these cases, a subacute nursing facility with less intense therapy may be a more reasonable option.

However, for the vast majority of children and adolescents with moderate to severe brain injury secondary to stroke, a dedicated neurorehabilitation program is indicated. Eligibility criteria for admission to comprehensive neurorehabilitation services have been developed and refined over the past decade (Table 43.5). Many childhood stroke patients meet these criteria, which include: a medically stable stroke condition that mandates intensive and multidisciplinary rehabilitation care; a premorbid physical and cognitive level that allows for meaningful recovery; a patient who has sufficient alertness to participate in the rehabilitation process; and finally, a stroke for which there is a reasonable expectation for improvement and the potential to achieve clearly identifiable goals over a reasonable time frame.

Current Neurorehabilitative Care for Children With Stroke

A comprehensive pediatric stroke program should provide a very highly intensive service through a multidisciplinary coordinated team approach, with an initial minimum of three hours of therapy each day. As recovery proceeds and endurance improves, the duration and scope of treatment are expanded to a full day of activity. Although therapeutic interventions carried out by physical and occupational therapists and speech–language pathologists are the mainstay of any treatment program, most rehabilitation teams also include psychologists, social workers, child-life specialists, music therapists, chaplains, orthotists, and dieticians. Psychologists and neuropsychologists are essential members of the team, both in the acute setting and over the life of the patient, as psychological and social support and intervention likely will be required at frequent intervals. Written team evaluations typically are mandatory and often guided by the child's case manager. These evaluations measure progress; determine impediments to recovery and potential solutions to the impediments; reassess and adjust established goals; and develop and implement discharge plans (218). Although an inpatient setting provides support as the family learns to cope with the child's injury, the team must concentrate on a process that also facilitates transition into the community.

Rehabilitative Treatment of Motor Impairments

Perinatal stroke is the most common cause of congenital hemiplegic cerebral palsy. In addition, motor impairments after stroke in childhood and adolescence are frequent and often the most common source of functionally adverse outcomes, occurring in 40% to 50% of patients (22,126). Motor rehabilitation in the adult stroke population is predicated on long-standing therapies within the fields of physical and occupational therapy designed to improve motor performance (10). Similar strategies are endorsed in pediatric stroke patients (105), despite lack of strong empirical evidence to substantiate or quantify the actual benefit. The early phase of treatment in most pediatric stroke rehabilitation programs is similar to successful interventions employed in adults and includes physical, occupational, and speech therapy (219,220), along with utilization of assistive devices and/or medications to facilitate postural alignment and minimize abnormal tone. As recovery proceeds, aerobic conditioning, muscle strengthening, and task-specific training assume greater importance. In addition, newer techniques for improving motor function, such as constraint-induced movement therapy (CIMT) and both central and peripheral stimulation, have recently been implemented with varying benefit.

Treatment of Spasticity

Almost every single child requiring acute neurorehabilitation services following stroke will manifest alterations in tone (219,221). In addition, spastic weakness is a characteristic feature observed in infants, children, and adolescents with hemiplegic cerebral palsy secondary to perinatal stroke. Spasticity is characterized by excessive and inappropriately timed activation of skeletal muscles, which typically impedes a child's ability to move in a normal fashion. Clinical manifestations of spasticity will vary depending upon the extent of damage and the sites of injury within the brain; intrinsic characteristics of recovery also influence the presentation of spasticity. In many pediatric stroke patients, spasticity will impair static postural alignment and limit passive movement (216). In addition, impaired activation of volitional movement resulting in weakness and clumsiness is often associated with spasticity (222). The main focus of tone management in the earliest stages of pediatric stroke rehabilitation is to minimize the complication of joint and

TABLE 43.6 Management of Spasticity

REHABILITATIVE MEASURES	PHARMACOLOGIC AGENTS
Muscle stretching	Central-acting antispasticity medications
ROM exercises	Baclofen (oral and intrathecal)

Heat, cold, sound	Botulinum toxins
Muscle strength training	

muscle contractures, with a secondary goal of eliminating painful spasms (218). Motor rehabilitation should be directed toward outcomes that improve a child's functional capabilities (222), such as increased upper-extremity utilization to achieve greater independence in activities of daily living or greater coordinated leg and trunk movement resulting in improved ambulation.

Role of Therapies. Proper positioning, range-of-motion (ROM) exercises, and often splinting (216), are mainstays in the treatment of spasticity in obtunded stroke patients (Table 43.6). It is essential that ROM be carried out daily to all joints regardless of alteration of tone; later, as recovery ensues, the ROM exercises can be combined with adjunctive physical agents such as heat, cold, water, and electrical stimulation and specific affected muscles targeted (223). These physical agents are thought to reduce spasticity through inhibition and fatigue that directly relax a spastic muscle; however, facilitation of the antagonists of a spastic muscle, thereby creating relaxation by reciprocal inhibition, has been suggested as an alternative mode of action. Positioning can facilitate appropriate proper postural alignment and correct weight-bearing distribution throughout the body. Using gravity to stretch spastic muscles and promote relaxation is also a function of postural techniques (224). In the latter stages of recovery, proper position can facilitate active contraction of functionally weak muscle groups, especially in the distal lower extremities. Other mainstays in the treatment of motor disability following stroke are casting and splinting, which are designed to prevent formation and worsening of contractures in a spastic extremity (225). Inhibitive casting may also result in a lowering of tone via multiple mechanisms. Splints or orthotics may be utilized in children who have progressed further in their recovery to produce functional benefit without necessarily altering spasticity (Figure 43.8). For example, an appropriately designed wrist and finger extension splint may improve functional hand activities such as keyboarding without altering the underlying tone (225). In the latter stages of recovery, or in patients with chronic motor deficits such as hemiplegic cerebral palsy, equipment typically is a very important adjuvant to the rehabilitation process. Standing frames allow a child with reduced weight-bearing ability to be placed in an appropriate position to minimize the development of contractures. Other benefits to partial weight bearing include improved bone maturation and better pulmonary function.

FIGURE 43.8 Ankle–foot orthotics often are a beneficial adjunct to promote greater independence in ambulation.

Oral Medications. Pharmacologic agents are a potential treatment modality for the management of spasticity in the acute pediatric stroke patient and in a child with chronic motor disability resulting from stroke. Despite the fact that a large

number of antispasticity medications have been available for many years, there are limited data available to conclude that any of these agents is truly effective in reducing spasticity in pediatric stroke patients (224,226,227). In children with hemiplegic cerebral palsy, efficacy data with regard to tone reduction exist, but there are no well-designed studies that have evaluated the impact of these agents on improving functional capabilities. In addition, studies have rarely analyzed outcome data as a function of stroke etiology. Thus, in view of the systemic and nervous system adverse side effects produced by antispasticity medication in the pediatric population, pharmacologic agents should be utilized only when severe spasticity cannot be adequately managed by other therapeutic modalities. In addition, continued use must be justified by ongoing demonstrable benefit to the child. Finally, antispasticity medication should be prescribed only for pediatric stroke patients who can achieve meaningful functional goals, as opposed to mere clinical ones (224). A notable exception to this recommendation is the institution of an oral medication to facilitate hygiene, improve appropriate positioning, reduce the requirements of caregiving, and ease rehabilitation procedures such as proper fitting of orthotics.

Commonly employed medications treating spasticity in the general pediatric population include diazepam (and other benzodiazepines), baclofen, tizanidine, and dantrolene (Table 43.6) (222,224,226–228). Based on adult studies, one could postulate that the efficacy of tizanidine and baclofen are comparable, with global tolerability data favoring tizanidine (224,228). Use of either medication may be limited owing to sedative side effects, often producing impaired arousal and attention even at relatively low doses. Dantrolene sodium is the least sedating of the antispasticity medications. Yet, as its site of action is within the muscle, it must be carefully titrated to minimize the potential for severe generalized weakness, even in unaffected muscles. Thus, dantrolene's usefulness in hemiplegic motor disability secondary to stroke is limited.

Concerns regarding efficacy and adverse side effects from the more standard antispasticity medications have prompted investigation of newer agents, such as gabapentin, modafinil, and pregabalin (224,229,230). However, presently there are no published reports on any of these medications in children with stroke. For further details regarding pharmacologic management of spasticity in childhood, an evidence-based practice parameter has recently been published (231).

Neuromuscular Blockade: Botulinum Toxin Injections. Botulinum toxin is increasingly being used to manage severe spasticity that involves only a few muscles or muscle groups (224,232). Reduction in spasticity and modest functional improvement in injected muscle groups both in the arms and legs have been documented in many studies, mainly in children with cerebral palsy (233–235). Unfortunately, it is not possible to separate out those patients whose chronic motor disability was the result of a stroke. On the adult stroke side, there is stronger evidence for a reduction in focal spasticity and increased gait velocity following botulinum toxin injection into the lower extremities. Evidence for improved function and quality of life is not as compelling (224,236). The effects of botulinum injections are local, dose dependent, and temporary. Thus, this form of therapy is best suited for those children with a limited number of "problem muscles" that interfere with major functional abilities such as ambulation or upper-extremity movement. A clinically apparent reduction in tone typically is most notable two to four weeks after injection, and ongoing benefit may persist for three to four months or longer depending on severity and the particular muscles involved. There are, however, significant limitations to the use of botulinum toxin, including: (a) maximum dose that can be administered at a single time; (b) appropriate spacing between injections (even to different muscles) to minimize the development of antibodies to the toxin; (c) cost; and (d) tolerability in pediatric patients (237,238). Judicious use of this agent in patients intolerant of splinting or with severe postural deformities can be a beneficial adjunct to maintain ROM. In children who demonstrate significant motor recovery and lessening of spasticity over time (221), the temporary neuromuscular junction denervation created by botulinum toxin is a favorable trait. In children with chronic motor disorders such as spastic hemiplegia, serial injections are typically coupled with an intensification of therapy and/or serial casting to secure maximum benefit (239). However, there have been reports of systemic side effects, including botulism, resulting in deterioration in respiratory and oral-motor function (240,241).

Intrathecal Baclofen Therapy. In patients with more severe or extensive spasticity, typically from brainstem hemorrhage or bilateral hemispheric infarction, intrathecal baclofen (ITB) therapy can be considered (218,224). The components of an ITB system include: a pump implanted under the skin on the abdomen that infuses the drug at a predetermined rate; a catheter that delivers the drug to the intrathecal space of the spinal cord; and a programmer that allows for adjustable and precise dosing (242). ITB therapy should be considered only in those pediatric stroke patients whose severe spasticity interferes with function or care. This population typically has chronic motor disability with either quadriplegia or a mixed pattern of both spasticity and dystonia. Timing of pump placement has not been adequately addressed in pediatric stroke patients, but a minimum of three to six months from stroke onset seems reasonable, given the typical rate of recovery witnessed in most children and adolescents.

Limitations in ITB therapy include: refilling the pump reservoir percutaneously every two to six months (depending on the daily dose) and replacement of the entire pump every five to seven years owing to limited battery life. Of greater concern are potential complications emerging from surgical implantation and refilling procedure, such as CNS infection and peritonitis. Complications from components of the device are also encountered, as are side effects such as somnolence, dizziness, headache, and hypotonia. Withdrawal from the medication is a medical emergency, presenting as somnolence, exaggerated rebound spasticity, muscle rigidity, and most notably fever and pruritus; this condition may advance to rhabdomyolysis and organ failure causing death (243).

Orthopedic Interventions. In stroke-related chronic motor disability, spasticity may progress and cause contractures and bony deformities despite optimal treatment. In such cases, orthopedic surgical intervention may be considered. The most common orthopedic procedures in this group of patients are tendon releases for fixed contractures at the ankle, surgery to correct hip subluxation or dislocation, and spinal instrumentation for scoliosis (105). The benefit of orthopedic surgery is most pronounced in patients who have achieved some degree of skeletal maturation (typically between ages 6 and 12 years), but evidence of efficacy specifically in the pediatric stroke population is limited. Many of these operations require intensification of a physical therapy program to strengthen muscles and improve the ROM in the involved extremity.

Selective Dorsal Rhizotomy. Selective dorsal rhizotomy (SDR) is thought to minimize aberrant muscle spindle input believed to trigger muscle overactivity and thus reduce spasticity in the legs. The operation is performed on the first two lumbar segments (244). Clinical investigation has demonstrated that the combination of SDR and physical therapy is beneficial in reducing spasticity in children with spastic diplegic cerebral palsy (245). Randomized studies indicate that SDR produces gains in strength, gait speed, and overall gross motor function (246,247) and that the degree of functional improvement relates directly to the percentage of dorsal nerve roots transected (248). Patients with spastic diplegia or mild quadriplegia who have good strength and trunk control (249) or those with a history of prematurity appear to be the most suitable candidates for SDR. Recently, however, favorable results have been reported for SDR in children with spastic hemiplegia, some of whom had a stroke as the cause of their motor disability (250).

Treatment of Dystonia and Other Hyperkinetic Movement Disorders

Dystonia following pediatric stroke, especially with basal ganglia involvement, has been reported with a frequency of roughly 1% to 3% (251) (Figure 43.9). Diagnosis may be a challenge given the often overlapping presence of spasticity and the typically delayed presentation, often measured in weeks to months (252,253). Treatment should be individualized based upon the type of movement disorder, recognizing that dystonia is observed most commonly. Though there are little data regarding the efficacy of pharmacologic agents in poststroke, acquired dystonia, trihexyphenidyl (anticholinergic), tetrabenazine (dopamine depleting), and botulinum toxin injections are often utilized (254).

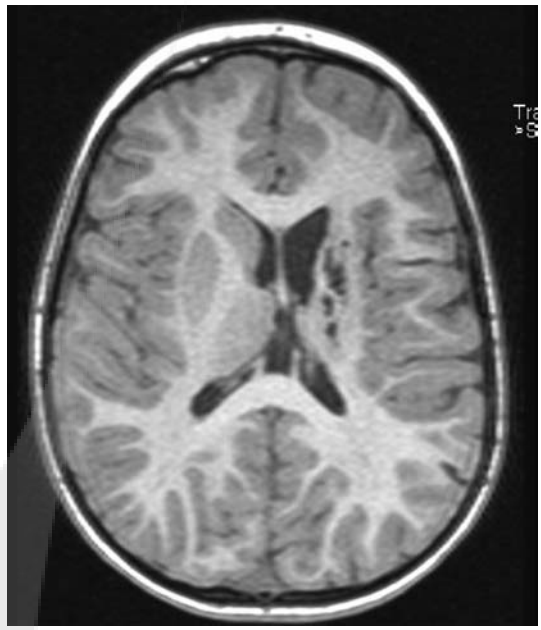

FIGURE 43.9 MRI demonstrating cystic encephalomalacia of the left basal ganglia in a 5-year-old with right arm and leg dystonia. He sustained an acute left MCA stroke 2 years previously, as seen in Figure 43.4.

Rehabilitative Treatment of Cognitive Impairments

Permanent cognitive impairments frequently are observed in survivors of pediatric stroke, impeding performance in academics and success in activities and even limiting independence in ADL skills (255,256). Childhood and neonatal stroke typically produces a moderate degree of global intellectual disability (147,257), with size and location of injury and age at stroke onset the strongest predictors of cognitive outcome (127,258,259). With dominant (usually left) hemisphere strokes, aphasia or other forms of language impairment are seen (256,260) and permanent deficits in complex language function often follow (261,262), as can memory and learning impairments (127,263). Academic skill impairments are more likely to be observed in children with stroke than in their adult counterparts. This finding is consistent with studies demonstrating that lesions acquired in childhood before literacy acquisition detrimentally affect the development of reading skills. This is true both in children who suffer general declines in verbal processing and in those who merely show a deficit in basic phonics skills without poor verbal IQ (264). Studies assessing language function following neonatal onset stroke have suggested that expression and comprehension skills are age appropriate at entrance to school (265,266), but subsequent development of more complex language-based abilities is impaired (267,268).

Age-appropriate neurocognitive evaluations are necessary in all at-risk stroke patients to ascertain educational and psychosocial support needs. Timing of initial assessment will be predicated on rate of recovery, age of patient, and intensity of educational demand (i.e., return to school). Subsequent evaluations typically are necessary, as deficits in higher cognitive abilities, such as executive functioning and specific language skills, may not become evident until years after the stroke when the skills fail to emerge at the expected developmental age (145,146,269).

Role of Therapies. There are several fundamental principles that should guide therapeutic interventions for communication and cognitive impairment in stroke rehabilitation, some of which have applicability to the pediatric population (270). First, therapy should be initiated in the acute care setting where the main focus is on providing appropriate sensory modulation. Cognitive retraining should pervade all aspects of the rehabilitation process; informal memory training should be attempted in every therapy or medical activity, including time spent with nursing, music therapists, and child life specialists. Interventions should be predicated on location of stroke, such as training of visuospatial skills following nondominant hemisphere stroke or cognitive interventions for specific language impairments, including reading comprehension in dominant hemisphere injury (270). Finally, rehabilitation should enhance preserved function as well as remediate residual deficits (218). Continual reassessment of cognitive and linguistic capabilities is essential to structure an appropriate program of therapeutic interventions. Sensory deficits, especially visual, should be ascertained, as they will impair the response to therapy as well as affecting the neurological assessment.

Oral Medications. In the early stage of childhood stroke rehabilitation, establishing an appropriate level of arousal and sustained attention is essential in furthering recovery. Agents that act upon the cholinergic, adrenergic, dopaminergic, and serotonergic neurotransmitter systems commonly are employed in the pharmacologic management of underarousal and/or reduced attention in pediatric patients with traumatic brain injury, but data on childhood stroke are scarce. Stimulants may have a role in children with poor arousal, inattention, and slow cognitive processing, which can be seen in younger stroke patients (263). Tricyclic antidepressants and dopaminergic agents, commonly amantadine, also have been utilized (271). Although not overwhelming, the results do demonstrate a likely overall beneficial impact on arousal/attention. Unfortunately, there are no credible published reports regarding the efficacy of pharmacologic intervention in children or adolescents with respect to memory and learning of new information (272,273).

Rehabilitative Treatment of Behavioral Impairments

Behavioral aberrations can be observed during recovery from pediatric stroke (256). Emotional regression and impaired information processing typically are seen in the initial phase of recovery. For most pediatric stroke patients, in contrast to other forms of acquired brain injury in childhood, their resolution typically occurs over the course of days to weeks. In stroke patients with more severe brain injury whose behavioral symptoms persist, sedative medications still should be avoided, as they often only aggravate the situation by further clouding the sensorium. Therapists and family members should strive to prevent these behavioral disturbances from evolving into learned patterns that can impair recovery and reduce the response to treatment. Unfortunately, there are rare children with stroke-acquired brain injury in whom aberrant and uncontrolled behavior persists. Though medication may be deemed necessary in such cases, use of pharmacologic agents to manage behavior in this clinical setting has not been investigated in children in a scientifically rigorous manner (274). The proposed benefits of most medications are derived from a limited number of studies typically involving only adult stroke patients carried out in a nonblinded fashion and without appropriate controls (275). The most pressing behavioral issues in the pediatric stroke population usually are aggression and severe agitation. Reasonable medications to try in these situations include beta-blockers, carbamazepine, valproate, and tricyclic antidepressants; others would advocate for clonidine, amantadine, and buspirone (276).

Permanent behavioral disorders in pediatric stroke patients can significantly impair social function (277), although the manifestations may not become apparent until midchildhood when the stressors of school are encountered (274). Lesions involving the putamen seem to predict attention deficit hyperactivity disorder (278), whereas bilateral hemispheric strokes raise the risk of emotional disturbances (256).

Psychosocial Family Support

Psychosocial family support must also be considered. Complete care of children with stroke includes their families. Complex psychosocial challenges are likely common and underestimated. Though psychosocial care resources are slowly improving, there is an ongoing need for the development of educational and emotional support to improve pediatric stroke care (105). Adverse effects of stroke on quality of life are measurable in most childhood stroke survivors and their families (279) and relate to both neurological deficits and psychosocial factors (255). Social factors and environment have been shown to affect adult stroke recovery and may be even more important in children (10). Therefore, it is important to introduce families to local and national pediatric stroke advocacy and support groups.

Family support also includes assistance in making informed decisions regarding the increasing number of controversial therapies and alternative medicines directed toward survivors of pediatric stroke. These interventions, such as hyperbaric oxygen and the Adeli suit, typically are quite costly and are marketed despite little to no evidence of efficacy and often well-recognized adverse effects (280–283). In addition, the time and effort wasted on these pseudotherapies both detracts from and often interferes with rational rehabilitation therapies (284). Stem-cell therapies are another controversial and increasingly sought-after intervention for childhood stroke and other forms of pediatric neurological disability (285). Despite their attractive promise, utilization of stem-cell treatments in either the acute or chronic management of childhood stroke is unlikely in the foreseeable future (286,287). A more appropriate focus for families of pediatric stroke survivors and their physicians is to ensure availability of rational therapies for all children with disabilities.

CURRENT RESEARCH ON ENHANCING STROKE RECOVERY

Fueled by the growing understanding of stroke recovery mechanisms at the systems, neuronal, and molecular levels, various novel rehabilitation treatments are currently in different stages of development and efficacy testing, mostly in adults (170,202). These novel treatments all build on some of the basic mechanisms thought to be important for stroke recovery. Many interventions known to improve learning are also being applied to stroke patients, because stroke recovery utilizes some of the same systems-level, neuronal, and molecular mechanisms as learning. Systems-level therapies are specifically aimed at enhancing activity in perilesional cortex and diminishing maladaptive interference from the contralesional hemisphere.

Currently, proposed stroke rehabilitation treatments fall into three basic categories. A large number of the proposed treatments consist of therapeutic training programs that build on existing physical, occupational, and speech therapy paradigms. Compared to more standard therapies, these treatments may incorporate novel technologies, or they may vary some of the specifics of training. A second group of novel treatments electrically stimulates the nervous system both centrally and peripherally. Finally, several medications are being tested in the hope that they might boost recovery from stroke. Not surprisingly, different combinations of novel treatments are also under investigation.

As with research on the basic mechanisms of stroke recovery, rehabilitation treatments have mainly been focused on improving motor deficits. However, efforts are under way to extend some of the more successful motor recovery therapies toward other domains, such as the restoration of sensory, language, attentional, and executive deficits (288,289). Treatments for children recovering from stroke have all been extrapolated from adult interventions.

Taken together, studies on the mechanisms of stroke recovery suggest that a critical period for stroke recovery spans from 5 to about 30 days after stroke. It is considered standard of care for stroke patients with significant deficits to receive multidisciplinary neurorehabilitation consisting of physical, occupational, and speech therapy during this period. However, for practical reasons, such as ease of recruitment, many clinical studies of novel neurorehabilitative interventions have been carried out in chronic stroke patients at a time when further functional improvements are much less likely.

Training-Based Therapies to Improve Stroke Recovery

Constraint-Induced Movement Therapy

Learned Nonuse. Edward Taub proposed that a process he termed "learned nonuse" might contribute to poor upper-extremity function after motor stroke, based on studies with macaque monkeys who stopped using a limb after it had been deafferented, even though they had full strength in the limb (290). He hypothesized that the additional effort and frustration of using a limb that could not provide sensory feedback drove the animals to rely on the unaffected limb. However, when these macaques had their healthy limb restrained, they regained use of the deafferented arm with the help of operant conditioning and behavioral shaping paradigms (291).

CIMT in Adult Stroke Rehabilitation. Taub's hypothesis led to the development of constraint-induced movement therapy (CIMT) as a treatment. Patients treated with CIMT have their unaffected arm restrained with a sling, cast, or mitt for the great majority of their waking hours. At the same time, as patients improve, they practice motor skills that advance in difficulty for about two hours a day. This intensive program is typically carried out for two weeks.

The largest published trial of CIMT to date (EXCITE) randomized 222 adults with hemiparesis at 3 to 9 months after stroke to either 2 weeks of CIMT or customary care (292). This trial showed clear motor benefits of CIMT over customary care at both 12 months (292) and 24 months follow-up (293). A crucial aspect of this study was that customary care meant very little or no rehabilitation therapy for many of the control patients. Thus, it was unclear if the benefits of CIMT were due to the upper-extremity restraint, the intensive motor skill practice, or the combination of both.

The follow-up VECTORS trial investigated CIMT within the first 4 weeks (mean 10 days) after stroke (294). This study randomized 52 patients to receive either intensive inpatient therapy, standard CIMT (2 hours practice, 6 hours restraint per day), or high-dose CIMT (3 hours practice, 90% waking hours restraint) for 2 weeks. No difference in outcome was noted between standard CIMT and dose-matched intensive inpatient therapy at two-week and three-month follow-up.

A meta-analysis that included the EXCITE and VECTORS trials and 16 additional CIMT studies found no significant effect of CIMT on disability and only a moderate benefit for arm function (295). Studies directly comparing CIMT to dose-matched intensive bilateral arm training paradigms showed both of them to be superior to lower-intensity approaches (296,297). Additional trials are needed to establish the parameters within which CIMT is most likely to be beneficial, as it still must be considered a promising treatment (172). Animal studies of CIMT have not provided a more detailed mechanistic explanation of how CIMT could augment stroke recovery in humans (298). A reasonable hypothesis is that in humans decreased activation of the contralesional hemisphere could lower harmful IHI and force systems-level reorganization toward the ipsilesional hemisphere.

CIMT in Children. Studies of CIMT in pediatric patients have focused almost exclusively on children with congenital hemiparesis, many of whom likely had a perinatal stroke. Standard pediatric CIMT used either a cast or a bivalved cast to restrain the more functional arm (Figure 43.10A). Just as in studies of adult stroke, CIMT caused lasting improvements in motor function when compared to standard treatment (Figure 43.10B), which was not dose-matched and therefore significantly less intense (299–301). A more recent study randomized 63 children with congenital hemiparesis to

A B

FIGURE 43.10 Constraint-induced movement therapy typically has two major components: constraint of the more functional arm via a cast (A); and a behavioral program that repetitively encourages graded unilateral movements of the more impaired arm and hand. Play activities, such as crawling over a ball pit, can be utilized to achieve therapy goals, such as finger and wrist extension on the less functional side (B).

dose-matched CIMT or a bimanual intensive therapy (BIT) regimen and found slighter better outcomes for CIMT immediately following the treatment period, but these differences were not sustained at 12-month follow-up (302–305). Given how important intensive practice seems to be for the efficacy of CIMT, a recent study in children with cerebral palsy noted no difference in the benefit of three hours per day of CIMT compared to six hours per day (306,307).

Robot-Assisted Therapy

With advances in robot technology, it has become a possibility that standard therapies could eventually be augmented by robot-assisted therapy. The largest trial randomized 127 patients with chronic (greater than 6 months) upper-extremity hemiparesis from stroke to either receive 36 hours of robot-assisted therapy, dose-matched intensive therapy, or significantly less intensive standard care (308). Patients were followed for 36 weeks. Overall, robot-assisted and dose-matched intensive therapy were equivalent, and both were more efficacious than standard care. Both robot-assisted and dose-matched therapy delivered about 1000 targeted movements per session, whereas standard therapy included about 45 movements per session. A cost analysis revealed that robot-assisted therapy was about $2,000 cheaper than dose-matched intensive therapy.

Robot-assisted therapy may eventually make it easier to deliver the high volume of repetitions needed to affect use-dependent neural plasticity even in the chronic stroke phase (309). A follow-up trial is currently comparing the efficacy of robot-assisted therapy at different doses, given the seeming importance of high numbers of repetitions (180). Besides fine-tuning the optimal dosing and timing of robot-assisted therapy, further technological advances are improving the sophistication of the movements that such robots can perform (310). Use of robot-assisted therapy in children with cerebral palsy and stroke (Figure 43.11) is now also under investigation (311).

FIGURE 43.11 A child with right hemiplegia works to improve shoulder and elbow movement using the maze pattern on the robot.

Dosing and Timing of Movement Training

One common denominator between CIMT and robot-assisted therapy is the high intensity of therapy. When matched for

dose, neither CIMT nor robot-assisted therapy is clearly superior to standard therapy or bilateral therapy. Thus, the main benefit of CIMT and robot-assisted therapy may be that they provide convenient approaches for the delivery of very intense therapy. Animal studies have only shown use-dependent neural plasticity after training programs that were many times more intensive than current standard stroke rehabilitation therapies (196,197,312). A better understanding of the dose-response curves for movement practice is critically important for the delivery of optimal stroke neurorehabilitation. Fortunately, such efforts are currently underway.

Effect of Feedback on Training-Based Therapies

Besides researching the impact of different dosing and timing regimens for task-specific practice regimens, much effort has been devoted to finding ways to further enhance the effectiveness of practice-based therapies. In healthy subjects, motor learning is improved by both implicit and explicit feedback (313). Moreover, it has been suggested that feedback discourages compensatory movements in favor of restoring typical movement patterns. Hence, a wide variety of different mechanisms for delivering feedback to stroke patients have been investigated. Meta-analyses of stroke rehabilitation interventions that provided feedback via different sensory modalities have concluded that feedback about the success and performance of movements seems to be generally beneficial (314). The divergences in methodologies and the small number of patients have precluded the identification of any significant differences between feedback methodologies.

Mirror Visual and Other Sensory Feedback. Mirror visual feedback (MVF) therapy initially was developed as a treatment for phantom pain (315). MVF is based on the hypothesis that the mismatch between motor commands sent to an amputated limb and the corresponding visual feedback contribute to phantom pain. Ramachandran and colleagues asked amputees to perform bimanual tasks while seated in front of a mirror that was placed perpendicular to the patient's chest (315,316). Mirroring the movements of the healthy arm created the visual illusion that patients were controlling two healthy arms and the mismatch between motor commands and visual feedback was alleviated. Mirror therapy has been applied to stroke patients, with the paretic extremity hidden from view by a cover or barrier, as it was thought that mismatched motor outputs and visual feedback might also contribute to learned nonuse of a limb.

A recent meta-analysis of 14 studies that together had enrolled more than 500 patients concluded that mirror therapy seems to improve arm function, but that, similar to the CIMT literature, many of these studies lacked appropriate control conditions (317). It has been proposed that mirror therapy works by activating the contralesional hemisphere, which has been correlated with greater stroke severity. Thus, mirror therapy may be most appropriate for severely paretic patients with the greatest mismatch between motor output and visual feedback and the greatest reliance on contralesional hemisphere involvement.

Other forms of visual feedback, as well as auditory and somatosensory feedback, have all been explored as adjuncts to standard stroke therapies, either alone or in different combinations (314). Overall, enhancing visual feedback seemed beneficial, but none of the relevant studies could demonstrate a clear additive effect of providing feedback in multiple sensory domains simultaneously.

Virtual Reality. Therapies using virtual reality technology have generated much excitement, because they can provide simultaneous feedback via several sensory streams. Virtual reality paradigms also have the potential for high numbers of repetitions, and they can provide motivating environments. The technical sophistication of virtual reality therapies can range from the use of a commercially available gaming console to the use of motion capture technique and concave head-mounted video displays.

So far, only several small-scale studies have evaluated the utility of virtual reality-based therapies (318–321). Most of these studies showed greater improvements for the intervention than the control groups, yet the control interventions were often inadequate, such as passively viewing someone else receive rehabilitation.

Effect of Imagery on Training-Based Therapies

Human neuroimaging experiments have clearly demonstrated that both observing and imagining movements reliably activate the brain's motor systems (322–324). Furthermore, several studies had documented instances of improved motor learning with motor imagery in healthy subjects and athletes (325), and thus these strategies have been considered potential additions to standard stroke therapies.

The largest trial randomized 121 hemiparetic patients within 6 months of their stroke to receive standard therapy, standard therapy plus twelve 45-minute sessions of structured supervised motor imagery, or standard therapy plus nonmotor imagery practice, but the study found no differences between any of the three groups (326). Action observation as an adjunct has only been evaluated in very small samples so far (327). Thus, although some aspects of neuroscience point toward possible benefits from imagery and observation, the clinical studies carried out so far have not documented any.

Training-Based Therapies to Improve Nonmotor Functions

More recently, some of the practice-based therapy principles that guide motor rehabilitation have been applied to the rehabilitation of cognitive abilities, namely language, attention, memory, and executive function, as well as sensory deficits. Like therapies for motor deficits, these cognitive and sensory therapies are mostly based on the massed practice of specific tasks.

Language. Language impairment, or aphasia, is common after strokes in adults and children and is a cause of significant disability (256,260). Patients with impaired language

following stroke typically receive speech–language therapy (SLT) as the standard of care. A recent systematic review of all available adult trials concluded that SLT improves language outcomes when compared to no intervention (328). However, when comparing SLT to control interventions that provided stimulation or support, such as social activities, SLT has not been shown to be superior. The National Health Service in Britain randomized 170 patients with language impairment 2 weeks after stroke to receive either 18 hours of SLT over the subsequent 13 weeks or 18 hours of social visits (329). This study found no differences in language outcomes between the groups.

Attentional Neglect. Attentional neglect, typically of the left side of the patient's body and visual field, is a common deficit after stroke in adults. It has been hypothesized that a 30-degree visual orientation bias to the right is central to the pathophysiology of left neglect (330). Thus, the use of prism glasses during rehabilitation has produced promising results (331). Patients with left neglect wear right-shifting wedge prisms, making it appear as if all visual objects are shifted to the right. Over time, this leads to a rightward shift of visual orientation, which can persist for hours after a session and for up to five weeks after repeated sessions (332). However, a randomized trial of prism adaptation (333), using a small degree of shift, could not identify any lasting benefits.

Executive Function and Memory Deficits. Practice-based strategies to rehabilitate executive function and working memory deficits are still in their infancy. A systematic review of 10 small trials that evaluated a varied collection of therapies for memory and executive deficits (334) identified some benefits when compared to no intervention. However, it is unclear how well any of these improvements on specific tasks will transfer to real-world scenarios.

Sensory Deficits. Training-based therapies for sensory losses are currently least advanced when compared to motor and cognitive rehabilitation. The majority of studies have simply stimulated the areas of sensory deficit (335). However, a few small-scale studies involved practicing sensory discrimination tasks, more similar to the strategies used in motor rehabilitation. The efficacy of any of these interventions is still unclear.

Damages to early visual cortex seem difficult to restore. Therefore, visual therapies have focused on compensatory strategies, such as scanning to improve reading ability, the efficacy of which is supported by multiple smaller studies (336).

Stimulation of the Nervous System to Improve Stroke Recovery

Neuroimaging and neurophysiological studies have revealed some of the correlates of improved outcomes after stroke. Moreover, other such studies have shown how the functional neuroanatomy of the brain's distributed systems can be reshaped by task practice (196,197,337). Repetitive training on specific tasks clearly improves recovery after stroke, but is very time-consuming. Thus, there is significant interest in directly stimulating specific parts of the nervous system, usually by inducing electrical currents, to bypass or at least enhance the process of task practice.

Stimulation of the Peripheral Nervous System

Fifty years ago, electrical stimulation of peripheral nerves was developed as a functional orthotic or neuroprosthesis. Currently, several devices are available to treat foot drop and hand weakness, therapies termed functional electrical stimulation (FES). Research as to whether FES might enhance motor recovery after stroke typically involves stimulation paradigms that have utilized external or internal EMG electrodes to trigger electrical stimulation tuned to elicit functional movements. A host of small studies have found standard therapy plus FES to be superior to standard therapy alone, but they unfortunately did not control for dose effects (338). Human neuroimaging studies have shown that FES can alter activations in motor systems (339). In healthy volunteers, simultaneous voluntary motor activity and FES led to greater cerebellar activation, launching the hypothesis that the coupling of FES and volitional movements may enhance the formation of cerebellar feed-forward models, so important for normal movement (340). Clearly, further studies are needed to evaluate the utility of FES, but it holds special promise for more severely affected stroke patients who are too weak to move without electrical augmentation.

Brain Stimulation

Directly stimulating or inhibiting specific brain regions electrically moves the level of intervention even closer to the final effectors of stroke recovery. Two methods for providing gentle electrical stimulation either directly (transcranial direct current stimulation—tDCS) or indirectly (repetitive transcranial magnetic stimulation—rTMS) are under investigation as potential treatments for enhancing stroke recovery. These methods have received much attention in recent years because many small studies have shown that they can enhance cognitive, sensory, and motor skills in healthy subjects and stroke patients.

Transcranial Direct Current Stimulation. The basic setup of tDCS requires a cathode, an anode, a reference electrode, and a current source, for which a battery suffices; thus, it is technically straightforward. Currents are too small to elicit cortical action potentials (typically 1–2 mA). During stimulation, cortex underlying the anode becomes relatively more excitable because of a depolarization of the resting membrane potential, whereas cortex under the cathode is relatively inhibited because of a hyperpolarization of the resting membrane potential (341–343). In tDCS, current below 2 mA is typically applied for somewhere between 5 and 15 minutes, but subjects can only feel the current for the first few seconds of a treatment and thus cannot discriminate between full treatment sessions of many minutes and sham control sessions during which the current is turned off again after 30 seconds.

Experiments in animals and humans suggest that anodal tDCS lowers GABAergic tone via $GABA_A$ receptors, inducing a state of heightened neuroplasticity that is conducive to learning (341,343,344). Experiments in mouse brain slices showed that anodal DCS paired with repetitive low-frequency synaptic activation induces NMDA receptor-dependent long-term potentiation, a learning mechanism. These effects depend on BDNF signaling and were abolished in mice with a genetic block in BDNF signaling (345).

Studies in both healthy volunteers and stroke patients have shown a great host of performance improvements when comparing tDCS to sham treatments. Improvements were seen across many cognitive domains, including social cognition (346), memory (347,348), language (349), vision (350), and motor function (351–353). In healthy volunteers, tDCS of primary motor cortex during practice enhanced learning on a difficult novel task, and the effect was still apparent at three-month follow-up (351). However, most other studies of tDCS so far showed persistence of beneficial effects for at least several days, but lacked long-term follow-up.

Prior imaging studies suggest that greater ipsilesional and lesser contralesional neural activity correlates with better motor outcomes in stroke. Thus, several small studies have investigated the effects of tDCS in stroke patients with chronic hemiparesis. One study randomized 20 patients to receive either sham therapy paired with rehabilitation exercises or a combination of inhibitory tDCS contralesionally and excitatory tDCS ipsilesionally, also paired with rehabilitation. The treatment group showed an almost 20% improvement in arm function scores, and these benefits persisted at 1 week follow-up (354). A similar study separately compared ipsilesional excitatory tDCS, contralesional inhibitory tDCS, and sham treatment in chronic motor stroke patients (355). Ipsilesional excitatory tDCS was associated with a 5% to 10% performance improvement as well as increased activations on the ipsilesional side as measured by fMRI. Other small studies demonstrated that contralesional cathodal tDCS enhanced function in mildly paretic patients (356) but worsened it in severely paretic patients, consistent with prior studies showing that severely paretic patients rely more strongly on contralesional activations (357). Studies of the functional connectivity between brain regions within the motor system have shown that tDCS also enhances the coupling between motor regions (358–360). Although tDCS treatment is low cost and very safe, unfortunately it remains largely unstudied in children.

Repetitive Transcranial Magnetic Stimulation. TMS uses rapidly shifting magnetic fields to induce small currents in the underlying brain tissue and induce neurons to fire action potentials; when applied over motor cortex, it can cause muscle movements. Repetitive TMS (rTMS) is similar to tDCS in that it can increase or decrease the excitability of underlying cortex without causing the generation of action potentials. Low-frequency rTMS (1 Hz) diminishes brain excitability, whereas high-frequency rTMS (5–20 Hz) enhances it. Typically, rTMS is applied for about 20 minutes at a time. Modern TMS coils can target small areas of the brain, including deeper-lying structures (361). Repetitive TMS is generally well tolerated; however, there have been some reports of rTMS treatments causing seizures (362).

It is thought that rTMS, similar to tDCS, induces a local state of heightened use-dependent neuroplasticity (343). Yet, rTMS may affect brain plasticity through somewhat different molecular and cellular mechanisms. MR spectroscopy studies in humans, for example, have shown that inhibitory rTMS increases GABA levels locally (344), whereas inhibitory tDCS lowers both GABA and glutamate levels (344).

Neuroimaging studies in humans have shown that rTMS tends to modulate activity throughout the entire functional system that was targeted by the treatments (343,363,364). During post-rTMS task performance, focal brain activations can be altered as well as the relationship between brain regions belonging to the system (e.g., motor system) (343,363,364).

Evidence for the clinical efficacy of rTMS in stroke patients is limited to small-scale studies. A recent double-blinded trial randomized 30 chronic stroke patients with hemiparesis to receive either 25 minutes of inhibitory rTMS (1 Hz) or sham treatment to the contralesional hemisphere twice a day for 10 days. Half the group received treatment prior to 45 minutes of standard therapy and the other half received therapy first followed by rTMS. At 90-day follow-up, the treatment group overall had significantly better motor outcomes. Furthermore, the benefit was significantly greater if the rTMS treatment was followed by therapy and not vice versa (365). A recent meta-analysis of rTMS studies in adult stroke patients suggested that rTMS might be beneficial when added to standard therapy and that contralesional inhibitory rTMS may be more beneficial than ipsilesional excitatory rTMS (366), although patients with larger strokes are less likely to demonstrate positive benefit (367).

In contrast to tDCS, rTMS has been studied in children with chronic paresis after stroke. A total of 10 children who had suffered a subcortical stroke anywhere between the ages of 1 month and 17 years were randomized to receive either contralesional inhibitory rTMS or sham treatment (368). These children received 20 minutes of rTMS daily for 8 days and showed improved grip strength at 17 days after treatment. A follow-up study showed that the treated group had decreased IHI (369). As with tDCS, rTMS has generated some promising results, but more research is needed before it can become a clinical treatment.

Medications to Improve Stroke Recovery

Using medications during the subacute phase to help restore function after stroke represents a separate endeavor from using these same or similar medications to treat persistent symptoms following stroke, such as depression or inattentiveness. Efforts to find such neurorehabilitative medications have focused on compounds shown to improve use-dependent neuroplasticity and learning.

Selective Serotonin Reuptake Inhibitors

Four small clinical trials enrolled a total of 84 patients and each trial showed motor improvements, albeit using different outcome measures and time points and 2 different selective serotonin reuptake inhibitors (SSRIs) (370–373), but each reported a beneficial effect. One trial studied patients with fMRI following a single dose of fluoxetine and found increased ipsilesional motor cortex activation and improved function of the corresponding hand (371).

The fluoxetine for motor recovery after acute ischemic stroke (FLAME) trial was a randomized, placebo-controlled, double-blinded multicenter clinical trial that randomized a total of 118 adults with moderate to severe motor deficits to receive either standard rehabilitative care plus 20 mg of fluoxetine daily, or standard rehabilitative care plus placebo (374). Patients were randomized between 5 to 10 days after stroke and received fluoxetine or placebo for 90 days. Motor outcomes were significantly better in the treatment group, without significant adverse effects. Even though the fluoxetine treatment group had lower levels of depression at 90 days, it seems unlikely that the motor benefits were solely driven by decreases in depression (375). Any patient who developed clinical depression in the treatment or placebo arms was treated with fluoxetine 20 mg, but the data were still analyzed on an intention-to-treat basis.

Although the FLAME trial enrolled only patients between 18 and 85 years, it seems reasonable to extrapolate its findings to include at least teenage patients who have suffered a motor stroke, especially given fluoxetine's safety profile in the pediatric population (376,377).

Stimulant Medications

Stimulant medications have a potent activating effect on the brain and induce the release of norepinephrine, dopamine, and serotonin neurotransmitters. Positive results in animal studies suggested that stimulant medications might be beneficial for human stroke recovery (378). Many studies have shown enhanced poststroke recovery in animals treated with amphetamines, with some of these benefits preserved for up to eight weeks (379,380). A close temporal relationship between stimulant treatment and skill training seemed necessary for lasting improvements. Several studies also reported that the behavioral improvements in stimulant-treated animals were associated with increased axonal sprouting (380–382).

Unfortunately, human trials so far have not replicated the encouraging animal data (383,384). These failures may have been caused by a variety of reasons, such as improper stimulant dosing, incorrect timing of stimulant treatment to rehabilitative therapy, selection of the wrong stroke subpopulations, and inadequate therapy intensity (385,386). Data from pediatric studies are scarce, but stimulants in children actually have a better safety profile than in adults and thus deserve ongoing consideration.

Medications That Increase Dopamine

Similar to animal studies of amphetamines, pharmacologically increasing dopamine also induces neuroplasticity and improves stroke recovery in animal models (387,388). Studies in healthy human volunteers have shown that the administration of levodopamine modulates use-dependent neuroplasticity (389,390) and that it can facilitate motor memory in healthy volunteers (391) and stroke patients (392). In the largest clinical trial of levodopamine in stroke recovery so far (53 adults), those receiving standard therapy plus 100 mg levodopamine daily at 3 weeks to 6 months after stroke had significantly better motor scores when compared to those who were treated with standard therapy plus placebo (393). No data currently exist to determine whether pediatric patients might benefit from levodopamine as an adjunctive therapy during stroke recovery.

Medications That Could Negatively Impact Stroke Recovery

Medications that counteract the neuropharmacological effects of drugs deemed beneficial during stroke recovery could theoretically worsen stroke recovery. There are no human data that speak directly to this point. However, animal studies suggest that increasing GABAergic signaling during the subacute recovery phase, for example, through the use of benzodiazepines, could worsen stroke outcomes (159). Similarly, haloperidol, a neuroleptic that decreases catecholamine release, blocks the benefits of stimulant treatment in rats (378). Thus, it might be prudent to avoid such medications in all patients recovering from stroke, including children, unless absolutely necessary.

CURRENT RESEARCH ON COMPENSATING FOR STROKE DEFICITS

Brain–Computer Interface

Some stroke patients will continue to suffer debilitating deficits despite maximal rehabilitative efforts. For example, adults and children with brainstem strokes often have very poor motor recovery, possibly because important brainstem circuitry is concentrated in a small area and less redundant than circuitry in other parts of the brain (181,182). Despite causing severe motor impairments, brainstem strokes often spare cortical and subcortical motor systems. Thus, though the restoration of typical function may be out of reach for some of these patients, they may benefit from neuroprosthetics controlled by brain–computer interfaces (BCIs). The basic BCI approach is to use the brain's own motor command signals to control a computer-controlled prosthetic device. The prosthetic device can be anything from a cursor on a screen to a complex robotic limb. At least in theory, any type of neural signal can be used to power a neuroprosthetic. BCIs represent a rapidly growing area of research fueled by continued improvements in computing power and algorithms for extracting critical information from extremely large data sets, as well as advances in robot design (394).

Intracortical Multi-Electrode Arrays

Although standard EEG signals recorded from electrodes placed on the scalp can be used to create a BCI (395,396), intracortical recording of neural signals to power BCIs is the more advanced and also the most invasive approach. Multi-electrode arrays that can record extracellular neural signals from many neurons simultaneously are implanted in primary motor cortex. The highly mathematically processed neural-derived signals are then used to control a robotic device. A few tetraplegic human patients have been implanted with electrode arrays in primary motor cortex, which have been used to control a computer cursor (397)—an ability that has remained stable for years (398)—and more recently to move robotic arms in three dimensions, allowing a patient to drink coffee from a bottle (399). Currently, the use of robotic arms is limited to laboratory settings (399) and none have been tested in the pediatric population.

Opportunities and Challenges Specific to Stroke Recovery in Children

Almost all basic research on the molecular, neuronal, and systems-level mechanisms of stroke recovery has been carried out in animal models of adult stroke and adult stroke patients. Similarly, almost all clinical studies of various treatments meant to enhance stroke recovery were carried out in adults. By sheer necessity, much of pediatric stroke rehabilitation has therefore been extrapolated from adult stroke rehabilitation. Thus, it is important to be mindful of the particular opportunities and challenges posed by studying and caring for children during their recovery from stroke.

Children May Have Potential for Better Overall Outcomes

When compared to adult stroke patients, children have better survival rates after stroke (14,400). On average, children who suffered strokes also seem to recover to a greater degree than adults (174,400). In children, many individual cases of complete or near-complete recovery after severe strokes have been highlighted. For example, near-complete recovery from neglect and hemiplegia (401) or major improvements of visual deficits following bilateral occipital stroke (150) have been reported. Children who suffered large left hemisphere strokes perinatally can often develop normal language skills (402,403).

Stroke outcomes are not uniform across age (11). Historically, it had been argued that the youngest stroke patients should have the best outcomes, as their brains were presumed to be the most plastic. However, more recent studies showed that children who suffered a stroke between the ages of 1 to 6 years relatively have the best outcomes (148,404). Stroke outcomes were relatively worse in children younger than 1 year and older than 6 years. Similar to adults, it seems that most of the functional recovery in children occurs in the first three months after stroke (174).

Even though children overall seem to have better outcomes after stroke than adults, the majority of pediatric stroke patients will still have to contend with some neurological deficits for the rest of their lives (139).

Potential Differences in Recovery Mechanisms Between Children and Adults

It often has been argued that the apparently better stroke outcomes in children are at least partly caused by greater neural plasticity. One often-cited example for this is that children who have undergone complete surgical disconnection of one hemisphere commonly show a remarkable recovery of function on the affected side of the body, which by definition can only be supported by the contralesional hemisphere (405). This has led to the hypothesis that recovery of function in children can depend on contralesional activity to a greater degree than in adults. However, a small study of inhibitory contralesional rTMS in children with stroke (mean age 13 years old) showed that it enhanced hand function, just as it does in adults (368). Thus, though children may have better outcomes after functional loss of a whole hemisphere, IHI may still have a negative effect on stroke outcomes in children.

Normal language development following large perinatal lesions of the left hemisphere lesions is also typically attributed to greater neural plasticity in children. Functional MRI studies of language function in such patients documented differences in activation patterns when compared to age-matched controls (402,403). However, the specific differences varied across patients, suggesting that the development of language after stroke differed from child to child.

CONCLUSION

Stroke is an important cause of morbidity and mortality in the pediatric population. The risks and benefits of stroke treatments in children may differ significantly from those in adults, probably because of developmental differences in the cerebrovascular, neurologic, and coagulation systems. The variety of etiologies of pediatric stroke makes it difficult to develop stroke prevention strategies based on adult studies. Despite the fact that the incidence of pediatric stroke is lower than stroke in adults, the consequences of stroke in children can have a lifelong impact on function, families, and use of resources. Lo et al. determined that the median cost for pediatric poststroke care during the first year after diagnosis was $42,338 (7). The cost for stroke care was higher for hemorrhagic stroke than for ischemic stroke. Cost had a significant positive correlation with neurologic impairment.

There is a growing consensus among those who study pediatric stroke that a common terminology is needed to enhance research and multicenter trials (34,151). Increased awareness of unique pediatric stroke subtypes, their clinical presentations, and findings on imaging studies can improve early identification and development of optimal treatment strategies. Furthermore, improved recognition of subtypes may lead to more effective secondary stroke-prevention measures (28).

A pediatric stroke rehabilitation model should be utilized to help parents and the treatment team members embrace the multidisciplinary process for recovery. Encouraging family members to become active participants in the rehabilitation process may help with the advocacy that is necessary in the educational setting. Preconceived notions of what a child may or may not be able to accomplish may interfere with his or her ability to participate fully in athletic and social activities. As is true with all children, it is incumbent on the caregiver to help maximize each child's functional potential. The pediatric rehabilitation team is a resource for families to help accomplish this goal.

Stroke rehabilitation of children and adolescents has improved dramatically over the past two decades. Advances in surgical and medical management and technology have produced a dramatic impact on the mortality/morbidity and quality of life of the acutely affected child. Our understanding of the biologic mechanisms of stroke recovery has accelerated, leading to the hope that this knowledge can be translated into specific therapies that can serve as the basis for restorative rehabilitation. The more immediate need is to upgrade the rehabilitation treatment we provide for our children who survive stroke. Few of the currently employed therapeutic interventions, medications, and physical modalities implemented in the rehabilitation of children and adolescents with stroke have been subjected to rigorous scientific research with appropriate control subjects. Most published investigations involve limited populations with little regard for the impact of normal development on recovery; many fail to recognize that only achievement of functional goals are meaningful and appropriate end points. Objective research investigations with quantifiable, clinically relevant outcomes using double-blinded protocols are essential for the future growth of rehabilitation and improvement in the care given to the survivors of pediatric stroke.

Stroke in Young Adults

Randie M. Black-Schaffer

Approximately 4% of strokes in the United States occur in adults younger than 45 years old (1). Although the 32,000 strokes in this age group are a small fraction of the 795,000 total occurrences in the United States each year, they are a significant source of neurologic impairment in this group. The fact that stroke occurs in those under 45 years old more than twice as frequently as both spinal cord injury (12,000/year for all ages) and multiple sclerosis (12,000/year for all ages) in the United States has not been well recognized (2,3), perhaps because of the tendency to consider young adult stroke in the context of all strokes rather than in the context of all causes of neurologic impairment in the young. In contrast to the United States, in developing countries with younger populations, stroke in adults under the age of 40 accounts for between 19% and 30% of all strokes, leaving no doubt about its significance as a source of neurologic impairment in these societies (4). Numerous investigations over the past 25 years have established important differences in the incidence, epidemiology, etiology, treatment, and outcomes of stroke in young adults compared to older populations. These are discussed in this chapter.

EPIDEMIOLOGY

Incidence

The incidence of stroke in adults under 45 to 50 years of age has been found to range from 8.6 to 26.4 per 100,000 in European and American populations (5–13). Notably higher rates are reported in two studies of African populations (4,14) (see Table 44.1). These numbers contrast with the much higher incidence of stroke in older adults, which, in the United States, ranges between 230 per 100,000 in white females and 660 per 100,000 in black males for those 45 to 84 years old (15).

Not only is the frequency of stroke different in young adults compared to adults of all ages, but the distribution of stroke types differs as well. Among people in the United States of all ages, 87% of strokes are ischemic infarctions and 13% are intracerebral (ICH) or subarachnoid (SAH) hemorrhages (15). In most studies of young adults, there is a higher frequency of hemorrhagic events. The population-based study of young Italians by Marini et al. found 57% infarction and 42% hemorrhages (ICH and SAH) (16). Moreover, Nencini et al. in Florence and Leno et al. in Spain found fewer than 50% infarctions in their young adult stroke populations (5,9). In contrast, studies in Israel and Libya have chronicled rates of 81% and 78% infarction among young adults with stroke (Table 44.2). The reasons for this variation from one population to another are unclear, but may relate to differences in genetic susceptibility, acquired risk factors, or temporal bias.

There is evidence that within the "young stroke" population, incidence increases with age. Under the age of 35, incidence is less than 10/100,000; but between ages 35 and 44, the rate increases to 22–45/100,000/year (17).

A recent investigation using the Nationwide Inpatient Sample (NIS) suggests that the rate of hospitalization for ischemic stroke in young adults in the United States both male and female aged 15 to 44 increased significantly between 1995 and 2007. A second study of the Greater Cincinnati/Northern Kentucky population notes a significant increase in stroke incidence in persons 20 to 54 years old between 1993 and 2005. Both of these studies found a greater increase in ischemic than hemorrhagic events in the studied groups. The extent to which their observed increases are due to improved case ascertainment related to greater use of MRI versus earlier onset of stroke risk factors remains to be clarified. In the Cincinnati study, for example, 18% of stroke patients received an MRI in 1993, compared to 58% in 2005 (18,19).

Location of infarct appears similar in young and older populations, though comparative data are limited. Anterior circulation infarcts comprise 70% of infarcts in older populations and 59% to 64% in two Scandinavian young adult populations (6,10,20).

Gender

Women, as a group, experience an increase in stroke risk during their childbearing years because of the hazards of pregnancy and the puerperium as well as the use of oral contraceptive (OC) medications, particularly in combination with smoking. In many studied populations, young women's incidence of stroke exceeds that of young men. This was the case for all strokes in Rochester, Minnesota, during most of the period from 1955 to 1989 (21); in Denmark from 1977 to

TABLE 44.1 Incidence of Stroke in Young Adults (Population-Based Studies)

STUDY	POPULATION	AGE RANGE	TYPE OF ARTERIAL STROKE	INCIDENCE /100,000
Nencini (1988) (5)	Florence, Italy	15–44	All	8.8
Guidetti (1993) (12)	Northern Italy	15–44	All	13.6
Kristensen (1997) (6)	Northern Sweden	18–44	Infarction	11.3
Lidegaard (1986) (7)	Denmark	15–44	Infarction, TIA	15
Jacobs (2002) (8)	Northern Manhattan	20–44	All	23
Leno (1993) (9)	Cantabria, Spain	16–45	All	12.0
Naess (2002) (10)	Western Norway	15–49	Infarction	11.4
Rozenthul-Sorokin (1996) (11)	Israel	17–49	All	10.4
Radhakrishnan (1986) (4)	Benghazi, Libya	15–40	All	47
Rosman (1986) (14)	Pretoria, South Africa	20–54	Infarction, ICH	33
Gross (1984) (22)	Alabama	20–54	All	Whites: 42
			All	Blacks: 50
Ghandehari (2006) (104)	Southern Khorasan, Iran	15–45	Infarction	8
Corbin (2004) (23)	Barbados	25–34	All	11
		35–44	All	30

1982, where Lidegaard et al. found an increased incidence of cerebral infarction in women aged 15 to 34 compared to men; in Western Norway for those under age 30 (10); in Cantabria, Spain, where strokes were more frequent in women in the 31 to 35 age cohort (9); and in Florence, Italy, where women aged 15 to 34 suffered more strokes than men (5). In southern Alabama, black women in the 20 to 54 age cohort were found to have twice as many strokes as black men and white women. In Barbados, women aged 25 to 44 also exceeded men in the number of strokes (22,23). More recently, this trend was confirmed in an analysis of data from the Helsinki Young Stroke Registry (24).

This trend was not found in the Northern Manhattan study, where men aged 20 to 44 had 1.2 times the risk of stroke and a high proportion of ICH (8). In the African population of Ibadan, Nigeria, the incidence of stroke in those 20 to 29 years old was equal in men and women and higher in men in all other decades (25). Population differences in prevalence of different risk factors in men could account for these differences.

Race and Ethnicity

Population-based studies in American cities have documented a higher incidence of stroke in young blacks compared to whites. In the Greater Cincinnati/Northern Kentucky area, the incidence of stroke was higher for blacks at all ages, but the greatest increase in risk (five-fold) was in young and middle-aged blacks. The risk of first-ever stroke was twice as high for blacks in the less than 35 age group, rising to five-fold higher in those aged 35 to 44 and then declining in succeeding age groups to a 1.3-fold increase in those older than 85. The authors hypothesized that the higher incidence in blacks was related to a higher burden of hypertension and diabetes and to socioeconomic factors (26). A similar trend was seen in the Northern Manhattan study, where the increase in risk of stroke in blacks compared to whites, present in all age cohorts, peaked at nine-fold in those aged 35 to 44 years (27). In southern Alabama, the increase in stroke risk for blacks compared to whites peaked at 2.5-fold in the 55 to 64 age range. In the Baltimore/Washington area, blacks had

TABLE 44.2 Distribution of Stroke Subtypes in Population-Based Studies of Young Adults With Stroke

STUDY	POPULATION	INFARCT %	ICH %	SAH %
Marini (2001) (16)	L'Aquila, Italy	57	20	23
Leno (1993) (9)	Cantabria, Spain	47	27	25
Nencini (1988) (5)	Florence, Italy	38	21	36
Rozenthul-Sorokin (1996) (11)	Israel	81	10	8
Radhakrishnan (1986) (4)	Benghazi, Libya	78	13	10

a 2.1-fold higher risk of ischemic stroke and a 3.1-fold higher risk of ICH compared to whites (22,28). In addition, in 1984, Gross et al. found a higher risk of stroke in black females but not males, compared to their white counterparts aged 20 to 54 in southern Alabama. The actual numbers of strokes in each age and race category in this study were small, and confidence intervals (CI) were not given (22).

These findings corroborate those of the pre-CT era literature (29). Eckstrom et al. in 1965 in Missouri and Heyman et al. in 1971 in Evans County, Georgia, found a higher incidence of stroke in young blacks compared to whites, with young black women showing the highest risk in the latter study (29,30).

The question of black and white racial differences outside of the United States has been less explored. Stewart et al., studying a mixed population in South London, found a higher incidence of stroke in blacks under the age of 45 compared to whites (44 per 100,000 in blacks aged 25 to 34, compared to 5 per 100,000 in whites and 42 per 100,000 in blacks aged 35 to 44 compared to 28 per 100,000 in whites) (31). Whether there are regional differences throughout the world in the susceptibility of different, young black populations to stroke has yet to be investigated.

The Northern Manhattan Stroke Study examined relative risk (RR) of stroke in Hispanics aged 20 to 44 and found a 2.5-fold higher risk compared with whites, whereas blacks showed a RR of 2.4 (8). A population-based study of stroke rates over a 20-year period among New Zealand women found an increasing incidence in Pacific women, a decline in European women, and no change of rate in Maori women. These two studies illustrate the need for further exploration of ethnic and racial differences in stroke incidence around the globe.

ETIOLOGY

An Evolving Spectrum of Causes

More than 60 different disorders causing stroke in young adults were identified in a comprehensive list published in 1983 (32). A few of these, particularly valvular disease caused by rheumatic fever and infectious arteropathies, have diminished in importance in developed nations since that time. However, a number of new potential causes of stroke in young adults have appeared. Prothrombotic states caused by antiphospholipid antibodies (first described in 1978), deficiency of proteins C (1981) and S (1984), Factor V Leiden (FVL) (1993), and the prothrombin 20210A mutation (1996) can increase the risk of arterial stroke as well as venous thrombosis in young adults. Cerebral venous thrombosis (CVT) in young adults has also been characterized (33). Drugs of abuse, including cocaine, heroin, and the ephedra alkaloids, have been recognized as significant causes of stroke at the same time that the risk of stroke from OCs has declined with the advent of lower dosing. The risk of stroke in young adults with HIV/AIDS, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), mitochondrial encephalopathy lactic acidosis and stroke (MELAS), and the reversible cerebral vasoconstriction syndrome have been discovered (34,35). Finally, there is dawning acknowledgment of the role played by our increasing array of medical and surgical interventions in supporting the incidence of stroke in young adults. For example, cervical and brain radiation, transplant surgery, artificial valves, carotid stenting, and chiropractic maneuvers all have an associated risk of stroke, and all tend to be offered to younger patients. The failure of stroke incidence rates in the United States to decline since the 1980s may, in part, reflect an increase in the iatrogenic opportunities for stroke (36–43).

Advances in craniocervical imaging in the past two decades have improved detection of several important causes of stroke in young adults. Magnetic resonance and computed tomography imaging and angiography have greatly enhanced our ability to diagnose large vessel dissection, intracranial vasospasm, vasculitis, and CVT.

Distribution of Causes by Age Subgroup

Although an extensive literature on aspects of stroke in young adults has developed over the past 30 years, the definition of *young* has not been standardized. Case series variably use 30, 40, 45, or 50 as their upper age limit for young adult patients. This fact—and the small sample size of most reported series—have made it difficult to discern natural age subgroups within the broader category of young adult stroke. Nonetheless, it is clear that the distribution of causes of stroke in adults 15 to 35 years of age differs from that in adults 35 to 50 years of age. In the younger group, cardiogenic embolism, drugs (both therapeutic and illicit), migraine, traumatic dissection, prothrombotic states, and premature atherosclerosis caused by inherited conditions such as homocystinuria are prominent factors, whereas in the older subgroup, dissection, antiphospholipid antibodies, and atherosclerosis caused by hypertension and other traditional risk factors are prominent (44–47). Neto et al., using the Trial of ORG 10172 in Acute Stroke Therapy (TOAST) criteria (48), examined the distribution of stroke mechanisms in 106 patients admitted to a university hospital in Sao Paulo with cerebral infarction and found that those aged 15 to 29 had a higher proportion of strokes because of "other determined causes" and the group aged 30 to 40 had more "cardioembolism"-related events (49). The study of larger populations and series will enable further definition of etiology patterns in different decades of adulthood.

Many case series have considered the causes of stroke in young adults. These studies frequently come from tertiary care hospitals, with their attendant bias toward cases of unusual/complex etiology. For this reason, true frequencies of the specific etiologies of stroke in young adults have been difficult to determine. There is fair agreement on broad categories of causation, however, and Hart and Miller's 1983 categories have proven durable, with the addition of drug use, which is an increasing cause of stroke in urban settings in the developed world (50). Hart and Miller attributed stroke in young adults to atherosclerotic disease in 20%;

cardiac emboli in 20%; arteropathies, particularly large vessel dissection, in 10%; coagulopathy in 10%; and peripartum cerebrovascular events in 5%. Another 20% was related to mitral valve prolapse, migraine, and OC use, and 15% remained unexplained after full evaluation (32,47).

Specific etiologies of stroke in young adults described in the literature are listed in Table 44.3. Even though it is beyond the scope of this chapter to discuss all of these in detail, we will review several of the important and controversial causes of stroke in this age group.

Cervicocranial Dissection

After cardioembolic stroke, dissection is the second leading cause of stroke in patients younger than 45 (51). This mechanism accounts for 10% to 25% of strokes in young and middle-aged adults (52). Large vessel dissection is a disorder of midlife; its incidence peaks in the fifth decade. A population-based study from Rochester, Minnesota, found a mean age of 45.8 for dissection cases (53). Both internal carotid and vertebral arteries have segments vulnerable

to the effects of head and neck movement. In the internal carotid artery (ICA), the distal half of the extracranial segment is most often affected, whereas in the vertebral artery, the V3 segment from C2 to the artery's entrance into the skull and the V1 segment in the neck are commonly involved. The external and common carotid arteries are rarely affected. The mechanism usually involves an intimal tear with dissection of arterial blood between the intimal and medial layers of the arterial wall or rupture of vasa vasorum leading to intramural hematoma. This can cause bulging of the inner arterial wall and stenosis or occlusion of the lumen. The intimal tear can become a nidus for formation and embolization of platelet and/or fibrin thrombi. In some cases, trauma to the artery may instead cause intramural hematoma formation with secondary rupture from the intima into the lumen, or there may be primary intramural hematoma dissecting between arterial layers and causing luminal stenosis or occlusion without rupture into the lumen. Cerebral infarctions resulting from a carotid dissection can thus be small, cortical insults caused by emboli, watershed territory lesions caused by low flow from a sudden carotid stenosis, or major anterior circulation infarction from rapid development of carotid occlusion. The

current belief is that approximately 80% of dissection-related strokes are caused by embolization and 20% by carotid thrombosis.

Carotid dissection has historically been difficult to diagnose. Patients present with pain, often above or behind the eye or along the side of the neck, jaw, and face. They may describe pulsatile tinnitus and transient monocular blindness. They may see scintillating scotomata and have transient cranial nerve dysfunctions, especially of XII, which may be irritated by an expanding ICA in the neck. An important clue in nearly half of patients is a partial Horner's syndrome with miosis and mild ptosis on the side of the pain. This is caused by irritation of the sympathetic plexus carrying oculomotor fibers, which runs along the ICA. Sympathetic fibers supplying the ipsilateral facial sweat glands run along the external carotid artery and are not affected in ICA dissection, hence sweating function remains intact.

The symptoms of vertebral dissection include pain in the posterior neck and face, which typically precedes vertigo, nausea, staggering, and/or dysarthria. Embolization is most often to the PICA territory. Signs of lateral medullary dysfunction, including nystagmus, skew deviation, and first division trigeminal sensory loss, may occur (54–57).

Dissection of a major artery may be related to a variety of diseases and types of trauma, many of them seemingly trivial. The spectrum of these is illustrated in Table 44.4. Symptoms of dissection frequently evolve from migraine-like headache to neurologic deficit over days to weeks, making recognition of the inciting event difficult for the patient and clinician. The diagnosis of dissection can be made by MRI/MRA, ultrasound, or catheter angiography. Axial cuts on MRI/MRA can be helpful in demonstrating a contracted arterial lumen surrounded by clot, and CTA can demonstrate segmental narrowing or rapid tapering of the arterial lumen in sagittal views. Treatment commonly is six months of full-dose Coumadin or aspirin to prevent further embolization, with no significant difference in outcomes or recurrence between the two treatment options demonstrated to date. The risk of recurrent dissection is approximately 1% per year (58).

Pregnancy and Childbirth

Pregnancy and the puerperium are a time of increased risk of stroke for young women. The overall incidence of stroke during this period in the United States in 2000 to 2001 has been calculated at 34.2 per 100,000 deliveries (59). Recent studies suggest that the risk of stroke is less during the first two trimesters and surges in the peri- and postpartum period. In the Baltimore/Washington area, the RR was 5.4 [95% CI 2.9–10] for cerebral infarction and 18.2 (95% CI 8.7–38.1) for ICH during the peripartum weeks (56). A Swedish population-based cohort study found a markedly elevated RR of SAH of 46.9 (95% CI 19.3–98.4), of ICH 95.0 (95% CI 42.1–194.8), and cerebral infarction 33.8 (95% CI 10.5–84.0) from 2 days before to 1 day after delivery, compared to the nonpregnant state (60). Figure 44.1 shows the distribution of stroke risk during pregnancy in this study. The most frequent cause of both ischemic and hemorrhagic stroke in the puerperium is eclampsia, found in 24% to 47% of infarctions and 14% to 44% of ICHs (61,62). Rapid and severe elevation

Trauma	Attempted strangulation
	Blunt trauma to neck (cow's tail, car door, car shoulder seatbelt)
	Sharp trauma to neck (gun, knife injuries)
	Hyperextension of neck (dental chair, beauty parlor stroke, bottoms-up, dissection, painting a ceiling, CPR, roller coaster)
	Head rotation (chiropractic manipulation, shoveling snow, backing up car, yoga, tennis, bow hunter's stroke)
	Forceful head and body rotation (golfer's stroke)
	Vigorous aerobic exercise (treadmill, rowing machine)

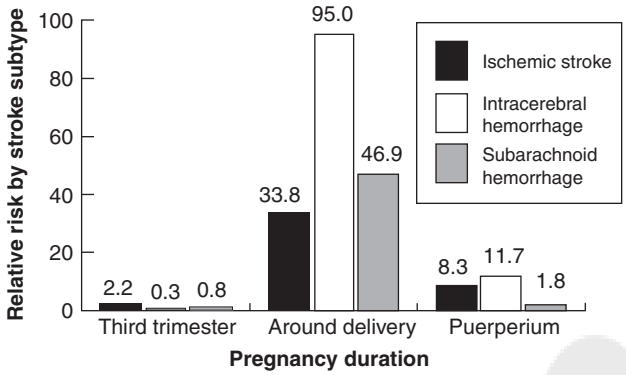

FIGURE 44.1 Risk of stroke in women in the third trimester, peri- and postpartum periods versus risk of nonpregnant women and women in the first two trimesters.

Source: Adapted from Refs. (15,60).

of blood pressure is a likely mechanism, and women with underlying aneurysm, arteriovenous malformation (AVM), or other vasculopathy are particularly vulnerable. Other less common associations with pregnancy-related stroke include amniotic fluid embolism, choriocarcinoma, postpartum cerebral angiopathy, infection, cardiomyopathy, and use of ergot derivatives (59,63). An NIS analysis from the United States using 2000 to 2001 data found a number of factors associated with increased risk with an odds ratio (OR) of six or higher:

- Age older than 35 years
- Migraine
- Thrombophilia
- Pre-existing heart disease or hypertension
- Systemic lupus erythematosus
- Sickle cell disease
- Thrombocytopenia

Regarding race and ethnicity, black women had a higher risk of stroke than Hispanic or white women in this study. Of those who suffer a pregnancy-related stroke, 4% to 15% die, and 10% to 22% of survivors are too impaired to be discharged home from the acute hospital (59).

Cerebral Venous Thrombosis

CVT also occurs in late pregnancy and the postpartum period, as well as in hypercoagulable states of other causes. It may cause ischemic and/or hemorrhagic stroke. Its incidence in a recent U.S. population-based study of pregnancy-related stroke was calculated at 11.6 cases per 100,000 deliveries, nearly as high as the incidence of arterial stroke (13.1 per 100,000). The risk of CVT increases in the presence of an underlying coagulopathy or malignancy, and it is associated with cesarean delivery, infection, and hypertension (64). The initial symptom is most often headache, which may progress after days or weeks to seizures and/or focal neurologic deficits. Sinus thrombosis causes increased intracranial pressure caused by impaired venous drainage. This may progress to venous infarction, usually of superficial cortical veins, often bihemispheric. The superior sagittal, transverse, and straight sinuses are most often involved. MRI, which clearly delineates the venous sinuses, has greatly improved diagnostic accuracy. Treatment in cases without ICH is evolving from anticoagulation with heparin toward targeted thrombolysis, both followed by warfarin for several months. Functional outcome of CVT is usually good, with 75% to 85% achieving full functional recovery (65).

Migraine

Migrainous infarction is a fixed, focal neurologic deficit following an attack of migraine. In population studies, it accounts for 0.5% to 1.5% of all ischemic strokes and 10% to 14% of ischemic strokes in young patients (66). Infarction occurs more often in migraine with aura. The mechanism is thought to involve unusually severe cortical spreading depression with hypoperfusion during the aura and/or the headache. One-third of these infarcts involve the occipital lobe. Common deficits include visual field cuts, perceptual disturbances, and dysphasias. Migraine is a disease of younger adults and is three times more common in women than men. Consistent with this, a recent meta-analysis found the risk of ischemic stroke to be increased 2.7-fold in women younger than 45 years who suffer from migraine headaches (67). That risk rises further in those with migraines who smoke and/or use OC (66,68). Despite this data, the relationship between migraine and cerebral infarction and its true incidence has been difficult to clarify because it is difficult to obtain a detailed and precise headache history from patients during an acute neurologic episode. In addition, the definition of migraine has changed over time in the literature. Finally, some large vessel dissections cause unilateral headache with migraine-like features, but they are not true migraine episodes.

Drugs

A number of drugs of abuse and medications have been linked to stroke in young adults. This section reviews the major drugs of both classes and their relationship to ischemic and hemorrhagic stroke. Illicit drug use is an important risk factor for stroke in urban young adults. It was associated with 12% of strokes in the Baltimore/Washington young adult population and with 2% to 39% of strokes in other published case series (69).

Cocaine

Cocaine is responsible for the majority of strokes caused by illicit drug use and has been most studied. It is a local anesthetic and sympathomimetic alkaloid first extracted from the leaf of *Erythroxylon coca*, a tree native to Peru and Bolivia, in the mid-19th century. For thousands of years in that region, the leaves have been chewed (mixed with lime) or drunk as

tea for their stimulant effects. In the early 1900s, cocaine was a frequent component of medicinal tonics for a variety of ailments in the United States, and it was an ingredient in early cola formulations. Growing recognition of its abuse potential led to its inclusion as a Category II drug in the Controlled Substances Act of 1970. The two chemical forms for illicit use are the hydrochloride salt and the freebase. The hydrochloride salt, or powdered form of cocaine, is water soluble and can be taken intravenously or intranasally. Crack cocaine is a freebase formulation, and, although it is short acting, it is the most concentrated form of cocaine. The smoke of the freebase is inhaled. Cocaine is sold on the street as a fine, white, crystalline powder, known as coke, C, snow, flake, or blow. It is often diluted with cornstarch, talcum powder, sugar, or the active drugs procaine and amphetamine (70). The incidence of new cocaine users in the United States peaked in 1983 at 1.5 million and then declined to 0.5 million in 1992. In 2000, the number of new users had risen again to 0.9 million (71).

Cocaine use is associated with an increased risk of both hemorrhagic and ischemic stroke. In an HMO population in California, young women reporting cocaine or amphetamine use had an OR for stroke of 6.5 (95% CI = 2.5–16.6) compared to those reporting no drug use, with the OR for hemorrhagic stroke at 9.6 (95% CI = 2.7–33.5) and for ischemic stroke at 4.5 (95% CI = 0.9–21.6). Case series have reported 2% to 39% of young stroke patients having associated illicit drug use, predominantly cocaine (72), and the population-based Baltimore/Washington Young Stroke Study found 9.7% of young stroke patients to have a history of recent cocaine use. A number of mechanisms that may lead to hemorrhage have been suggested, such as drug-induced acute hypertension, particularly in individuals with AVM or aneurysm. Other mechanisms include increased platelet aggregation, vasospasm, vasculitis, and apoptosis of cerebral vascular smooth muscle. Complications of cocaine use that can cause stroke include cardiomyopathy leading to arrhythmia or ventricular clot, endocarditis with embolization of septic material, and contaminants in intravenous preparations that embolize to the brain through a pre-existing patent foramen ovale (PFO) or atrial septal defect (ASD).

The plasma half-life of cocaine is 60 to 80 minutes. Smoking provides the fastest route of entry into the cerebral circulation (6–8 seconds), with the intravenous route taking 12 to 16 seconds. The majority of strokes occur within one hour of ingestion. In one series, a positive urine toxicology screen at the time of presentation was associated with more severe stroke (70,73).

Amphetamines have similar sympathomimetic effects and spectrum of potential mechanisms in causing hemorrhagic and ischemic stroke (74). Methamphetamine is most often implicated in stroke cases.

Heroin

Heroin, a derivative of morphine, is usually taken intravenously but can be used by oral, nasal, subcutaneous, or inhalational routes. It has been associated with ischemic stroke, with deficits appearing from immediately to more than 24 hours after use. Hypoxia caused by hypotension or respiratory depression, vasculitis, positional vascular compression, and septic embolization caused by endocarditis have been proposed as mechanisms (70,75).

Clinical studies of the cerebrovascular effects of individual illicit drugs have been hampered by patients' reluctance to admit using drugs, inconsistent toxicology screening, frequent concomitant ingestion of multiple drugs of unknown purity and potency, and patient populations who have, in addition, a substantial burden of traditional risk factors for stroke.

Sympathomimetics

A number of sympathomimetic agents available in the United States without prescription have been associated with stroke. Dietary supplements containing ephedrine and related alkaloids (also known as ma huang) are taken by young women and others to promote weight loss and boost energy. Pseudoephedrine, phenylephrine, phentermine, oxymetazoline, and fenoxazoline are decongestants included in cough and cold preparations. Phenylpropanolamine has both appetite suppressant and decongestant effects and has been used in both types of preparations. These drugs have all been implicated in cases of stroke, primarily hemorrhagic. In a prospective tertiary center series of 2,500 strokes, 2.5% were associated with use of decongestant preparations, and all but one of these were hemorrhagic. A series of 702 hemorrhagic stroke cases in patients 18 to 49 years of age found a significant association between stroke and phenylpropanolamine use (76–78). The mechanism of a causal relationship may include drug-induced hypertension, vasoconstriction and secondary hemorrhage, and/or vasculitis (76,78,79). In 2004, the Food and Drug Administration (FDA) prohibited the use of ephedra in dietary supplements because of health risks (80). Additionally, since March 2006, the FDA has limited the availability of medications containing pseudoephedrine, phenylpropanolamine, and ephedrine to behind-the-counter rather than over-the-counter sales, with quantity limits and purchaser identification required. The Combat Methamphetamine Epidemic Act of 2005 mandated these restrictions, not because of adverse health effects of the agents, but because of their frequent use in the illicit production of methamphetamine (81). Manufacturers of cough and cold preparations have responded by removing them from most formulations.

Cannabis

Despite decades of experience with medical issues related to marijuana use, it is only recently that reports have appeared exploring a possible link between cannabis use and ischemic stroke. Wolff et al. found that within a series of 48 consecutive young strokes, 10 of the 13 cannabis users in this group displayed a similar pattern of multifocal intracranial stenosis on MRI. This pattern partly or completely resolved on repeat imaging at three to six months of all six patients who stopped using, but not in those who continued (82). In a subsequent review, the same author and colleagues note

a preponderance of posterior circulation ischemic stroke in cannabis-associated cases and suggest that these strokes be considered a variant of the reversible cerebral vasoconstriction syndrome (83). Once again, greatly improved imaging techniques will aid case ascertainment and exploration of this link.

Alcohol

In many societies, alcohol consumption begins in adolescence, increases during the young adult period, plateaus during midlife, and decreases in the eighth and ninth decades. The relationship of alcohol consumption to stroke is thus germane to young adults. Although few studies have looked for an association between alcohol and stroke in young adults specifically, many studies of subjects of all adult ages have found that alcohol use increases the risk of ICH and SAH in a linear manner as dose increases. Heavy drinkers, usually defined as persons imbibing more than 40 grams of alcohol per day (3 cans of beer or 15 ounces of wine) have a two- to eleven-fold increase in their risk of hemorrhagic stroke (84,85). The relationship between alcohol consumption and ischemic stroke, in contrast, follows a U- or J-shaped curve, where moderate drinkers have fewer events than either nondrinkers or heavy drinkers. This finding was confirmed specifically in young women in the Baltimore/Washington area (86). However, the definition of *moderate drinking* in this literature has varied from less than once per day to amounts up to two drinks per day, and concern has been expressed that the comparison groups of nondrinkers in some studies may have been self-selected for greater burden of comorbidity (87). The mechanism of the protective effect of moderate alcohol vis-à-vis ischemic stroke is unclear, but may involve raising HDL cholesterol levels, thereby slowing plaque formation (70). A prospective community study of 826 subjects in northern Italy found a slower progression of carotid atherosclerosis over a 5-year period among drinkers of 1 to 50 grams of alcohol per day than among those who drank less or more (87,88). Alcohol also decreases platelet aggregation and fibrinolytic activity, which may play a role both in increasing risk of hemorrhagic stroke and in protecting moderate drinkers from ischemic events (70). The association of alcohol abuse with cardiomyopathy and atrial arrhythmias provides another possible mechanism for ischemic stroke (85). No specific vascular territory or brain structure has been associated with stroke related to alcohol use. Clinical features and treatment are the same as for other strokes, with the caveat that the presence of an overt coagulopathy caused by alcoholism may complicate therapeutic anticoagulation. Chronic heavy drinkers may experience slower and/or less complete recovery because of prior alcohol-induced brain damage.

Oral Contraceptives

OC medications came into use in the United States in the 1960s. It was first suggested that they might increase the risk of cerebrovascular events in 1962. The mechanism of thrombosis from OC medication may involve the elevation of plasma levels of Factors VIIc and XIIc, which occurs in a dose-related fashion in OC users and may promote generation of thrombin (89).

There is convincing evidence that current low-dose OCs (less than 50 mcg estrogen) do not increase the risk of arterial stroke in women without vascular risk factors. However, hypertensive users, as well as smokers and women with migraine headaches, have an increased risk of arterial infarction, and the risk of CVT is increased. In the WHO international study, RR was 10 to 14 for hypertensive OC users and 4.7 for OC users who smoke (90).

Low-dose OCs should be used with caution in women with migraine headaches, who smoke, who are hypertensive, or who have genetic thrombophilic defects, owing to variably increased, though still low, risk of stroke (91).

Thrombophilic States

A number of acquired and inherited thrombophilic states related to stroke in young adults have been described in recent decades. Even though all of them (deficiency of proteins C, S, and antithrombin III [AT3], FVL, prothrombin gene 20210A, and the antiphospholipid antibody syndrome [APS]) are strongly associated with venous thrombosis, only the APS has a strong correlation with arterial stroke. The latter is also the only one of these conditions with distinctive clinical features. First described in 1983, the APS is diagnosed when a patient has had one or more episodes of arterial or venous thrombosis in any organ leading to tissue infarction or fetal loss and when the patient is demonstrated to have antiphospholipid antibodies (lupus anticoagulant [LA] and/or cardiolipin) in plasma on at least two occasions six weeks apart (92). Other frequently associated findings in APS are thrombocytopenia (40%–50%); livedo reticularis, a lacey pattern of microvascular occlusion occurring in the skin of the back and extremities (11%–22%); and hemolytic anemia (14%–23%) (93). The brain is the most common site of arterial thromboembolism, and neurologic manifestations may include TIA, cerebral infarction, CVT, multi-infarct dementia, seizures, encephalopathy, migraines, transverse myelitis, chorea, and mononeuritis multiplex. In situ arterial thrombosis of vessels of all sizes and embolism from cardiac valvular vegetations that occur in approximately 4% of patients are the mechanisms underlying these diverse phenomena. A wide variety of effects involving other organs have been described as well (93).

Primary APS occurs in patients without an autoimmune disease; secondary APS occurs in patients with autoimmune or other disease, most often systemic lupus erythematosus. Treatment recommendations continue to evolve with accumulating evidence. Anticoagulation with warfarin, but not antiplatelet agents, is beneficial in preventing recurrent thrombosis, and the benefit of antiplatelet therapy for asymptomatic individuals with LA or anticardiolipin antibodies is unclear (92–94).

FVL, prothrombin 20210A, and deficiencies of protein C, S, and AT3 cause thrombosis by impairing the normal

modulation of thrombin generation and inactivation. They are strongly associated with venous thrombotic events and variably with arterial stroke. Their frequent clinical expression in the early adult years, with the majority of patients experiencing their first thrombotic event before the age of 45, makes them relevant to our discussion (33).

Resistance to activated protein C is caused by base substitution (adenine for guanine) at position 1691 on the Factor V gene. The resulting mutation is called Factor V Leiden (FVL). This mutation occurs in about 5% of the Caucasian population but is rare in Africans and Asians. Even though its association with increased risk of venous thrombotic disease is clear, its relationship to arterial stroke is less certain. A recent meta-analysis found a modest increase in risk of ischemic stroke primarily among patients less than 55 years of age carrying FVL (33,94,95).

Another substitution of adenine for guanine, at nucleotide 20210 of the prothrombin gene 20210A, has similarly been associated with an increased risk of venous thrombosis at all ages and a modest risk of arterial stroke in younger adults. The greater effect of these two mutations on producing venous rather than arterial thrombosis may relate to the difference in the thrombotic process, with stasis as an important predisposing factor on the venous side and endothelial damage with platelet activation driving arterial clot formation.

In large blood vessels, proteins C, S, and AT3 all act by different mechanisms to control thrombin generation (33). Several case series of stroke in young adults have found approximately 5% of patients with protein C deficiency, though others have seen no increase over the control rate (96). Case reports and series describing stroke associated with deficiency of protein S, which may be inherited or acquired in sepsis or pregnancy or caused by hormonal therapy, are more extensive. Arterial stroke and CVT may occur in the same individual, and the frequency of protein S deficiency appears to be higher in young adult stroke patients than in older groups (94). Evidence linking deficiency of AT3 to arterial stroke is weak, and it appears that this deficiency, which slows thrombin inactivation, is nearly exclusively involved in venous thromboses.

These conditions of modest effect in promoting stroke may be potentiated by the addition of acquired thrombophilic factors, including pregnancy, OCs, smoking, migraine, hypertension, diabetes mellitus, and dyslipidemia. Most experts currently believe that population screening for inherited thrombophilic states is not warranted because of the low incidence of major vascular events. Clinicians treating individual patients must exercise judgment on this point based on the patient's composite of medical and family history as well as acquired risk factors.

Patent Foramen Ovale

PFO is a persistent fetal communication between the right and left atria of the heart. It is present in more than 25% of adults and is associated with ischemic stroke in adults less than 55 years old and less clearly with stroke in older adults. PFOs are thought to cause stroke by allowing paradoxical embolization across the opening from venous to arterial sites, although the possibility of in situ thrombus formation in a tunnel-like PFO or an increased risk of atrial arrhythmia and thrombus because of the presence of the defect has not been excluded. First described in 1877, PFO was difficult to diagnose in vivo until the advent of contrast echocardiography.

The presence of an atrial septal aneurysm with a PFO significantly increases the risk of ischemic stroke. In addition, atrial anatomic variants, including a prominent Eustachian valve or Chiari's network and lower extremity or pelvic venous thrombi or a predisposition to these—caused by presence of the FVL mutation, the prothrombin gene mutation 20210A, an elevated factor VIII level, the APS, or May–Thurner syndrome—can increase the chance of a PFO leading to a stroke. An intriguing association between PFO and migraine with aura has been found in case control studies, and others have noted a decrease in migraine attacks after PFO closure. The mechanism of this association remains speculative, but may involve the presence of a gene modulating both cardiac and vascular development, left to right shunting of an endogenous substance normally metabolized in the lung (such as serotonin) into the systemic arterial circulation, or left to right shunting of microemboli (66,97).

Strokes of Undetermined Cause

An important feature of the literature on stroke in young adults is the high percentage of strokes of undetermined cause in most series. A number of these are summarized in Table 44.5. In addition, Bevan et al., reviewing the literature in 1990, noted that a cause is found in 55% to 93% of the stroke cases in young adults (98). Even though it is reassuring in clinical practice to be able to say to a young stroke patient after an exhaustive workup that no serious disease or defect has been found to explain the stroke, it is at the same time frustrating and worrisome when no cause can be identified. Without a cause, no estimate of risk of recurrence can be made, and no focused plan developed to minimize that risk.

Several definitional issues contribute to the high rate of strokes of unknown etiology. First, the TOAST criteria, a five-category classification of stroke mechanism developed for the TOAST, have been used in a number of young stroke series and also have the advantage of widespread use and familiarity (48). However, the five categories—large artery atherosclerosis, small vessel occlusion, cardioembolism, other determined etiology, and unknown etiology—were designed for an older population with a predominance of atherosclerotic disease. Other than the 10% to 20% caused by large artery atherosclerosis and the 20% of young adult strokes caused by cardioembolism, most strokes in young adults fall into the "other determined etiology" and "undetermined etiology" categories of this classification.

TABLE 44.5 Stroke of Undetermined Cause in Young Adults

AUTHOR	STUDY TYPE	LOCATION	UNDETERMINED CAUSE (%)
Kittner (1998) (50)	Population-based	Baltimore, Maryland	31.8
Adams (1995) (167)	Population-based	Iowa	34.3
Camerlingo (2000) (116)	Hospital series	Bergamo, Italy	21.5
Naess (2004) (115)	Population-based	Western Norway	47.8
Quereshi (1995) (72)	Hospital series	Atlanta, Georgia	26
Lee (2002) (163)	Hospital series	Taiwan	23.5
Putaala (2009) (24)	Hospital series	Helsinki	22.4

Further, these categories are broad and refer to the vascular mechanism rather than the specific etiology of the stroke. Other than TOAST, however, there are no widely recognized classification systems for stroke etiology, and young stroke studies have used a variety of ad hoc instruments, with variable definitions of *unknown* or *cryptogenic, probable cause*, and *possible cause*. Conditions of disputed or unclear etiologic importance—migraine, mitral valve prolapse, PFO, alcohol, and OCs—are classified differently by different authors. An etiologic classification scheme specifically for young adult stroke has been proposed, taking into account our recently acquired ability to diagnose large vessel dissection and CVT reliably via MRI. Hoffman et al. propose the following categories for stroke in young adults:

- Large vessel
- Small vessel
- Cardiogenic
- Dissection
- Prothrombotic states
- Migraine-induced
- CVT
- Vasculitides
- Vasculopathy other
- Miscellaneous
- Unknown (99)

Use of classification schemes such as this one designed for this population segment may help to reduce the number of strokes reported as "unknown cause."

The historical emphasis in American and European medical culture on finding the one unifying cause for an illness or group of symptoms is beginning to yield to the recognition that a constellation of factors—some genetic and some environmental or behavioral—often come together to cause a medical event (100). Many strokes in young adults are likely multifactorial, the result of several mild genetic predispositions or the intersection of genetic predisposition and acquired risk factors. A case control study by Martinelli et al. found women taking OCs to have 13 times the risk of stroke if they also have the FVL and 9 times the risk if they have the prothrombin 20210A mutation, compared to women on OCs without either mutation (101). Smoking and hypertension also appear to increase the risk created by genetic predispositions. Pezzini et al. found that patients with two of four predisposing polymorphisms (prothrombin 20210A, FVL, the TT677 genotype of the methylenetetrahydrofolate reductase [MTHFR] gene, and epsilon-4 carriership of the apolipoprotein gene) had OR for stroke of 3.5 (CI 1.40–9.98), but, if they also smoked, the OR rose to 15.99 (CI 4.01–63.3). If they had two polymorphisms and were hypertensive, the OR for stroke rose to 10.79 (95% CI 1.01–115.4) (100). It may turn out that many of the strokes categorized as "cryptogenic" occur because of alignment of several genetic and acquired risk factors in the individual.

Population Differences

Population-based studies, though superior to case series in gauging the spectrum and distribution of causes of stroke, are subject to the variations among populations studied. In U.S. urban populations, for example, stroke caused by illicit drug use accounts for as many as 12% of young adult cases, whereas, in a Saudi university hospital series, it accounted for 2% and, in the Bern and Zurich stroke registries, just 0.5% of cases (102,103). In Khorasan province in Iran, 54% of infarctions in young adults are of cardioembolic origin, twice the frequency found in American and European populations. Chagas disease, rare or absent as a cause of stroke in most studies, accounted for 4 of 106 young adult stroke cases in a Brazilian series (49,104). As knowledge of stroke in young adults accumulates, our appreciation of its variability over time and from place to place increases.

DIFFERENTIAL DIAGNOSIS OF STROKE IN YOUNG ADULTS

A number of other illnesses can confuse the diagnosis of stroke in young adults. A list of these is provided in Table 44.6. The relative rarity of stroke in young adults predisposes providers to consider first and sometimes exclusively the more routine etiologies of headache, neck pain, ear pain, and dizziness. Reliance on noncontrast head CT

TABLE 44.6 Differential Diagnosis of Stroke in Young Adults

Brain infection
Brain neoplasm
Cranial nerve palsy
Peripheral nerve palsy
Hemiplegic migraine
Demyelinating diseases
Benign positional vertigo
Vestibulitis
Unrecognized seizure with postictal neurologic deficit
Toxic metabolic encephalopathy (hypoglycemia, hepatic encephalopathy)
Brown–Sequard syndrome (hemiplegia and contralateral hemisensory loss)
Conversion disorder
Progressive multifocal leukoencephalopathy (PML)
Subcortical leukoencephalopathy (Binswanger's disease)
Mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS)

as the sole imaging screen for CNS disease will allow some strokes in young adults to be missed because of CT's limited sensitivity to acute infarction and ischemic territory at risk. In a recent series of 15 misdiagnosed cases of cerebellar infarction, half of the patients were younger than 50 years. A normal head CT and a poorly documented neurologic exam were frequent findings in this series, and incorrect diagnoses included migraine, toxic encephalopathy, gastritis, meningitis, myocardial infarction, and polyneuropathy (105). Younger adults may be more prone to misdiagnosis because of both their lesser frequency of stroke and their higher prevalence of certain easily confused conditions, such as multiple sclerosis and conversion disorder. Increased recognition of the importance of stroke in the younger population and routine availability of more definitive imaging techniques will improve our ability to identify stroke rapidly in this group.

The converse is also true: Patients may be diagnosed with stroke in the emergency room and later be found to have other illnesses. Postictal weakness and confusion, for example, may persist for days to weeks after an unwitnessed seizure, and serial scans, EEG, and further history may be needed to clarify the diagnosis. Brain tumors, multiple sclerosis, and PML may present with neurologic findings, and scan appearances consistent with stroke and the diagnosis may not become clear until deficits progress and/or scans evolve. In an emergency department study of 463 patients given diagnoses of stroke or TIA, 19 were later discharged from the hospital with different diagnoses, including seizure, migraine, peripheral neuropathy, cranial nerve neuropathy, and psychogenic paralysis. The mean age of those misdiagnosed was 55, whereas it was 65 for those correctly diagnosed (106). Conversion disorder with motor symptoms occurs on average at age 39. Symptoms include paralysis, ataxia, tremor, sensory loss, pain, blindness, and dysphonia in patterns consistent with stroke (107). This disorder may be suspected but is infrequently diagnosed early in the patient's hospital course, particularly during the first episode of psychogenic symptoms. Conversion symptoms typically respond well to rehabilitative therapies, though relapse is common.

TREATMENT

Young patients are offered the most advanced and aggressive treatments available for all illnesses more readily than elderly patients. In acute stroke treatment, this tendency is reflected in the use of hemicraniectomy for malignant middle cerebral territory infarction. This procedure is offered to appropriate patients under 50 to 60 years of age because of accumulating evidence that younger patients have better survival and functional outcome (108,109). Younger patients are also offered the most aggressive and technologically advanced rehabilitation treatments because of their lesser burden of comorbidity and prior disability and, therefore, their greater tolerance and lower risk of complications.

OUTCOMES

Survival

The case fatality rate (death within 30 days of the ictus-CFR) for stroke in young adults ranges between 10% and 34% in published series. As in the older population, CFRs are higher in ICH and SAH than infarction. In an epidemiological study evaluating racial differences in CFR in the 1990s, no significant difference between white and black young stroke patients in Cincinnati was found (8,110). Mortality is highest in the first year after stroke, declining in subsequent years (111). Mortality was 1.7% per year among ischemic stroke patients under the age of 45 in the Iowa Registry of Stroke in Young Adults (112), and 86% of these patients were alive at follow-up, a mean of 6 years after the stroke. This last finding was consistent with that of Marini et al., who found an 86.5% 10-year survival rate for ischemic stroke in patients aged 15 to 44 in a multisite series (112,113). As would be expected given these survival rates, the prevalence of young stroke survivors has increased over time. In the United States, there were 590,000 aged 25 to 59 in 1973, growing to 965,000 in 1991 (114). Individual survival, of course, depends on the cause and severity of the stroke and the burden of comorbid conditions.

Function

Global functional outcomes for young adults are generally good. In Western Norway, 80% of young infarction patients achieved a Modified Rankin Scale (mRS) less than or equal to 2 at 3 months after stroke and 78% at long-term follow-up (mean

5.7 years) (10,115). Case series have consistently corroborated this finding, with 96% of the 272 cases studied by Varona et al. achieving mRS less than or equal to 2 at 3 years after stroke (106). Camerlingo et al. found that 91% of their 135 cases evaluated at 1 year had achieved mRS scores less than or equal to 3 (116), and Neau et al. found that 86% of their 65 cases at follow-up (mean 32 months) had RS less than or equal to 3 (117). In the series of Musolino et al., 89% of 54 young patients evaluated a mean of 6.12 years after stroke had mRS less than or equal to 3 (118). Moreover, in a recent large Austrian Stroke Registry analysis of 2223 stroke survivors aged 55 or younger, Knoflach and colleagues found that functional outcome at 3 months varied by decade of age within the under-55 group. Those under 35 years had the highest probability of mRS score less than or equal to 2, whereas this favorable outcome declined by 3% to 4% in each subsequent decade (119).

In population-based studies as well as case series, the great majority of young stroke survivors have achieved good functional outcome in self-care and mobility. Marini et al. in northern Italy recorded 84% achieving a Barthel index of greater than or equal to 90 at the end of follow-up (113). Varona et al. found that 90% of their 272 cases were independent in ADLs and 95% could walk without assistance at follow-up (mean 12 years) (111), and Kappelle et al. noted 92% with Barthel Index scores greater than 90 (112). Poor outcome after stroke in young adults has been associated with a history of diabetes mellitus, severe deficit at presentation, stroke involving the total anterior circulation, and large artery atherosclerosis (103,111,115). There is evidence that functional recovery occurs more quickly in younger than elderly patients in an inpatient rehabilitation setting. In analyzing a large consecutive series of stroke patients stratified into five age subgroups, Black-Schaffer and Winston found that younger patients had significantly higher FIM efficiencies (FIM points gained per day) during inpatient rehabilitation (120). Older patients often enter rehabilitation at a lower level because of prestroke functional limitations and progress more slowly related to a greater burden of comorbid conditions (120–123). Because treating staff feel that young patients have greater functional potential and more complex goals than their elderly counterparts, young adult stroke patients tend to remain in rehabilitation facilities longer than the elderly (120) and are offered the newest and most aggressive rehabilitation regimens.

Community Discharge

In keeping with their higher functional level at discharge, young adult stroke patients are discharged back to the community more often than the elderly. Black-Schaffer and Winston found that, in a cohort of 979 stroke rehabilitation inpatients, 84% of those under age 55 were discharged home, in contrast to 54% of those older than 85 years. Alexander and Granger et al. found the same trend in separate American cohorts of inpatient rehabilitation patients examined a decade earlier (120,124,125). In the United States, skilled nursing facilities are often reluctant to accept young patients because of lack of appropriate programming, further reinforcing this trend.

Return to Work

The ability to perform valued work is central to self-esteem and an important goal for most young stroke patients (126). Between 3% and 84% of patients achieve this goal, with the wide range reported in this literature caused by differing age ranges of patients reported, variable definitions of work, and disability compensation systems with different incentive structures (127). Numerous series have examined the percentage of patients returning to work after the stroke. Those that evaluate patients less than 45 years of age find notably higher percentages of patients returning to work than those that evaluate patients up to the age of 65. These studies are summarized in Table 44.7.

Many case series have been analyzed for factors associated with success in returning to work. Variables cited have included:

- Perceived importance of work (128)
- Pure motor or no hemiparesis (129,130)
- Good self-care and mobility function (115,127,131–133)
- No aphasia or apraxia (117,127,134)
- Advanced education (115,117,135,136)
- Preserved cognition (126,129)
- White-collar job (132,133,135,136; also 128)
- Higher income (137)
- Married status or social supports (115,128)
- Younger age (115,131,133,138)

Variables identified as barriers to successful vocational rehabilitation include, in addition to the reverse of these factors:

- Visual/perceptual impairment (129)
- Depression (117,129)
- Economic disincentives related to disability and retirement benefits (132,139)

Of those returning to work after a stroke, about two-thirds reduce hours and/or duties (126,140). The rehabilitation physician is often asked to certify that the young stroke patient is "medically cleared" to return to work. This may mean certifying only that the patient has sufficient cardiovascular capacity to perform the job, but, more often, it is a request for a detailed evaluation of the patient's cognitive, physical, and psychological capacity as they relate to specific job requirements. This assessment is complex and ideally is accomplished with the assistance of a coordinated multidisciplinary team, including physical, occupational, speech therapist, neuropsychologist, and vocational rehabilitation counselor (139).

Patients who are able to resume work after a stroke on average do so within the first six months. In the United States, the 1990 Americans with Disabilities Act had a positive impact on employers' responsiveness to the requests of stroke survivors for accommodations on their prestroke job, not only regarding physical access and equipment but also for personal assistance, schedule flexibility, and task modification (139). However, employers' concerns regarding possible costs associated with stroke survivors as new hires may, in some cases, make it hard for survivors to change to a different job.

Driving

Throughout the developed world, a return to driving has become a necessary step to resuming a normal lifestyle and avoiding social isolation. In many locations, it is a prerequisite for returning to gainful employment. It has been estimated that half of stroke survivors in the United States return to driving without advice or reevaluation of their fitness to drive (141). Of those who do seek reevaluation, approximately half are successful in passing driving evaluations (142,143). In the United States, many rehabilitation clinics offer written tests of driving ability. These can be useful for screening out patients with significant perceptual or cognitive problems who would be unsafe in a road test setting. In one study, two commonly used tests, the Motor Free Visual Perception Test and the Trail Making B test, were found to correlate closely with on-the-road driving performance (144). Computerized driving simulators also hold promise both as screening tools and training devices (145,146), though their adoption in clinical rehabilitation settings has been slow. In the published case series on this topic, a number of factors have been associated with driving performance after stroke:

- Right hemisphere location of stroke (143,147,148)
- Visual perceptual deficits (144,149)
- Reduced sustained and selective attention (150,151)
- Impulsivity or poor judgment (143,149)
- Lack of organizational skills (151)

All correlate with poor performance behind the wheel. Aphasia, though it may negatively impact performance on written and road tests because of compromised processing of verbal or written instructions, does not always interfere with self-directed driving (141,149,152). And physical impairment alone does not increase the risk of accidents or traffic violations (143). Physicians are often consulted about a patient's readiness to resume driving, and, though visual perception can be readily screened, the evaluation of attention, judgment, and organizational ability is more complex and benefits from involvement of a neurologic rehabilitation team (153). An on-the-road test performed either by a driving instructor or by a state licensing agency remains the gold standard for assessing driving ability.

Parenting

The young adult stroke survivor who needs to return to parenting faces physical as well as cognitive and perceptual challenges in the performance of child bathing, dressing, feeding, and transporting tasks. Fortunately, many helpful items of equipment are readily available. Disposable diapers with adhesive tabs require less dexterity than cloth diapers with pin closures. Microwaves make heating bottles of formula easier and safer than warming them in a pan of boiling water. Baby tub inserts help to stabilize an infant for bathing, and so on. Other adult family members, home care occupational therapists, and/or hired childcare assistants can provide valuable assistance to the stroke survivor in problem-solving performance of these tasks. When the survivor requires physical assistance to accomplish a childcare activity, he or she should be encouraged to assume the supervisory role whenever possible.

Even more challenging, potentially, is the establishment and maintenance of a loving and effective relationship between a disabled parent and a growing child, because children's needs and perceptions of their parents evolve as psychosocial development proceeds. The child's second parent, or another adult important to the child, can play an important role in helping both parties negotiate this relationship over time.

RECURRENCE

The likelihood of a second stroke increases as young patients' vascular disease risk factors multiply. In Hordaland County, Norway, risk of recurrence ranged from 2.1% during the mean 6-year follow-up period for those young adult stroke survivors without hypertension, diabetes, hypercholesterolemia, smoking, angina, myocardial infarction, or intermittent claudication to 67% recurrence for those with five of these risk factors (150). In the Helsinki Young Stroke Registry, the overall 5-year cumulative recurrence rate for ischemic stroke in those aged 15 to 49 was 9.4%. Survivors with diabetes, atherosclerosis, heart failure, and prior TIA were at increased risk (154). Recurrence rates are highest in the first year after ischemic stroke, ranging from 1% to 3% (111,113,155). For certain nonatherosclerotic stroke etiologies, recurrence risk is well defined. After carotid dissection, recurrences occur in approximately 10% at the rate of 1% per year, and they are usually in a different artery. Recurrences are more common in those with first dissection under age 45 (52). CVT carries an overall recurrence rate of 11%, which may reflect comorbid conditions such as cancer with continuing thrombophilia (65). Risk of recurrence after a drug- or pregnancy-induced stroke depends on whether intake of the drug is resumed or pregnancy is again undertaken.

It is important for the young stroke survivor and his or her physician to review the etiology of the patient's stroke, identify modifiable risk factors for recurrence, and jointly develop a plan to minimize those factors. The patient's motivation to comply with treatment for hypertension and diabetes, develop a habit of compliance with newly prescribed anticoagulation therapy, quit smoking, avoid excessive alcohol intake, and turn away from the use of street drugs will be maximal in the months following the stroke. Close medical follow-up to reinforce the risk reduction plan and monitor its effects will improve the likelihood of success. Young adult survivors with stroke of unknown etiology face unavoidable uncertainty regarding the risk of recurrence. It is not clear whether empiric prescribing of preventive medications for these individuals, in the absence of corresponding risk factors, is beneficial; though sometimes it is an attractive way to deal with the natural desire to do something (156). Recent evidence suggests that even for stroke of undetermined etiology in young adults, a statin for secondary prevention is associated with lower rates of new vascular events in an average follow-up of nine years after the stroke (157). Significant progress has been made in elucidating components of the stroke of unknown etiology category in recent years, and we can anticipate that future research will shed further light on this area.

Stroke in Older Adults

Marianne Shaughnessy and Kathleen Michael

Stroke is the fourth leading cause of death and a foremost cause of serious, long-term disability in the United States (1). As cardiovascular and metabolic disease incidences rise with age, so does the risk of stroke; and clinical and functional consequences may be compounded by other conditions associated with aging. However, stroke is not an inevitable consequence of aging. By identifying and modifying risk factors in older people, there are opportunities to reduce the incidence and mortality of this condition (2) and improve function, independence, and quality of life after stroke. Recent advances in emergency medical care have reduced mortality and stroke severity, resulting in greater numbers of older adults who survive strokes (3). Although stroke incidence in America appears stable and stroke mortality is slowly declining, the absolute magnitude of stroke is likely to grow over the next 30 years. With aging of the population, the number of older stroke survivors is likely to increase substantially (1). The very old are expected to become a growing part of the stroke survivor population (4).

This chapter presents a discussion of special considerations in the management of stroke recovery and rehabilitation for older adults. We describe the incidence, prevalence, and economic impact of stroke in the aging population. We discuss the management of common risk factors for recurrent stroke. We address challenges to successful rehabilitation in older adults with stroke, and suggest strategies to overcome barriers and optimize outcomes.

INCIDENCE, PREVALENCE AND ECONOMIC IMPACT

Age is the single most important risk factor for stroke. For each successive 10 years after age 55, the stroke rate more than doubles in both men and women (5). Nearly three-quarters of all strokes occur in people over the age of 65. Stroke incidence rates are 1.25 times greater in men, but because women tend to live longer than men, more women than men die of stroke each year (1).

Not only are they more likely to have strokes, but the physical, psychological, and social consequences may be more severe for older adults. The burden of stroke is heterogeneous and is greatest among the elderly, men, and African Americans (1). Furthermore, age is an independent predictor of outcome after an ischemic stroke. Older patients, especially those over 80 years old, are more likely to die in the hospital after stroke and less likely to make a favorable long-term recovery (4). Other factors, such as onset stroke severity, preexisting disability, and atrial fibrillation (AF), are also significant age-related independent predictors of prognosis after stroke (4).

Many stroke survivors (50%–70%) regain functional independence, but 15% to 30% are permanently disabled and 20% require institutional care at 3 months after onset (1). Effective rehabilitation interventions initiated early after stroke can enhance the recovery process and minimize functional disability (6). Stroke rehabilitation begins during the acute hospitalization, as soon as the diagnosis of stroke is established and life-threatening problems are under control. The highest priorities during this early phase are to prevent recurrent stroke and complications, manage comorbid illness, promote mobility and self-care activities, and provide emotional support to the patient and family (6). Poststroke guidelines recommend transfer to a stroke-specific rehabilitation unit as soon as possible to ensure early mobilization; availability of speech, physical, and occupational therapy; rehabilitation psychology; and the social support derived from interaction with other stroke survivors (6). There is a body of evidence indicating that patients do better with an organized, multidisciplinary approach to postacute rehabilitation after a stroke (7,8).

The economic impact of stroke has been and will continue to be substantial. Based on estimated incidence data from the Centers for Disease Control, the direct costs to the health care system associated with stroke are estimated to total approximately $70 billion by 2025 (8). As many older adults leave active employment, indirect costs such as those associated with premature mortality and lost productivity are lower, but are still estimated to approach an additional $38.9 billion. Both these estimates are calculated in 2008 dollars (8).

A recent literature review indicated that most studies on economic impact of stroke emphasize the short-term costs associated with hospital and ICU care. However, long-term ambulatory care and nursing home care also account for substantial portion of direct costs, at 35% and 17% respectively (9). Brown and colleagues projected the U.S. costs of ischemic stroke from 2005 to 2050 (in 2005 dollars) to be

approximately $2.2 trillion: $1.52 trillion for non-Hispanic whites, $313 billion for Hispanics, and $379 billion for African Americans (10). The proposed figures likely underestimate the true economic burden of stroke, because the estimates do not take into account the rise in salaries and treatment costs, growth among minority populations, and the increase in risk factors for stroke such as obesity, diabetes, and heart disease (9–11).

Uncontrolled risk factors dramatically increase costs associated with stroke. An analysis of data from the National Health and Nutrition Examination Survey (NHANES) II study examining cost data from short-term hospitalization and estimated first-year loss of productivity or premature death concluded that the annual costs of one undermanaged cardiovascular risk factor for subjects who had already suffered an MI or stroke are estimated between $3.2 and $11.1 billion (11). Among persons with previous MI or stroke, two or more inadequately controlled risk factors accounted for incurred cost ranging between $4.1 to $12.2 billion (11). Estimates using the same data for years of life lost due to uncontrolled risk factors range from 7.5 years for one uncontrolled risk factor to 8.9 years for 2 or more (11).

Still, stroke risk factors remain suboptimally managed in the poststroke population at large. In a group of 364 community-dwelling chronic stroke survivors, who were assessed by basic history and physical and laboratory analysis of a fasting sample, 99% had at least one suboptimally controlled risk factor. Ninety-one percent had two or more risk factors inadequately treated. Eighty percent of the participants had prehypertension or hypertension, 67% were overweight or obese, 60% had suboptimal low density lipoprotein (LDL) levels, 45% had impaired fasting glucose, 34% had low high-density lipoprotein (HDL) levels, and 14% were current smokers, despite the fact that all were reportedly receiving routine medical care (12). Clearly, in addition to public health efforts to educate all Americans about stroke risk and recognition of signs and symptoms, risk factors that persist must be managed as aggressively as possible.

Managing Common Risk Factors for Recurrent Stroke in Older Adults

Risk factors and the incidence of stroke peak in individuals 75 years old or older. Patients with the highest risk benefit the most from effective risk-reduction therapy (13). For this reason, all strategies of demonstrated value in stroke prevention are pertinent in the care of older adults. Control of hypertension, treatment of dyslipidemia, management of diabetes mellitus, anticoagulation for AF, promotion of exercise and healthy diet, and cessation of cigarette smoking are obligatory at all ages, but are of particular importance in older adults (13).

Management of Hypertension

High blood pressure, once believed to represent a normal and progressive component of the aging process, is now recognized as a sign of structural and physiologic abnormalities of vascular function (14). Elevated blood pressure is a significant determinant of the long-term risk of stroke (15). Casual systolic hypertension is a prevalent finding in older adults (50% of women over the age of 80 have casual systolic blood pressures >160 mmHg (16). Isolated systolic hypertension, defined as a systolic blood pressure greater than or equal to 140 mmHg with a diastolic blood pressure less than 90 mmHg, affects most individuals aged 60 years and older (14).

Antihypertensive treatment has established efficacy in the primary prevention of fatal or nonfatal stroke in hypertensive and high-risk patients who are more than 60 years of age, particularly through treatment of systolic hypertension (17). In a summary of 17 treatment trials of hypertension throughout the world involving nearly 50,000 patients, investigators found a 38% reduction in all stroke and a 40% reduction in fatal stroke resulting from systematic treatment of hypertension (18). Treatment was also highly effective in preventing stroke in individuals older than 65 years with systolic hypertension (18). Importantly, there was no less impact on stroke prevention above age 80, with incidence reduced by 40% (17).

The initial antihypertensive drug should be started at the lowest dose and gradually increased, depending on the blood pressure response to the maximum tolerated dose and following a stepwise approach as recommended in the JNC-7 guidelines (19). Before adding new antihypertensive drugs, possible reasons for inadequate blood pressure response should be examined. These include noncompliance, volume overload, and drug interactions (e.g., use of NSAIDs, caffeine, antidepressants, nasal decongestants containing sympathomimetics). Causes of secondary hypertension should be identified and treated (19). Altered pharmacodynamics resulting from changes in body composition due to aging, or organ function due to pathophysiology, should also be considered.

Polypharmacy and potential drug interactions are a greater concern in the elderly than in younger patients. The average elderly patient is taking three to five prescription drugs daily (20). Medications likely to be used in the elderly that increase BP include NSAIDS, corticosteroids, erythropoietin, amphetamines, ergotamine, and anabolic steroids.

The general recommended blood pressure goal in persons with uncomplicated hypertension is less than 140/90 mmHg. However, this target for elderly patients with hypertension is based on expert opinion rather than on data from randomized controlled trials (RCTs), and it is unclear whether the target systolic blood pressure (SBP) should be the same in 65- to 79-year-olds versus older patients (21). The HYVET study (22) results provide evidence that blood pressure lowering is associated with definite cardiovascular benefits in patients 80 years of age or older, including a decrease in mortality and a prolongation of life (22). This finding is highly relevant for public health because subjects 80 years of age and older represent the fastest growing segment of the population (21). Optimal clinical management accounts for specific aspects of pathophysiology and metabolic characteristics of older adults. Treatment should be initiated with lower doses of antihypertensive agents, bringing pressure down slowly, while monitoring for orthostatic hypotension, impaired cognition, and electrolyte abnormalities (14).

Management of Dyslipidemia

Elevated cholesterol levels are not uncommon in older adults. Sixty-one percent of women aged between 65 and 74 are reported to have total cholesterol levels over 240 mg/dL (23). Elevated total cholesterol and decreased HDL levels predispose older adults to ischemic stroke (23).

Possible benefits from lipid-lowering therapy are particularly relevant for the older population at high risk for stroke (23). Though associations are relatively weak, epidemiological evidence indicates that elevated total cholesterol and subfractions increase stroke risk (23). Lowering high serum cholesterol with HMG-CoA reductase inhibitors (statins) has been beneficial in the primary and secondary prevention of myocardial infarction, but further research is needed to determine the effect of lipid lowering on stroke occurrence (23). Few large-scale studies have investigated the specific effect of statins on stroke prevention in older individuals. To date, the largest trials suggest a beneficial effect for stroke prevention with statins in high-risk elderly subjects 82 years of age or less (17).

Indirect evidence suggests that the reduction in the stroke risk with statins is larger than would be expected with reduction of serum cholesterol level alone. Antioxidant and endothelium-stabilizing properties of statins may contribute to reducing the risk of stroke by protecting vascular walls (23). Although the relative risk (RR) of stroke associated with elevated lipids is only moderate, its population-attributable risk is high, given the increase in the elderly population worldwide (23). It is important to note that elevated serum cholesterol seldom occurs in isolation from other cardiovascular risk factors.

Recently published guidelines identify four groups of primary- and secondary-prevention patients on whom clinicians should focus their efforts to reduce cardiovascular events (24). In these four patient groups, the new guidelines make recommendations regarding the appropriate "intensity" of statin therapy in order to achieve relative reductions in LDL cholesterol.

The four major primary- and secondary-prevention patient groups who should be treated with statins were identified on the basis of randomized controlled clinical trials showing that the benefit of treatment outweighed the risk of adverse events. The four treatment groups include (24):

- Individuals with clinical atherosclerotic cardiovascular disease
- Individuals with LDL cholesterol levels greater than or equal to 190 mg/dL, such as those with familial hypercholesterolemia
- Individuals 40 to 75 years old with diabetes and with LDL cholesterol levels between 70 and 189 mg/dL and without evidence of atherosclerotic cardiovascular disease
- Individuals without evidence of cardiovascular disease or diabetes but who have LDL cholesterol levels between 70 and 189 mg/dL and a 10-year risk of atherosclerotic cardiovascular disease of 7.5% or higher

In those with atherosclerotic cardiovascular disease, high-intensity statin therapy should be used to achieve at least a 50% reduction in LDL cholesterol unless otherwise contraindicated or when statin-associated adverse events are present (24). In that case, clinicians should use a moderate-intensity statin. Similarly, for those with LDL cholesterol levels greater than or equal to 190 mg/dL, a high-intensity statin should be used with the goal of achieving at least a 50% reduction in LDL cholesterol levels (24).

For those 40 to 75 years old with diabetes, a moderate-intensity statin, defined as a drug that lowers LDL cholesterol 30% to 49%, should be used, whereas a high-intensity statin is a reasonable choice if the patient also has a 10-year risk of atherosclerotic cardiovascular disease exceeding 7.5% (24). For the individual 40 to 75 years old without cardiovascular disease or diabetes but who has a 10-year risk of clinical events greater than 7.5% and an LDL cholesterol level anywhere from 70 to 189 mg/dL, the panel recommends treatment with a moderate- or high-intensity statin (24).

Management of Diabetes

There is an age-related increase in total body fat and visceral adiposity that often is accompanied by diabetes or impaired glucose tolerance. The prevalence of type 2 diabetes increases progressively with age, peaking at 16.5% in men and 12.8% in women at age 75 to 84 years. Over age 65, glucose intolerance or diabetes was present in 30% to 40% of Framingham Study subjects (25). In a recent report, 80 chronic hemiparetic stroke patients were evaluated by fasting plasma glucose and oral glucose tolerance test to assess the utility of screening for abnormalities using fasting plasma glucose alone. Seventy-five of the 216 (35%) had type 2 diabetes by medical history. Another 70 were either diabetic (n = 11) or had impaired fasting glucose (n = 59) based on a single blood draw at the time of screening. Fasting plasma glucose among nondiabetic stroke patients had a sensitivity of 49% for predicting abnormalities in the 2-hour glucose level during oral glucose tolerance test. Cumulative results identify 77% as abnormal (impaired or diabetic) on the basis of medical history, fasting plasma glucose, and/or 2-hour glucose level, reflecting a very high prevalence of diabetic states in these chronic stroke survivors (26).

Type 2 diabetes and obesity are both associated with a clustering of atherogenic risk factors. Diabetes, often associated with high blood pressure, contributes to increased frequency and severity of cerebral vascular events (27). The risk of macrovascular disease is actually increased before glucose levels reach the diagnostic threshold for diabetes, and 25% of newly diagnosed diabetics already have overt cardiovascular disease (25). Diabetes, and related complications including untreated or poorly treated hypertension, may lead to premature arterial stiffening. The resulting stiffening and hypertrophy of the left ventricle yield a predisposition to coronary heart disease, heart failure, stroke, and other conditions (28). Other aspects of glucose metabolism may play a role in stroke risk, specifically hyperinsulinemia

and increased insulin resistance. Both were shown to be associated with ischemic stroke risk even among subjects with normal glucose status by laboratory values (26).

The risk of cardiovascular sequelae in diabetics is variable. The majority of events occur in those with two or more additional risk factors. Comprehensive stroke risk reduction in older adults should include not only normalization of the blood sugar, but also weight reduction, dietary fat restriction, strict blood pressure and lipid control, exercise, and avoidance of tobacco (25).

Atrial Fibrillation Management

AF is the most common clinically relevant arrhythmia in persons aged more than 75 years, and is strongly associated with ischemic stroke and other adverse outcomes. AF is also the most treatable cardiac precursor of stroke (29). The incidence and prevalence of AF increase with age (30). Data from the Framingham Study and hospital discharges suggest that the prevalence of AF in the U.S. population is increasing (15). More than 2.2 million Americans currently have AF, and this number is expected to increase by at least 2.5-fold over the next 50 years (29).

Stroke is the most feared complication of AF. Multiple clinical trials have shown that warfarin sodium anticoagulation therapy is effective in reducing the risk of stroke in older adults (31). However, the complex pharmacokinetics and narrow therapeutic window of warfarin make its use challenging. An adjusted dose of warfarin with a target international normalized ratio (INR) of between 2 to 3 prevents ischemic stroke in elderly patients with an acceptable hemorrhagic risk, but is still largely underprescribed (31).

Newer therapies for anticoagulation have been introduced in recent years, but evidence is limited by the small number of studies and lack of direct comparisons of novel anticoagulants (32). A comparative effectiveness analysis of relevant studies found that a factor IIa inhibitor (dabigatran 150 mg) was superior to warfarin in reducing the incidence of stroke (including hemorrhagic) or systemic embolism (RR 0.66; 95% CI 0.53 to 0.82) with no significant difference in the occurrence of major bleeding (RR 0.93; 95% CI 0.81 to 1.07) (32). The Xa inhibitor rivaroxaban was noninferior to warfarin in preventing stroke or systemic embolism and showed similar rates of major bleeding and death (32). The Xa inhibitor apixaban was superior to warfarin in reducing the incidence of stroke or systemic embolism (hazard ratio [HR] 0.79; 95% CI 0.66 to 0.95), major bleeding (HR 0.69; 95% CI 0.60 to 0.80), and all-cause mortality (HR 0.89; 95% CI 0.80 to 0.998) (32). Apixaban was also superior to aspirin in reducing the incidence of stroke or systemic embolism (HR 0.45; 95% CI 0.32 to 0.62) with similar hemorrhagic events, including major bleeding (HR 1.13; 95% CI 0.74 to 1.75), in patients who are not suitable for oral anticoagulation (32). However, no studies have as yet directly compared the new therapies to one another.

Carotid Stenosis Treatment

Carotid stenosis refers to the buildup of atherosclerotic materials within the carotid arteries, leading to occlusion of vital circulation to the brain. Management of carotid stenosis must take into account individual patient considerations and surgical risk. Carotid endarterectomy (CEA) has been the standard of care for years for severe carotid artery stenosis, but for less severe lesions, carotid angioplasty and stenting (CAS) have emerged as a therapeutic alternative and data suggest success and complication rates comparable to those for CEA (33). The advantages of CAS are its less invasive nature, decreased patient discomfort, and a shorter recuperation period, but its durability remains unproven, so CAS is mainly offered to those patients considered at high risk for open endarterectomy (33). Current recommendations for management depend on the degree of stenosis, surgical risk, and optimal medical therapy. This includes antiplatelet therapy, statin therapy, and risk factor modification, and is recommended for all patients with carotid artery stenosis (33).

Antiplatelet Therapy in Stroke Prevention

Finally, for most patients with noncardioembolic stroke, daily treatment with an antiplatelet agent is recommended. Four antiplatelet drugs are approved by the FDA for prevention of vascular events among patients with a stroke or TIA: aspirin, combination aspirin/dipyridamole, clopidogrel, and ticlopidine. On average, these agents reduce the RR of stroke, MI, or death by about 22%, but important differences exist between agents that have direct implications for therapeutic selection, including tolerance of specific agents, cost, comorbidities, safety, adverse event profiles, and patient preference (33). Aspirin is by far the least expensive agent, and ticlopidine is associated with thrombotic thrombocytopenic purpura and should be used only cautiously in patients who cannot tolerate other agents (33).

CHALLENGES TO SUCCESSFUL REHABILITATION

Even with identical stroke severity, increasing age is associated with greater disability in activities of daily living (ADLs) and mobility. Patients older than 85 years are nearly 10 times as likely to show a low response to rehabilitation in ADLs, and nearly 6 times as likely to show low response to mobility as younger patients (34). Nevertheless, rehabilitation treatment is still valuable in patients older than 85 years, because even small changes in function can improve independence and quality of life. Though possibly less effective than for younger patients, inpatient rehabilitation is still substantially helpful for older patients (34).

Rehabilitation and gerontology care professionals share a function-based assessment and management paradigm. Clinical challenges after stroke therefore should be considered within the context of age and any pre-existing disability.

Biological Changes With Aging

Visual Changes

Visual loss is usually defined as less than 20/40 in the better eye and is associated with functional consequences. Blindness is traditionally defined as vision less than 20/200 in

the better eye. Blindness or low vision affects 3.3 million Americans age 40 and over, or 1 in 28, and this figure is projected to reach 5.5 million by the year 2020. Low vision and blindness increase significantly with age, particularly in people over age 65 (35). *Presbyopia*, the loss of accommodative ability, is the major age-associated ocular change leading to low vision. It begins at approximately age 40 and progresses, so that by the seventh decade, little ability to accommodate remains. Other changes with senescence include increased light absorption by the lens, cornea, and vitreous humour, leaving less to reach the retina, resulting in decrease in sharpness of vision and the need for more light for certain activities, such as reading and driving. The prevalence of common ophthalmologic diseases also dramatically rises with advancing age, with those over 80 years of age suffering an increase in cataract (68%), age-related macular degeneration (35%), and open-angle glaucoma (7.7%; 35).

Consequences of stroke may also manifest in visual disturbances, such as homonymous hemianopsia, visual field defects, visual neglect, disturbances in color vision, or paralysis of conjugate gaze. Ocular motility disturbances may produce diplopia, vertigo, oscillopsia, or visual distortions. All of these visual disturbances have potential to complicate or hinder the progress of rehabilitation. For example, visual deficits may make it difficult for an older adult to orient to new surroundings, to follow directions, or to receive feedback and cues for mobility and self-care activities. Visual deficits may contribute to fear of falling, and impede progress in ambulatory activities. All stroke survivors should be screened for visual impairment as soon as they are medically stable, conscious, and communicative enough to participate in the examination, and an individualized plan should be formulated by the rehabilitation team to compensate for any losses.

Auditory Changes

Hearing loss is one of the most prevalent chronic conditions in the elderly population, affecting 31% of people over the age of 65, and 40% to 50% of persons over the age of 75. It is defined as the inability to hear a pure tone softer than 40 decibels (dB) at more than one frequency in one or both ears (36). The most common cause of hearing loss in the elderly is presbycusis, which is a sensorineural loss marked by difficulty hearing high-frequency tones, and by impaired speech comprehension. Other common causes of hearing loss in the elderly include cerumen plugs, otosclerosis, ototoxicity, tinnitus, Ménière's disease, and acoustic neuromas (36).

Again, stroke may impose comprehension or communication deficits that may compound hearing loss and negatively affect rehabilitation, such as aphasia, dysarthria, and apraxia of speech. Individuals with stroke are usually assessed for these problems, but all stroke survivors, especially the elderly, should also be screened for hearing loss and referred for treatment or adaptive strategies as needed. Adequate auditory acuity is critical for stroke survivors to understand the rehabilitation team's instructions, to participate in problem assessment and decision making, and to communicate effectively with family and members of the rehabilitation team, thereby improving chances for successful rehabilitation.

Body Composition

A potential confounder to reaching physical therapy goals for older stroke patients may be sarcopenia (age-related loss of muscle mass), commonly seen in older adults (37,38). Between 50 and 80 years of age, the number of fibers in the large thigh muscle, the vastus lateralis, of men decreased by 50%. Although a comparable study has not been undertaken for women, the age-related changes in muscle mass suggest that similar, if not identical, changes occur. The loss of type 2 muscle fibers appears to be immutable, but the impact of the fiber loss on muscle mass depends to a substantial degree on the regularity and intensity of the physical activity in which elderly people are engaged (38). Loss of skeletal muscle fibers is a major contributing factor to sarcopenia, but other factors, including decreased physical activity, altered hormonal status, decreased total caloric and protein intake, inflammatory mediators, and factors contributing to protein synthesis are also involved, and together may contribute to functional decline (39). Interventions targeted at combating sarcopenia of aging have included testosterone replacement, growth hormone replacement, and resistive strength training. Of these, only strength training has been shown to be an effective means of increasing muscle mass and strength in healthy older adults (41).

The additional loss of muscle in the hemiparetic limb(s) creates further difficulties for stroke survivors as they attempt to mobilize again following stroke. A recent study examining 30 chronic stroke survivors showed that lean mass of the paretic leg and thigh were 4% and 3% lower than the nonaffected leg; arm lean mass of the paretic side was 7% lower than the nonaffected side; and midthigh muscle area was 20% lower in the paretic limb than in the nonaffected leg (41). The mechanism of muscle atrophy following stroke is not well understood at this time, nor is the time frame over which the atrophy occurs. However, it appears that the sarcopenia associated with aging, combined with the disability of stroke, may conspire to place the survivor at a disadvantage from a rehabilitation perspective. Most stroke patients are carefully assessed for muscle strength throughout the rehabilitation course, and more research is needed to identify specific strength training recommendations for these patients.

Comorbidities

Early exercise rehabilitation is critical to maximizing functional outcomes following stroke (42). However, sedentary older adults with stroke often suffer from comorbidities that may limit their ability to fully participate or maximize physical therapy in the subacute and chronic phases of stroke recovery.

Disorders of the cardiovascular system can potentially impact rehabilitation therapy by limiting exercise tolerance, and are very common in older adults. With age, pre-existing coronary artery disease (often seen coincident with cerebrovascular disease), congestive heart failure, valvular dysfunction, and arrhythmias increase in prevalence (1). Chronic obstructive pulmonary disease, emphysema, and chronic bronchitis are also more prevalent in older adults. Stroke survivors with these and similar comorbid illnesses are likely to face additional challenges with rehabilitation and life beyond. These individuals may experience severe limitations in activity tolerance and progress more slowly toward their rehabilitation goals. It is likely that comorbid cardiovascular or pulmonary problems played a role in dictating a previously sedentary lifestyle that precipitated the stroke.

Rehabilitation may also be challenged by musculoskeletal disorders (osteoarthritis, rheumatoid arthritis, history of muscle or bone injury). Careful evaluations of pre-existing disability, the extent of neurological deficit, and motor control are critical to developing a realistic exercise prescription. Identifying and addressing barriers to mobilization (medication prior to physical therapy appointments, braces/orthotics for support, appropriate assistive devices, and environmental modifications) will maximize chances of success in reaching therapeutic goals.

Cognitive impairment is another potential barrier to successful rehabilitation. Stroke survivors are likely to have long-standing hypertension and other cardiovascular risk factors that can lead to vascular-related cognition impairments or dementia, and cognition may be further impaired by the stroke itself. In an observational study of 645 first-ever stroke survivors, 38% were judged cognitively impaired (Folstein Mini Mental State Exam score of <24) at 3 months after stroke. Those with cognitive impairment were matched with cognitively intact stroke survivors and outcomes were compared over time. Cognitive impairment was associated with advanced age (75 and older), ethnicity (Caribbean/African and Asian), lower socioeconomic class, left hemispheric lesion, visual field defect, and urinary incontinence. It is associated with poor long-term outcomes, including survival and disability, up to four years after stroke (43). These problems are very likely to impact the course of rehabilitation therapy and are discussed more comprehensively elsewhere in this text, but all older stroke survivors should be carefully screened in these domains of cognition to maximize therapeutic intervention.

Access to Care

Older adults in general face more barriers in accessing health care services than their younger counterparts. Older disabled stroke survivors face even more hurdles in their quest for both restorative and preventive health care services. Many older adults are dependent on Medicare benefits to pay for health care services, and may or may not carry an additional group or private gap coverage policy. The Medicare insurance system was developed to ensure that the older workers had insurance for health care expenses, and many have used it for incidental care only (44), as coverage for preventive services has been added incrementally over time. In a recent study of 46,659 respondents aged 65 years and older, 93% reported having a regular care provider, 98% had a regular place of care, and 98% were able to obtain needed medical care (45). Those with a regular care provider or a regular place of care were more likely to receive clinical preventive services than those without either of these. Reasons given for not obtaining needed medical care were cost (27%), too long a wait for an appointment (20%), distance or unavailability of transportation (9%), office not open when the individual could get there (8%), and other reasons (32%) (45). Another large study of older adults revealed that a perceived lack of responsiveness to patient concerns, cost, transportation, and street safety were substantial barriers for many older adults (46). Some older adults in the United States have no health care coverage at all, and therefore experience significant cost barriers to care, and do not regularly receive annual checkups or preventive health screenings (47).

For stroke survivors, economic barriers are only the beginning of the battle. As noted earlier, transportation becomes problematic, as driving ability is frequently lost because of disabilities resulting from the stroke. Independent older adults are forced to rely on family, neighbors, or public transportation to access health care services. Those who provide transportation for the stroke survivors must adjust schedules to accommodate primary and subspecialty physician appointments and multiple weekly physical occupational and/or speech therapy appointments throughout the subacute rehabilitation period. These barriers have potential to significantly reduce the ability of stroke survivors to access the care necessary to optimize recovery. Health care providers should remember to query stroke survivors regarding these potential barriers, and be sensitive to the multiple demands placed on survivors and caregivers.

Behavioral Barriers

Lack of physical activity is an important contributor to many of the most important chronic diseases for older Americans, including heart disease, diabetes, colon cancer, and high blood pressure. Few older adults achieve the minimum recommended 30 or more minutes of moderate physical activity on 5 or more days per week. Data from the Centers for Disease Control and Prevention (CDC) indicate that 35% to 44% of adults aged 75 or older are inactive, meaning they engage in no leisure-time physical activity. National data indicate that few older persons engage in regular physical activity. Only 31% of individuals aged 65 to 74 report participating in 20 minutes of moderate physical activity 3 or more days per week, and even fewer (16%) report 30 minutes of moderate activity 5 or more days per week (48). For those aged 75 and older, levels of activity are even lower: 23% engage in moderate activity for 20 minutes 3 or more days per week and only 12% participate in such activity for 30 minutes 5 or more days per week (48).

The tendency for older adults to be sedentary places them at risk in multiple ways. Inactive lifestyles alone, or in combination with other inadequately controlled risk factors (hypertension, hyperlipidemia, diabetes, smoking, imprudent diet) create a scenario that makes a stroke more likely. After stroke, an inactive lifestyle not only inhibits optimal recovery, but also accelerates the muscle atrophy and resultant cellular changes that raise the risk of recurrent stroke (26). Further, older adults who have been sedentary may be reluctant to adopt active lifestyles due to affective disorders, fear, or fatigue.

A substantial proportion of individuals with stroke (ranging from 39%–76%) report significant and persistent fatigue affecting their daily lives (49–51). The frequency of self-reported fatigue is about twice as high in individuals with stroke as in age-matched controls (51). Self-reported fatigue has been identified as an independent predictor for having to move into an institutional setting after stroke (49). For further discussion of fatigue after stroke, refer to Chapter 32.

OVERCOMING BARRIERS

Common poststroke problems include cardiovascular deconditioning, impairments in gait and balance, diminished muscle tone and weakness, alterations in glucose metabolism, and persistent cardiovascular disease risk factors. Because it is more difficult to get around and requires more energy to do so, survivors of stroke often become sedentary. Without regular physical activity, cardiovascular fitness may be lost, further compounding the imbalance of energy resources and expenditure. Add to the mix fatigue, loss of confidence, and social isolation, and a cyclical pattern emerges that negatively affects function, independence, and quality of life.

With effective interventions, many of these problems are remediable, if not reversible. The potential for recovery is not time limited, and relatively simple task-oriented activity programs can induce meaningful physiologic changes in function, fitness, metabolism, and brain activity.

The Role of Exercise

Conventional rehabilitation care typically provides little or no structured therapeutic exercise beyond the subacute stroke recovery period. Evidence now firmly indicates that task-oriented exercise has the potential to improve both upper- and lower-extremity motor function regardless of the time since stroke (53–56). Low-intensity treadmill training 3 times per week has been demonstrated to improve motor and gait function in 12 weeks, even in distant chronic stroke survivors (55,56). Repetitive task training was also trialed in 14 chronic hemiparetic stroke survivors who trained on a custom arm extension machine. They gained significant strength in elbow and wrist flexion and extension on the paretic side after six weeks of training three times per week (53,54). The task-oriented exercises referenced in these studies were conducted under close medical supervision, and studies are under way to identify appropriate training protocols for use in community settings.

Following stroke, regular exercise can facilitate motor recovery, and also help control the common comorbidities that influence recurrent stroke risk. Exercise can reduce hypertension, enhance glucose regulation, improve blood lipid profiles, and reduce body fat. Many older adults with stroke have never been advised by a health care professional to engage in a regular exercise or walking program (57), yet generalized recommendations have been formalized to promote physical activity following stroke (42). The field of poststroke exercise rehabilitation is still developing. Constraint-induced movement therapy (CIMT), body-weight-supported gait training, functional electrical stimulation (FES), robotic-assisted therapies, cognitive disorders interacting with movement (CDIM), constraint-induced language therapy, and noninvasive brain stimulation are some examples of the paradigms that are actively under investigation to identify the best singular and combination approaches to maximize functional recovery following stroke (58). All stroke survivors should be questioned regularly about physical activity and exercise patterns, habits, and beliefs. If a stroke survivor reports little to no physical activity, and he or she is capable of performing physical activity safely, each office visit is an opportunity to educate and prescribe daily exercise activity.

Role of Self-Efficacy in Behavior Change

Many of the cardiovascular risk factors associated with stroke require changes in health behaviors, such as choosing a healthier diet, losing weight, beginning an exercise program, and stopping smoking, or adhering to a medication regimen (59). Social cognitive theory indicates that specific efficacy expectations affect behavior, motivational level, thought patterns, and emotional reactions to any situation (60). Perceptions and beliefs affecting behavior include self-efficacy (i.e., an individual's judgment of his or her capabilities to perform a specific action) and outcome expectations (i.e., beliefs that if a certain behavior is performed, there will be a specific outcome or benefit). These beliefs are essential to the adoption and maintenance of self-care ADL after stroke (61) and exercise following stroke (57). Bolstering self-efficacy to make significant lifestyle modifications is accomplished through the following four steps: (a) educate and encourage, (b) provide specific tasks to accomplish and directions to complete the task, (c) identify and address barriers to compliance, and (d) cue with role-modeling or self-modeling. Finally, education regarding expected benefits may provide further incentive and motivation to change behaviors (62,63). Helping an older adult to begin an exercise program, choose a healthier diet, or adhere to a medication regimen requires time, care, and encouragement, and discussing these and other behavior modification goals should be a routine part of routine assessment and surveillance.

Evaluation and Activation of Support Systems

For many older adults, particularly those affected by stroke, support systems can make the difference between returning

to home in the community or life in an assisted living or skilled nursing facility. The support system of older adults is comprised of three components: the informal network, the formal support system, and semiformal supports (64). Informal supports provided by family and friends are based on long-standing relationships and form the basis for the older adult's social network. Neighbors who see the older adult on a daily basis to perform chores or errands, or offer to shop, are examples of informal support. Formal supports are those paid for and provided by Social Security, Medicare, Medicaid, other service providers, and social welfare agencies. Home-based therapists, home health nurses, and personal care aides are examples of formal supports. Semiformal supports are those provided by local or neighborhood organizations, churches, or senior centers. The local stroke support group may be another example of a semiformal support.

It is critically important to identify and mobilize social supports and resources as quickly as possible in order to smooth the transition to home and begin community reintegration. Identification of the informal and semiformal resources allows for an inventory of persons or services that can be called upon while waiting for formal supports to become available, such as applying for transportation service for the disabled. Similarly, home-based therapies and nursing/personal care assistance may be prescribed immediately upon discharge to home to allow the stroke survivor the additional time necessary to become independent with ADLs, or to allow identification of an informal or semiformal support that will take up care provision when formal services end.

Care providers should routinely inquire about support systems and changes in available supports for stroke survivors over time. In particular, providers should inquire about the well-being of the primary caregiver for the stroke survivor. Multiple studies have indicated that primary caregivers experience strain that is described as mild to severe in the first year following a stroke (65,66), and the chronic strain on caregivers over the long term takes a toll on health in higher levels of emotional and physical distress (67). Respite resources should be identified and used as needed to preserve the health and well-being of the primary caregiver.

Continuing Patient/Family Education: Recognizing Signs and Symptoms

Of the more than 795,000 strokes that occur each year, 185,000 are recurrent (1). About 25% of people who recover from their first stroke will have another stroke within 5 years. Unless specific interventions are directed toward modifying stroke risk factors, the potential for recurrence persists. Stroke survivors should be monitored regularly for recurrent stroke risk, and they and their families educated to self-monitor as well.

To minimize impact from stroke, early recognition of signs and symptoms and immediate initiation of evaluation and treatment are imperative. Quantitative estimates of the rate of neural circuitry loss in ischemic stroke emphasize the urgency of timely and definitive care. The adage that "time lost is brain lost" takes on added significance when one realizes that the typical patient loses 1.9 million neurons each minute during which stroke goes untreated (68).

Older adults often do not associate new-onset symptoms with acute stroke, but rather attribute them to other illnesses (arthritis, weakness, headaches, or fatigue) and fail to take immediate action. The American Stroke Association has launched a campaign to educate the general public about the signs and symptoms of stroke. The name of the campaign is FAST, which is an acronym for (a) Face Drooping, (b) Arm Weakness, (c) Speech Difficulty and (d) Time to call 9-1-1. Although the program was launched more recently in the United States and evaluation results are not yet available, similar programs in Australia and the United Kingdom have demonstrated limited success. A recent report of semistructured interviews conducted with 19 stroke survivors and 26 witnesses in the United Kingdom suggested that most participants were aware of the "Act FAST" campaign, but the majority reported no impact on their actions during the stroke event (69). In Australia, interviews were conducted with either stroke patients or a key bystander for consecutive eligible cases admitted to two metropolitan hospitals between August 2006 and April 2008. Of the 100 patients and 70 bystanders interviewed, only 12% were aware of the FAST campaign, and of these few (19%) were able to recall all FAST symptoms, with only one bystander using the FAST assessments to identify stroke. Awareness of the FAST and Signs of Stroke campaigns was low, with poor recall and little use of the FAST assessments (70).

A report of the Reasons for Geographic and Racial Differences in Stroke Study (REGARDS) indicated that 18% of more than 18,000 participants had no history of diagnosed stroke or TIA, but reported having had at least one stroke symptom, most reporting unilateral numbness, weakness, or sudden visual disturbance. Symptoms were more prevalent among African Americans compared with white participants and among those with lower income, lower educational level, and fair to poor perceived health status, indicating that continued educational efforts are required (71). Multiple public health organizations and researchers have developed and trialed programs, but an effective public education campaign to raise awareness of stroke symptoms and guides to action when symptoms are witnessed or experienced remains elusive.

CONCLUSION

There are nearly 5 million persons in the United States aging with the chronic disability of stroke, and with advancing age the risk for first-time stroke increases (1). Older adults often have age-associated factors that compound the risk for stroke and can potentially affect recovery trajectories. Rehabilitation therapies are effective at any age if comorbidities and functional changes associated with aging are taken into account. Careful, comprehensive assessment of the older stroke survivor, along with that person's family and support network, is necessary to design a customized, progressive exercise program to maximize recovery.

Example: Self-Efficacy Based Intervention to Encourage Exercise in Older Adults

ASSESSMENT/PLAN	EXAMPLE
Analyze risk factor profile for primary prevention	Comorbidities (diabetes, high blood pressure, hyperlipidemia) Medication regimen Lifestyle influences (smoking, poor diet, physical inactivity)
Consider deficit profile for stroke survivor	Hemiparesis, cognitive, language deficits, depression are common in survivors of stroke
Intervention	
Educate and encourage	Provide education on influences of comorbidities on risk for first or second stroke, and encourage patient to make changes in behavior to minimize risk.
Provide explicit direction and verify ability to perform activity	Give patient (and family, if available) clear instructions on self-monitoring, prescribed medication regimen, and symptom management. In conjunction with primary health care provider, provide detailed, customized activity program and calendar to mark off days as activity is accomplished. If an exercise program is warranted, a physical therapist or exercise physiologist may be consulted.
Identify barriers, physiological feedback	Pain, fatigue, and anxiety are some examples of physiological barriers. Depression may influence perceived ability to carry out activities. Age-related sensory changes may influence ability to perform tasks. Transportation and finances may be also identified as barriers to adherence to prescribed regimens.
Cuing and role modeling, self-modeling	Patients derive confidence in their own ability to perform any activity by watching others who are similar to themselves performing the same activity or seeing themselves successfully performing the activity. A photograph may be helpful as cue.
Evaluation	
Provide routine surveillance of risk factors/profile	Review risk factor profile at every visit.
Revise prescribed regimens as needed.	Medications, physical activity programs should be modified as needed in collaboration with primary provider.
Routinely provide encouragement to reach patient goals	Continue positive reinforcement for work accomplished. Behavior change is hard. Continue gentle reminders for healthy behaviors yet to be adopted.
Continue education as needed	Routine review of comorbidities, symptoms, new diagnoses as needed.

Ethical Issues in the Care of Stroke Survivors

Lynne C. Brady Wagner, Megan A. Morris, and Kristi L. Kirschner

> I wanted to communicate: Yelling louder does not help me understand you any better! . . . Speak more slowly. Enunciate more clearly. Again! Please try again! S-l-o-w down . . . See that I am a wounded animal, not a stupid animal. I am vulnerable and confused. (1)

Suddenly and without warning, 37-year-old neuroanatomist Jill Bolte Taylor sustained a large, left hemispheric intracranial hemorrhage from an arteriovenous malformation. After several years of rehabilitation, she wrote an account of her stroke experience and recovery, *My Stroke of Insight: A Brain Scientist's Personal Journey* (1). Embedded in her recollections and fragmented memories are examples of the moral dilemmas that are familiar to health care professionals who work with people after strokes. Questions that commonly confront the clinician working with stroke patients and the families of stroke survivors include:

- Does the stroke survivor have decision-making capacity (DMC)?
- How does one evaluate DMC when there is an obvious language disorder?
- Is the patient the "same person" with the same values as before, or is he or she forever altered? Should this matter?
- Should life-sustaining medical treatments be initiated or continued in the face of sometimes devastating neurologic impairment?

These questions are just a few of the common ethical issues that are frequently encountered after stroke. This chapter is intended to provide some guidance for health care professionals navigating these uncertain waters. There are no easy answers. There are only some ethical principles and guidelines that can help clarify the range of acceptable choices. The rapid pace of change in this field compounds the complexity of these ethical dilemmas. As new research is produced, new stroke treatments and technologies become clinically available, and the equations change related to the potential benefits and burdens of existing treatment choices. Individual outcomes are often uncertain, not only in terms of level of impairment, but also in those of disability and life satisfaction as well. Patients and families frequently feel overwhelmed and daunted by the decisions that must be made—often within a constrained time frame—about the most routine to the more complicated interventions and procedures. The lack of societal and financial resources to support people who need care after stroke can add a layer of complexity and create ripple effects on family members, friends, and others in the environment. Stroke, though an individual medical event, affects a community of people.

This chapter addresses a range of potential ethical issues faced by patients, family members, and various individuals who are part of the health care team. One of the most common ethical issues encountered in the care of stroke survivors is questions regarding decision-making ability. Because stroke can result in a host of neuropsychologic impairments that may affect a person's cognitive–communication skills, questions regarding the stroke survivor's level of ability to participate in decision making after stroke are familiar to all clinicians caring for this population. Other common dilemmas include issues related to personhood, social justice, and restrictions people face in choices of where and how to live, the role of the family and surrogate decision makers (2,3), the use of therapies and technologies that have limited evidence of effectiveness, and controversies that arise when patients need alternative nutrition and hydration caused by dysphagia (4–6).

We use excerpts from patient narratives about the lived experience of stroke to illustrate how the ethical problems may present to clinicians. Rehabilitation clinicians have stated that they face a number of clinical ethical issues in their daily practice (7); these are often recognizable as situations in which values are in conflict and the right course of action is not clear. Differentiating the clinical questions or options from the ethical questions or duties can often be accomplished by considering how the question should be phrased. Clinical questions begin with the phrase "Can we?" Can we achieve the medical goals for this patient by applying this treatment approach or technology? For example, "Can we place a feeding tube in Mr. Jones? Is it medically feasible and reasonable?" Ethical questions begin with the phrase "Should we?" Should this particular outcome be a goal for this person at this time? For example, "Given that Mr. Jones values the pleasure of eating above his nutritional status, should we insert a gastrostomy tube for this purpose?" An additional question could be "Should we

proceed with the use of technologies or therapies such as electrical stimulation for swallowing in light of conflicting or limited evidence of its benefit?"

INFORMED CONSENT

> Later in the morning, it was time for me to have an angiogram that would outline the blood vessels in my brain . . . Although, I thought it absolutely absurd that anyone would ask me to sign a form of consent while in this condition, I realized that policy is policy! How do we define "of sound mind and body" anyway? (1)

The first and most pressing issue that commonly arises after a stroke is to what degree the patient is able to understand and make important medical decisions. From the time the person enters the emergency room through the course of rehabilitation, the medical team will need to engage in an evaluative process to decide if the person has the requisite capacity to make informed decisions (8). The ethical principle of respect for autonomy demands that medical decisions be a result of a shared communication process between the health care professional(s) and the patient whenever possible (9,10). As a conceptual framework, the terminology of informed consent is fairly recent and did not become fully integrated into medical care in the United States until the 1970s (9).

Though the initial emphasis for obtaining informed consent focused on the obligations of the health care professional or researcher to disclose the appropriate information, the process of assessing the patient's or subject's comprehension and ability to make an uncoerced choice quickly became of paramount interest. For this reason, some bioethicists began to use the terminology *valid consent* rather than *informed consent* to emphasize the interactional nature of the process. In his classic textbook, *Ethical Issues in Neurology*, neurologist and bioethicist James L. Bernat identifies three critical elements for valid consent:

> (1) physicians must convey adequate information to their patients; (2) consent must be obtained without coercion (or be "voluntary"); and (3) patients must be competent to consent or refuse. (11)

"Adequate information" is further clarified to include the basic facts about the available medical therapies, including their risks and benefits, the risk of no treatment at all, the course of treatment recommended by the health care professional, and the rationale thereof (11).

Assessment of Decision Making Capacity (DMC)

As one of the three criteria required for valid consent, assessing competence, or DMC, is a critical skill for all health care professionals. In the hospital setting, people who were previously competent may become temporarily or permanently compromised in their ability to make decisions on their own behalf. Reasons include a direct injury to the brain (as in stroke) or secondary factors such as medications, metabolic abnormalities, hypoxia, or psychiatric conditions (12–14).

In the health care setting, competency is more accurately referred to as DMC. The distinction is not merely a matter of semantics. In our society, adults age 18 or older are presumed to be competent and able to make their own decisions. Only a court of law can declare someone "incompetent," and the specific areas of incompetence must be delineated in the court decision. For example, a person may be declared incompetent to manage his financial affairs, but be deemed competent to participate in medical decisions (15,16). Usually, a guardian is appointed by the court to oversee the areas in which the person has been judged incompetent.

It is important to note that the assessment of DMC is not a global concept, but is assessed in the context of the question at hand. In other words, it is a situation- or question-specific assessment. In the classic model for assessing decision making, as articulated by Appelbaum and Grisso (15,16), the person must in some way—either verbally or behaviorally—be able to communicate a choice. Thus, adequate consciousness and a method of reliable communication are essential. The person must also be able to understand relevant information, such as the nature and rationale of the treatment and its risks and benefits, as well as alternatives to the proposed treatment. Applying this information to his or her particular circumstances, which requires insight and appreciation of one's own medical condition, is the next critical capacity. Finally, the person should be able to demonstrate a logical process of reasoning.

Various tools have been developed to assist clinicians in assessing DMC in the health care setting, including the Aid to Capacity Exam (ACE) developed by the University of Toronto Joint Centre of Bioethics (see http://jointcentreforbioethics.ca/tools/ace.shtml) (14,17). In addition to providing training and a framework for the assessment of DMC, a series of suggested questions and a scoring system allow the evaluator to tabulate a total score. The determination of capacity thus falls along a continuum, acknowledging that capacity is not an all-or-none phenomenon. Depending on the score, at that specific point in time, the person may be considered:

- Definitely capable
- Probably capable
- Probably incapable
- Definitely incapable

The circumstances of the assessment are noted, as are any factors that might be interfering with DMC so that these issues can be addressed medically, if possible. Ideally, a final determination of DMC will be deferred until such confounders are corrected (17).

It is possible for patients to have DMC for some medical decisions and not others. For example, a patient may not be able to decide if the benefits of a carotid endarterectomy are worth the risks, but the same person may be

able to tell clinicians who he or she wants to speak for him or her if there are important medical questions to be addressed. The issue here is the congruence between the complexity of the information involved in the decision and the person's capabilities. It is also possible that, for decisions that involve greater risks (for example, a patient's refusal of life-sustaining treatment), a higher level of evidence may be required than for decisions with less consequence, such as whether to wear a splint or what to eat (9,14,16–18). It is not the outcome that is at issue here, that is, whether the health care team agrees with the decision or not. It is the evidence that the process the person used to arrive at the decision is sound. This concept is also known as the sliding scale for standards of evidence in the assessment of DMC (9).

A sliding scale also exists for the extent to which a patient physically participates in decisions about his or her care. Even when a patient lacks the capacity to make informed choices, he or she can be included in the decision-making process (19). One model that captures this continuum is the shared decision-making model (20). This is a process in which the provider, patient, and, at times, the family member or caregiver actively contribute to and collaborate in making medical decisions. It is not a substitute for informed consent, but a broader concept that includes communication about medical options and the patient's values and preferences (20). The extent to which each of these stakeholders contributes may differ based on patient need and the decision at hand. This allows for customized participation of patients with impaired DMC. To facilitate the patient's involvement and to ensure that his or her wishes are included in the decision, the health care team may need to provide accommodations. These modifications can vary and might even be as simple as having the discussion in the patient's presence. It may be appropriate to include a speech–language pathologist (SLP) in the decision-making process, as SLPs have been increasingly involved in facilitating these discussions for persons with communication disability (19). The SLP can serve multiple functions, such as developing a communication tool for the patient to use or physically assisting the patient during the actual discussion. Whatever method is used, it is paramount that the health care team attempt to discover the patient's values and preferences related to the decision at hand.

The Effects of Stroke on DMC

> To someone looking on, I may have been judged as less than what I had been before because I could not process information like a normal person. I was saddened by the inability of the medical community to know how to communicate with someone in my condition . . . I wanted my doctors to focus on how my brain was working rather than on whether it worked according to their criteria or timetable. I still knew volumes of information and I was simply going to have to figure out how to access it again. (1)

When patients make choices that are compatible with the team's recommendations, there is typically little concern about DMC. It is when decisions are contrary to the team's recommendations or when certain medical conditions occur, such as brain diseases or injuries, that clinicians raise the question of DMC. Decisional processes, after all, involve a complex integration of neurologic systems and processes (12). A neurologic condition such as a stroke has the potential to affect the patient's ability to understand, contemplate, and communicate a choice—all critical skills for decision making (21–23).

The process of shared decision making requires the patient to possess basic comprehension and expression skills, verbal or nonverbal (21,23). Persons with impaired communication skills are at risk for unnecessary exclusion from this process (23,24). A stroke can result in a myriad of problems, including dysarthria, aphasia, dyslexia, agraphia, dysphonia, abulia, and other cognitive–communication impairments. Patients with these impairments may be especially vulnerable to judgments that their participation in the informed consent process would be invalid because they may not be able to communicate without accommodation or facilitation from a trained assistant (either a clinician, family member, or volunteer) (21,23,25). In general, poststroke deficits that can affect DMC fall into four general categories: disorders of consciousness, communication, insight and awareness of one's condition, and mood. Freedman et al. have further classified that the cognitive processes fundamental to decision making include attention, language, memory, and frontal lobe function (12).

DMC and Disorders of Attention

Attention can be considered the sine qua non for all other cognitive neurologic processes (26), without which encoding, problem solving, and essentially all other cognitive functions cannot optimally operate. It is also highly distributed in the brain, from the brainstem/reticular activating system to the thalamus and bilateral frontal and nondominant parietal lobes.

In the context of such a neurologic model, it is easy to see how attentional mechanisms may be disrupted when a stroke occurs. Patients who have had strokes may have attentional problems from both the brain lesions as well as from seizures, or toxic-metabolic factors such as medications, hypoxia, infectious processes, or electrolyte abnormalities that can result in acute confusional states (26). Patients who are unconscious are de facto unable to participate in decision making until they regain consciousness. If attention is fluctuating or drifting, capacities may be emerging, but they are often not adequate for in-depth discussions and assessments about medical decisions (12). Patients need to be able to attend to information long enough to decode information, apply the information to their circumstances, and reason.

Another interesting attentional problem occurs with lesions in the nondominant hemisphere, resulting in neglect syndromes. For example, there are well-described syndromes

that result in disruptions of the internal template of the body (26), such as anosognosia, as well as syndromes that disrupt the exploratory motor components. Such lesions can result in disconnection syndromes in which patients can verbally comprehend information, but have difficulty applying this information to their particular circumstances. Such verbal–behavioral disconnections pose particular difficulties for clinicians when assessing DMC (12,27), as the assessments tend to be heavily weighted to the verbal realm. It is possible for patients to verbally demonstrate an accurate understanding of information, but be unable to apply this information to their own particular circumstances. Such defects in intrapersonal awareness or perception can pose serious challenges to DMC.

DMC and Aphasia

> "Answer this, squeeze that, sign here!" they demanded of my semiconsciousness, and I thought, How absurd! Can't you see I've got a problem here? What's the matter with you people? Slow down! I can't understand you! Be patient! Hold still! That hurts! What is this chaos? . . . They couldn't hear me because they couldn't read my mind. (1)

Aphasia is an acquired disorder of the language system that can result from a stroke or other damage to the language centers of the brain (28,29). Linguistic or verbal (language) ability is critical to decision making. As noted earlier by Appelbaum and Grisso, among the requisite skills for DMC is that the person must in some way—either vocally or behaviorally—be able to consistently communicate a choice. Furthermore, the person must also be able to understand relevant information, such as the nature and rationale of the treatment and its risks and benefits, as well as alternatives to the proposed treatment. The complexity of the decision will thus determine the level of detail required for accurate communication.

Under the diagnosis of aphasia, many taxonomies exist (29). Relative to the area and size of the neurologic lesion, diastasis, and an individual's premorbid linguistic capabilities, aphasia can present a number of challenges for a stroke survivor. The most recognizable form of this impairment presents as problems with word finding that can range from the very mild (minimally affecting a person's word choice and fluency) to the very profound (resulting in absence of the ability to produce or communicate words). The situation may be further complicated by the fact that the person with an aphasia affecting verbal expression and others who interact with him or her may not be fully aware of the extent of any accompanying impairment of comprehension, raising the risk of incorrectly assuming accurate communication (23,30).

Unfortunately, health care professionals receive little or no formal training specifically in methods to facilitate and accommodate communication with patients who are aphasic and who have communication impairments (31,32). Kagan (33) demonstrated that, even without objective improvement in the linguistic abilities of a person with aphasia, training medical professionals and other caregivers who work with persons with aphasia can lead to more successful communication outcomes. The presence of aphasia should not preclude attempts to involve the patient in making decisions, with appropriate accommodations as needed. Indeed, it would be an injustice to the patient to exclude him or her a priori (12,25,33). When a patient has a way to demonstrate that he or she can comprehend the information provided and make or contribute to a choice regarding treatment, a very significant measure of respect for individual self-determination is fulfilled.

When patients with communication impairments have the ability to participate in decision making but are denied the opportunity because of lack of either awareness or of training on the part of their health care providers or family members, their autonomy is usurped. The opposite can also occur. Linguistic representation in the brain is complex, and one's ability to recognize and convey nonverbal communication can be preserved while the ability to encode specific words and concepts may be severely limited. Because of this, persons with some language impairments may communicate by responding to head nods, tone of voice, or gestures and might therefore be assumed to understand information that they do not. In this example, DMC may be assumed when it is not present, and the stroke survivor is denied the protection and involvement of a surrogate (21,23). When possible, a detailed assessment of language abilities by a SLP is critical if questions of DMC arise in the context of aphasia. Not only can the SLP clarify the type and extent of aphasia, but he or she can also provide guidance for compensatory strategies in many cases. For example, communication with a patient who has comprehension impairments may be more successful if information is presented visually, in shortened segments, or accompanied by diagrams, rather than through lengthy auditory presentations (32).

DMC and Disorders of Speech

> So I usually have the skimpiest arsenal of facial expressions, winks, and nods to ask people to shut the door, loosen a faucet, lower the volume on the TV, or fluff up a pillow. I do not succeed every time. As the weeks go by, this forced solitude has allowed me to acquire a certain stoicism and to realize that the hospital staff are of two kinds: the majority, who would not dream of leaving the room without first attempting to decipher my SOS messages; and the less conscientious minority, who make their getaway pretending not to notice my distress signals. (34)

In his book, *The Diving Bell and the Butterfly* (34), Jean-Dominique Bauby described the devastating loss of his communication abilities following a stroke at the age of 43. He became "locked in" as a result of a massive stroke affecting his brainstem. Though his cognition was intact, he

TABLE 46.1 Strategies for Maximizing Communication When a Patient Requires Increased Time to Interact

1. Partner with the patient to develop strategies together so he or she knows you are purposefully attempting to optimize communication.
2. Be thoughtful about scheduling. For nonurgent discussions, try to schedule meetings when you are not rushed to get to another appointment.
3. Encourage the patient to record questions or statements ahead of time. If the patient has computer access, he or she can email the questions before the appointment or may be able to work with an assistant who can write down the questions ahead of time. These can either be sent to you or read at the appointment.
4. Physicians and other team members may call on the SLP or other trained individuals to assist by asking the patient specific questions. The physician can then schedule time to be there at the end of the appointment, and the information gathered can be shared. The trained facilitator can then assist in facilitating a discussion about the particular issue.
5. If you cannot understand the message and do not have more time to stay with the patient, let the patient know that you will return to this question at a later time or use one of the above strategies.

was paralyzed and unable to phonate or articulate (anarthria). His only preserved movement was blinking his left eye. It was through this movement that Bauby communicated, meticulously and tediously blinking in response to the presentation of letters from the alphabet to spell out his thoughts, needs, wishes, and feelings. Indeed, his book is a remarkable product of such efforts. It provides a distressing perspective on the health care system, in which a man with a rich inner life is considered by some to be a vegetable or treated as an object with his only interaction with staff through the provision of tube feedings, baths, and repositioning. This is in striking contrast with the many care providers and friends who invested the time to learn the laborious communication strategies and facilitate Bauby's connection with humanity.

Though a number of authors have addressed the various ethical issues that are a consequence of aphasia (21,23,31,33), less has been written about the issues involved in the face of speech disabilities (25,35,36). Yet, the impact of motor impairments of speech on DMC can be devastating. A person like Bauby, who clearly has the ability to make decisions when given the opportunity to do so with appropriate facilitation, can easily be discounted or prevented from doing so. Even health care professionals may have limited understanding of the association between cognitive abilities and one's ability to speak, often presuming that a person who is unable to articulate well has related difficulty with the ability to understand and think. The importance of a careful neurologic evaluation and frequent reevaluations by trained professionals cannot be overstated; furthermore, once the appropriate methods and techniques for facilitated communication are identified, all staff and contacts with the person need to be trained in their use (25,35).

Augmentative and alternative communication (AAC) techniques have been used successfully to assist in the decision-making process for persons with neurologic disease or disorders that have severely affected motor control of speech (25). The aid of a knowledgeable facilitator and the necessary high-tech (for example, electronic or computerized equipment) or low-tech (e.g., alphabet boards and picture books) device(s) can reveal the decisional abilities of persons whose profound communication difficulties may lead clinicians and families to believe that the patient cannot possibly participate. SLPs and occupational therapists with experience in the use of these strategies are invaluable resources for the physician, nurses, family, and all other team members (25) and should be involved early after the stroke.

AAC solutions are frequently not easy to implement. Their use often requires a great deal of time on the part of both the patient and facilitator (see Table 46.1 for suggestions to maximize communication). Allowing patients to participate fully in discussions contributes to respect for individual autonomy and fosters clinician understanding of the patient's authentic wishes. An additional challenge to allowing patients with severe motor output impairment to participate in medical choices is the lack of trained personnel, as well as the availability and funding for AAC devices (37). Even though some individuals who need this kind of equipment are able to obtain insurance coverage of higher-tech and expensive systems, other insurers fail to accept the medical necessity of this equipment. In light of increasing health care costs, devices or therapies deemed to have limited medical import are often not reimbursable (37). The onus is often on the clinician to advocate for the patient and appeal such adverse funding decisions, arguing that accurate and timely communication is essential for good, safe, medical care. In other instances, even when insurers cover the cost of an AAC device, they do so at such a low rate that the equipment is still unattainable for many people. Clinicians are then required to use low-cost alternative or turn to cheaper commercially available devices.

DMC and Mood Disorders

> My own mood seesawed wildly—at times I felt almost euphoric with relief and at the satisfaction of being alive, and other times almost suicidally depressed (38).

In his book *My Year Off: Recovering Life after a Stroke*, British editor Robert McCrum, 42 years old and newly married at

the time of his cerebral hemorrhage, describes his experience of emotional turmoil after his stroke. Neuropsychologic processes involved in mood regulation can be both caused and affected by the presence of stroke (39–42). Even though an affective disorder may be transitory and fluctuating, depression and anxiety can limit a stroke survivor's ability to engage fully in the process of deliberating about daily problems and considering future events and issues.

Depression and anxiety can impede two critical elements of DMC. First, a person may be unable to fully appreciate or remember information conveyed by others and therefore may be unable to comprehend various treatment choices presented. Additionally, the patient who is depressed or anxious may experience interference in the cognitive processes typically referred to as *executive functioning* (40), that is, the ability to identify problems, generate possible solutions, remember factors of these solutions, and weigh them against one another and select a reasonable approach to the challenge. In this situation, a patient may be unable to fully deliberate on the options presented in making a medical choice. Treatment for the underlying depression and/or anxiety may not only alleviate the patient's suffering, but may also help the patient imagine possibilities and process information in a more balanced fashion.

When a Patient Lacks DMC: The Role of a Surrogate

> Honestly, I didn't really understand all of the details about what they were proposing to do—partly because the cells in my brain that understood language were swimming in a pool of blood and partly because of the sheer speed of their conversation . . . In my condition, I thought I understood that they were planning on passing a suction instrument up through my femoral artery into my brain to suck out the excess blood and threatening tangle of vessels. I was aghast when I realized it was their plan to cut my head open! . . . I made it perfectly clear to everyone that under no circumstances would I ever agree to permit them to open my head . . . The meeting ended with the craniotomy option temporarily tabled, and though it was clear to everyone (except me) that it was G.G.'s job to convince me to have the surgery. (1)

When a determination is made that a person lacks the capacity to make a particular decision—even with the proper supports, compensatory strategies, and facilitation—then a proxy or surrogate decision maker is required (Figure 46.1). The least common, but most straightforward, situation for naming the surrogate is when the patient had previously

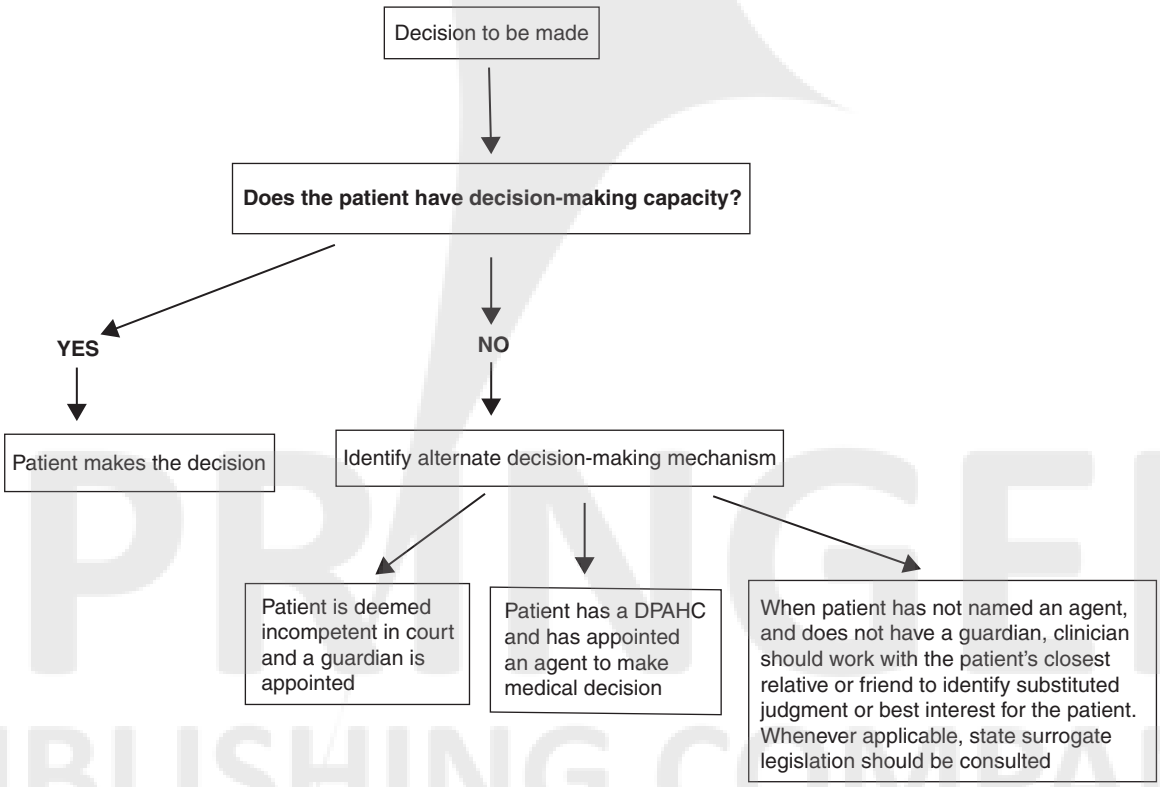

FIGURE 46.1 Who is the decision maker?

Source: Adapted from Ref. (16). Kothari S, Kirschner K. Decision-making capacity after TBI: clinical assessment and ethical implications. In: Zasler ND, Katz DI, Zafonte RD, eds. *Brain Injury Medicine*. New York, NY: Demos Medical Publishing; 2007:1205–1222.

executed an advance directive naming the individual he or she would want to act on his or her behalf in the event of incapacity. At present, it is estimated that only about 18% to 36% (43) of the population have completed advance directives, though this percentage varies widely by geographic region, socioeconomic background, ethnicity, and other factors (43–47).

The Patient Self-Determination Act of 1990 requires that all hospitals and health care facilities query patients upon admission about whether they have an advance directive and, if not, whether they wish to complete one (48).

There are two general types of advance directives: instructional documents such as the living will, and proxy directives such as the durable power of attorney for health care (DPAHC) (9). There are also a growing number of hybrid documents, such as the physicians' orders for life-sustaining treatment paradigm (POLST; www.ohsu.edu/ethics/polst) and Five Wishes (www.agingwithdignity.org/5wishes.html). The level of legal recognition each state gives to these documents varies, and it is therefore imperative to know the law in the state in which you reside.

The living will is the earliest form of an advance directive. It became prominent in the 1970s after the case of Karen Ann Quinlan (49) as a tool for allowing a person to exercise autonomy into states of future incompetence (50). The early living will was typically effective only when a person became terminally ill and unable to make his or her own decisions, and included instructions that allowed the physician to withhold death-delaying treatments. Unfortunately, these documents do not provide guidance for situations in which a person may become temporarily or permanently incapable of making health care decisions, but is not terminally ill, such as in the case of a stroke or brain injury. In general, living wills also do not include provisions for withholding artificial nutrition and hydration. After the case of Nancy Cruzan (51), a woman with a traumatic brain injury in a state of persistent unconsciousness whose father petitioned the courts to allow her feeding tube to be removed, the DPAHC became of greater interest. With a DPAHC, a person can name an individual to speak on his or her behalf (a *proxy*) if he or she becomes temporarily or permanently unable to participate in medical decision making. It is thus a more powerful and flexible document than a living will. Both the living will and DPAHC must be executed while an individual is considered to be competent in order to be legally recognized.

If a person has not completed an advance directive and is not able to make health care decisions, then the health care team must identify a surrogate. As of 2007, 38 states and the District of Columbia have formal state surrogate statutes that provide guidance on naming the appropriate surrogate decision maker (52). Usually, this follows a next-of-kin hierarchy, and the person highest on the list who is available and willing to serve in this capacity is the default legal surrogate. As opposed to the DPAHC, in which proxies can make any health care decision that the patient could (unless the patient restricted the proxy's authority in some way), the state surrogate laws typically establish some limits and restrictions on the types of decisions the surrogate can make, particularly when it comes to withdrawing or withholding life-sustaining treatments. Again, it is best to know the specific standards for the state in which one practices, as these laws vary from state to state (43,52). In the absence of a formal state surrogate law, health care providers will usually ask the next of kin to serve in this capacity. As with any situation, if there is concern about the appropriateness of the surrogate, conflict within the family, or the magnitude and extent of the decisions, the courts can be asked to appoint a guardian.

Some organizations, such as the Gunderson Lutheran Respecting Choices Program (www.gundluth.org/AdvanceCare), have attempted to assist patients and families by training health care professionals to facilitate the difficult conversations involved in making choices for medical treatment. The concept of advance care planning focuses on helping people identify aspects of life that they value most in order to guide a surrogate decision maker in selecting the most respectful choice for the loved one (53).

Whether a proxy is named by a DPAHC or via a state law, the surrogate is first and foremost asked to make the same decision that he or she believes the patient would have if he or she were capable. This principle is known as *substituted judgment* (9). Written directions are one source of information that can be referenced. Conversations and, in some instances, even lifestyle decisions have also been considered (16). In the absence of knowledge of a person's wishes, the surrogate is counseled to make a decision based upon what he or she believes to be in the best interest of the patient (9). This involves weighing the benefits and burdens of a treatment decision in the context of the person's condition. In theory, both substituted judgment and best-interest standards have great appeal, but they can be difficult to implement in practice. There is growing literature that questions whether it is ever really possible to put one's beliefs, values, and needs aside to make decisions on behalf of another (50,54).

Adjustment to Disability and the Concept of Personhood

> [Stroke] is an event that goes to the core of who and what you are, the You-ness of you. First of all, the event happens in your brain which is, without becoming unduly philosophical the command centre of the self. Your brain is you: your moods, your skills, your character, your intelligence, your emotions, your self-expression, your self. (38)

One of the thorniest problems with substituted judgment as a heuristic is the issue of personhood. Simply put, who is the person for whom the decision is being made (16)? The name, social security number, birth date, and even genealogy and personal history as defining characteristics of personhood are clear and unchanging. What is not clear, however, is whether somehow the survivor is literally a changed person

after the stroke, with different personality characteristics, values, interests, and capacities. Grieving the loss of the old self is commonplace after stroke. Grieving occurs not only by the person who experiences the stroke but also by his or her network of close family and friends. How then does a proxy take these issues into consideration when making decisions?

A rich and layered debate on this topic exists without a clear consensus (55–57). That being said, there are some general guidelines that can be offered (50). Patients who have very strong feelings about personhood are more likely to have made an advance directive and put their future care wishes in writing. Indeed, the advance directive is the best way for a person to maintain control of his or her treatment into states of future incompetence and should therefore be taken very seriously. It is also possible that the person may be temporarily incapacitated and, with time, may recover to the point where he or she can resume making personal health care decisions. People who are not fully capable may still be able to indicate wishes and preferences in such a way that their proxies and health care team can use this information to guide decisions. In the end, knowledge that people frequently change their minds when their circumstances change is relevant to decision making, and must be a part of an informed consent discussion about future treatment decisions (50,58).

Balancing the Patient's "Best Interests" in the Context of a Family

> But today we spend the whole of the symbolic day together, affirming that even a rough sketch, a shadow, a tiny fragment of a dad is still a dad. I am torn between joy at seeing them living, moving, laughing, or crying for a few hours, and fear that the sight of all these sufferings—beginning with mine—is not the ideal entertainment for a boy of ten and his 8-year-old sister. (34)

Though substituted judgment and best-interest standards have been extensively discussed in the ethics literature and are widely accepted, these standards are not without controversy. Some ethicists advocate considering the interests of the family, not just the patient, when decisions must be made, particularly when those decisions will have a substantial impact on others. A decision to place a feeding tube in a person with a severe brain injury may have financial repercussions, for example, or create an unspoken expectation that the family will take the person home and provide substantial care, usually without compensation (2,3,59,60). Some studies have found that, even if it is theoretically desirable, it is probably not truly possible to stand in another's shoes and put one's perspectives and wishes aside in making a decision on behalf of another (47,55). Interestingly, despite this observation, studies have also shown that many patients, even when told that their identified surrogate does not understand and make decisions as he or she would want, would still want a family member, rather than a stranger, to make these decisions (61).

In general, despite the limitations of surrogate decision making, the health care team should respect the choices made by a proxy unless there is evidence that the proxy is not acting in the best interest of his or her loved one. Disagreement among members of the patient's family or between the family and the patient's care team can lead to unresolved conflicts and has occasionally led to the need for legal adjudication of these matters (62,63). When reviewing questions regarding a surrogate's ability to authorize removal of life-sustaining treatments, the courts have affirmed that the state can stipulate the level of evidence required to support such decisions as being reflective of the patient's desires/wishes. Many states require the criterion of clear and convincing evidence based on a reasonable person standard. That is, would the evidence convince a reasonable person that the allegation is so? This standard is used in Missouri and other states. However, there has been some movement to accept a less stringent standard—for example, after the Wendland case in California (64).

When Conflicts Occur

Conflicts often arise because of fractured or incomplete communication (61,65). Ethics services in health care institutions promote education related to ethical distress and dilemmas in addition to providing ethics consultation when requested (66). This education gives team members a process and framework for understanding the ethical principles involved, such as autonomy, beneficence, nonmaleficence, justice, and virtue. One important goal for ethics consultation is to assist the team in prioritizing and balancing the principles and values in conflict and, ultimately, to achieve an ethically acceptable outcome in an individual case. Varied methods can be found in the literature (9,10,67,68) (Table 46.2) as well as in approaches developed by individual institutions. The Joint Commission mandates that all accredited hospitals provide a mechanism for resolving ethics conflicts in the medical setting (69).

Caregiver Burdens and Lack of Resources: When Patient and Family Interests Conflict

Very often, when a conflict regarding a medical decision occurs, the parties involved hope to identify the course of action that is ethically correct. In most ethics cases, there is no single right answer. More often, a range of ethically acceptable options can be identified as well as those that might be impermissible. Because the stroke survivor may have a temporary or permanent disability that requires the care of another person, the interests of the patient are frequently intertwined with those of his or her involved family members.

In many ethics cases, clinicians are taught that the interests and wishes of the patient supersede those of family members. Several authors caution, however, that dealing

Ethics: Identify and apply the appropriate ethical principles

Stakeholders: Ensure that all stakeholders are involved in the process

Options: Identifying and implementing the ethically acceptable options

Results: Evaluating the outcome of the ethical analysis and decision for all stakeholders

Miller, Fletcher, and Fins (1997) (69): Clinical Pragmatism

Detailed ethical decision-making model in outline/checklist format that gathers information for a moral diagnosis. Reflective analysis is used to develop approaches for managing similar situations in the future.

Purtilo (2005) (68): Six-Step Process of Ethical Decision Making

1. Getting the story straight: gather relevant information
2. Identify type of ethical problem (e.g., ethical distress, ethical dilemma, question of locus of authority)
3. Use ethics theories or approaches to analyze the problem(s)
4. Explore the practical alternatives
5. Complete the action
6. Evaluate the process and outcome

with the family issues and interests should not be an afterthought (2,3). Instead, clinicians should partner with families to optimize the choices for the patient. Indeed, when patients need care and/or supervision following a stroke, the patient's ability to recover may be directly related with the health of the family system. Family caregivers give assistance to loved ones who are ill or have disabilities. This care would otherwise cost tens to hundreds of thousands of dollars annually if the patient hired a third party to provide it. Some families may not be physically or psychologically equipped to participate in the care of their loved one. Others may lack the financial resources or flexibility to reduce work hours or leave a job to care for a relative/close friend.

Brashler (2) recommends a family-focused team approach to identifying, recognizing, and addressing conflicts between the interests of patients and those of their family members. Central to this approach is the understanding that the recovery and success of a person following stroke may be substantially dependent on the involvement of family members and their willingness to assist the patient, so their interests are inseparable. The key considerations in Brashler's model include bringing all family stakeholders into the discussion, dealing directly and openly with competing interests, and developing shared goals to create a family discharge plan (Table 46.3).

TABLE 46.3 Family-Focused Team Approach

Deal with family conflict and competing interests in the care of a stroke survivor by addressing the following:

1. Recognize all family members with standing
2. Identify family-focused goals
3. Communicate a commitment to the whole family
4. Address competing interests
5. Identify and protect vulnerable family members
6. Construct family discharge plans

Management of Dysphagia: A Predictable Ethical Challenge After Stroke

In the past 8 months I have swallowed nothing save a few drops of lemon-flavored water and a half-teaspoon of yogurt, which gurgled noisily down my windpipe. The feeding test—as they grandly called this banquet—was not a success. But no call for alarm; I haven't starved. By means of a tube threaded into my stomach, two or three bags of a brownish fluid provide my daily caloric needs. For pleasure, I have to turn to the vivid memory of tastes and smells, an inexhaustible reservoir of sensations. Once, I was a master at recycling leftovers. Now I cultivate the art of simmering memories . . . . (34)

Dysphagia is a common consequence of stroke, and may lead to inadequate food and/or liquid intake, or aspiration pneumonia. The use of dysphagia screening as a means of mitigating this risk is recommended or required for stroke specialty care in several countries (70).

Dysphagia is the impairment of one's ability to chew and swallow food and liquid safely and efficiently (taking in enough calories in a given time frame) to sustain life. It is estimated that anywhere from 64% to 78% of all persons surviving stroke develop at least some degree of dysphagia (71,72). The severity of problems following dysphagia can range from a mild condition in which the person requires extra time to complete a meal to very severe, in which an individual cannot manage his or her secretions safely and requires a tracheostomy tube to protect the airway. In cases of severe dysphagia, an alternative method of nutrition and hydration may be recommended and initiated in the acute phase of the illness (73).

Clinicians, patients, and family members may disagree over treatment when severe dysphagia is diagnosed. Clinicians may recommend alternative nutrition and hydration with the goal of avoiding aspiration and its complications while maintaining sustenance. The issue of food and nutrition often raises strong emotions for patients and families. Food has high symbolic value and is not simply a health necessity. It is an issue rooted in social habits and cultural values and patients often associate this with a higher quality of life. Even though various ethical issues arise in the treatment of dysphagia, including questioning the continuation of a life-sustaining treatment, perhaps the most challenging for many clinicians is balancing a patient's desire to eat, regardless of the hazard posed, when the clinical team believes that an alternative feeding approach is lower risk. The conflict between a clinician's sense of beneficence and the patient's preferences or desires frequently causes considerable ethical distress for the clinician.

Beneficence and autonomy are two of the cornerstones of Western bioethics principles. Beauchamp and Childress (9) state that *beneficence* is the obligation of the health care provider to do good for patients, based on what he or she believes to be in the patient's best interest. The principle of *autonomy* is the duty of the health professional to respect, support, and facilitate the patient's ability to make an authentic medical choice without coercion. When clinicians find themselves in a situation where these two principles directly conflict, the ethical distress can be high. Further complicating this issue is the active role that the health care team plays in assisting stroke patients with dysphagia. Thus, a patient who is deemed unsafe to take oral nutrition, but insists on receiving this feeding nonetheless, may require assistance by the nurse or SLP in eating. Health care professionals are trained to make recommendations that promote health. When a patient or a proxy makes a decision that appears to place a person at risk for a poor health outcome, and the health care team's participation is required, some clinicians are inclined to view such a decision as unethical based upon the principle of nonmaleficence—that is, "Do no harm."

Sharp and Genesen (74) describe how a case-based model of clinical ethical analysis can be useful in managing the ethical challenges inherent in such conflicts. Use of this model, based on Jonsen, Siegler, and Winslade (10) (Table 46.2), can assist clinicians and others in identifying ethically acceptable options. The primary challenge is balancing respect for a patient's autonomous wishes related to use of feeding tubes and oral intake after carefully weighing the risks and benefits of eating and drinking when one has dysphagia. As with all other medical decisions, recommendations related to dysphagia should occur in the context of an informed consent and shared decision-making process.

When such values conflicts arise in the clinical care of a patient after stroke, some health care providers wonder if they should continue to be involved in the care of that patient, even if they fundamentally agree with the principle that patients have the right to reject medical recommendations. We believe this consideration is based on two concerns:

1. The treating clinician will be complicit in a "bad decision" that may result in harm to the patient.
2. The clinician may be liable from a legal perspective if the patient experiences a bad outcome.

Clinicians are highly immersed in a medical culture that promotes improving health, and find participation in a treatment plan that may result in "avoidable" medical complications uncomfortable at best. These situations can be very difficult to negotiate. Even though in most scenarios professionals have the right to withdraw from a clinical case where they feel that care is in conflict with their own ethical values (a conscientious objection clause of sorts), it is critical to avoid abandoning the patient in the process. Because we recognize that people have the right to accept our recommendations, they also have the correlate right to refuse them. If a clinical recommendation is rejected, patients still may benefit from clinical interventions to mitigate potential harms. Additionally, patients may refuse recommendations for many reasons (Table 46.4). Without coercing or usurping a patient's right to make his or her own choices, clinicians should investigate the reasons behind a patient's refusal to accept treatment recommendations and to aid him or her in attaining as complete an understanding of the issues as feasible to ensure that this is an informed choice.

The degree of uncertainty regarding the outcome of a particular medical treatment (or foregoing that treatment) may guide the options and decisions made by patients, proxies, and health care providers. When the benefits of a certain treatment outweigh the risks—for example, an otherwise healthy person taking antibiotics for pneumonia—clinicians may try to assure or persuade patients through further education and discussion to accept the recommended treatment. In other cases, such as the treatment of dysphagia, the degree of uncertainty of the likelihood of a poor outcome (e.g., development of aspiration pneumonia) can be quite high (75). The clinical consequences of aspiration or risk of aspiration are not fully understood. In a

TABLE 46.4 Reasons for Patient/Surrogate Refusal of Medical Recommendations

1. Personal values and preferences (may include religious beliefs)
2. Desire to continue current behaviors (e.g., refusal to stop smoking, refusal to change diet). Patient values the behavior above the health-related concern (quality-of-life judgment)
3. Concern that the intervention will be painful or uncomfortable
4. Fear of the potential for negative outcome from the procedure (e.g., mortality risk in some surgeries)
5. Lack of full understanding of the recommendations (e.g., language barrier, belief that the treatment is something other than described, not yet realized lack of DMC)
6. Conflicting recommendations from various health care professionals
7. Cultural differences (e.g., family members helping persons with disabilities instead of facilitating independence in ADL)
8. Negative personal experience (self, family member, or friend) with the recommended treatment plan
9. Lack of understanding of the potential for recovery or possibility of a positive quality of life given the patient's current condition
10. Family conflict
11. Lack of insurance benefit (e.g., personal payment for the treatment would drain personal and family resources)
12. Lack of trust in the clinician or in medical personnel in general
13. Depression or thought disorder

medical record review of nursing home residents, Langmore et al. (75) concluded that, even though dysphagia was a risk factor for the development of aspiration pneumonia, it was not a leading determinant. The fact that an individual was dependent upon another person for feeding or had poor dental and oral hygiene were stronger predictors of the development of aspiration pneumonia.

Time-Limited Trials

Clinical ethicists have promoted the use of a time-limited trial of treatment in order to assist decision making and cooperation in cases of disagreement or uncertainty about the best course of action (76,77). For example, the use of an alternative method of nutrition and hydration is often recommended when a patient experiences moderate or severe dysphagia. The goal of using enteral or parenteral feeding is to reduce the risk of prandial aspiration by bypassing the oral route altogether. It is also to ensure adequate caloric and nutritional intake and hydration to foster recovery and avoid malnourishment. There is growing literature that questions these assumptions for certain patient populations, in particular persons with advanced dementia (78,79). Some studies (80) have found that the risk of aspiration of gastric reflux actually increases when feeding tubes are placed.

In a time-limited trial of treatment, the patient agrees to try a treatment for a limited period of time, followed by a period of reassessment and renegotiation. The patient will then either continue the trial treatment or change course (81). The following clinical vignette illustrates this concept:

> Mrs. E was admitted to a rehabilitation hospital after a pontine stroke. She presented with moderate to severe dysphagia and had a percutaneous endoscopic gastrostomy (PEG) placed in the acute care hospital. Several days after Mrs. E arrived, she told her SLP that she no longer wished to use the feeding tube and she wanted to eat and drink, despite her treatment team's strong recommendation that she continue to rely on tube feedings for the present time. After much discussion, Mrs. E and her team agreed to a time-limited trial of continuation of the PEG feedings and intensive swallowing therapy to target and remediate her difficulties. At the agreed reevaluation point 2 weeks later, the patient's swallowing was much improved. She was able to begin eating pureed solids at that time, consistent with the SLP's recommendations.

Another version of this time-limited trial scenario is as follows:

> Mrs. E was admitted to a rehabilitation hospital after a pontine stroke. She communicated to the staff via a letterboard that she would like to discontinue use of her PEG tube. Despite discussion and further education, the patient was not dissuaded from this decision, even though she was aspirating. Mrs. E agreed to begin eating a diet that had been deemed to be the safest and to use swallowing techniques taught her by her SLP for a period of 2 weeks. After this trial period, the patient had not developed any respiratory complications, and, indeed, her swallowing function had improved. The SLP upgraded her diet further.

Use of time-limited trials can be extremely valuable in many cases by clarifying what the goals and measurable risks are for a particular patient.

Combination Treatment

Another strategy for balancing conflicting values is to combine a therapy that has been recommended by the clinician with a high-priority desire of the patient that also has some risk (81). This vignette provides an example:

> Mr. B was a 46-year-old gentleman who sustained a right hemisphere stroke and now had left-sided paralysis, visual neglect, and severe dysphagia. Although he

demonstrated mild cognitive–communication impairments, he was felt to have adequate DMC regarding his feeding choices. Because of aspiration on all consistencies, Mr. B's physician recommended a feeding tube. After a thorough discussion about the risks, benefits, and alternatives, Mr. B refused. Though he wanted to get better, he placed higher value on eating and drinking orally and accepted the risk of aspiration pneumonia. The SLP considered removing herself from his case because of her discomfort with his decision. After discussing her concerns with the patient's physician and a clinical ethicist in the hospital, she was able to accept his decision as informed and authentic. She chose to stay involved and attempt to mitigate potential harms by educating Mr. B on a diet and techniques that were safest while carefully documenting all discussions and the process of decision making in the case. (Table 46.5)

Using combination therapy allows clinicians to engage in providing patients with needed expertise and care while acknowledging and supporting the person's informed choice to refuse a particular medical treatment.

The use of feeding tubes is perhaps one of the most widely discussed life-sustaining treatments in the field of medical ethics, as evidenced by the controversies surrounding Terry Schiavo (63). Differing conceptual frameworks for the meaning of a feeding tube seem to underlie at least some of the debate (82). A traditional medical ethics perspective is that a feeding tube is a form of medical treatment, similar to a ventilator, and can be withheld or withdrawn as such. A second perspective is that a feeding tube provides basic humane care of food and fluids without which a person cannot survive, so they should always be continued. A third perspective would be that a feeding tube is a disability accommodation. Just as a person uses a wheelchair for a mobility impairment, a person uses a feeding tube for a swallowing impairment. Understanding the perspective of the various parties involved when a discussion arises about withdrawing or withholding food and fluid can help in negotiating difficult conversations (82).

TABLE 46.5 Critical Documentation of the Shared Decision-Making Process

1. The clinical situation and recommendation(s)
2. Whether or not the patient has DMC to participate in the decision
3. If the patient is not the decision maker, indicate who is
4. Report information shared with patient and/or the surrogate
5. The response of the patient or proxy
6. If the response was a rejection of the clinical recommendations, state the reasons given
7. Further information provided to the patient and/or surrogate to address questions or concerns that may have been raised
8. The agreed-upon plan
9. Plan for monitoring the intervention

In general and importantly, documentation should consistently reflect who the decision maker is and that questions about care are appropriately directed to that person.

Decisions to withhold or withdraw a life-sustaining treatment are very emotionally charged because they are in most cases, by definition, final decisions.

Withdrawal or Withholding of Life-Sustaining Treatment

We make a distinction here between withholding and withdrawal of treatment and withholding and withdrawal of care. Medical and basic care is/should always be provided to a patient, but, in all but the most exceptional of circumstances, the withholding and withdrawal of medical treatment is the personal preference of an autonomous patient or his or her surrogate. *Withholding* life-sustaining treatment is a term applied to a situation in which a medical treatment is not initiated. *Withdrawal* of life-sustaining treatment is the discontinuation of a medical treatment after it has been started (9).

Withholding and withdrawing life-sustaining treatment are often within the purview of a proxy decision maker, just as they are for a patient (50,83), though the circumstances may be limited by a patient's advance directive or state law. Based on the presumed right to privacy, that is, to be free of unwanted medical treatment, case law in the United States recognizes this personal choice as a defensible construct (49). Ethical study also supports this as a correlate for the respect for patient autonomy. Both legal and ethical frameworks hold that there is no moral difference between withdrawing or withholding life-sustaining treatments (84,85), though clinicians do not always agree. Within the context of a clinical case, some clinicians feel that withdrawing life-sustaining medical treatment feels psychologically as if they have a direct responsibility for the patient's death (84,86).

Therapies and Technologies: Evidence and Resource Allocation

The economic climate is continually changing in the field of health care and unfortunately often results in reduced reimbursement for rehabilitation services. Health care teams face the dilemma of creating treatment plans that maximize effectiveness and can be implemented in a constrained time frame (87). Complicating these situations is an increasing number of new, expensive, and unproven technologies developed to help enhance function after stroke. Where research does exist on some interventions, the protocols may not have included significant number of participants with stroke. Patients and families may ask for or insist on receiving the newest technologies and therapy methods. Clinicians may then face dilemmas of determining the most appropriate treatment for the patient while considering the request (or demand) and any resource restrictions that may exist.

Consider Ms. K and Mr. G:

Ms. K recently had her second stroke which resulted in severe dysphagia requiring the placement of a PEG tube. After discharge from the hospital, Ms. K began therapy at an outpatient center. Her insurance company

allows only 10 speech therapy visits per year. Ms. K read an advertisement for electrical stimulation of the swallow musculature and is eager to try it during her SLP sessions. The patient's therapist is concerned that devoting all Ms. K's sessions to this intervention will limit her progress and that there are other impairments that require attention. Additionally, the SLP knows that evidence for the effectiveness of electrical stimulation for swallowing after stroke is inconclusive.

The SLP shares this information with and discusses her thoughts with Ms. K and together they develop a treatment plan in which all Ms. K's therapy goals are addressed.

Mr. G is a 63-year-old gentleman who survived a right hemisphere stroke. He participated in inpatient rehabilitation and has been discharged home with 2 caregivers who assist him 24 hours daily for safety and mobility. Mr. G has dense left hemiplegia and left inattention. Mr. G has personal wealth and is a celebrity in the community. While an inpatient, Mr. G completed a trial treatment on the hospital's robotic body-weight-assisted ambulation device. He feels he made improvement after using this device; however, he has not shown any functional increase in his ability to walk.

Mr. G tells his outpatient physical therapist (PT) that he would like to supplement his regular treatment sessions with use of the hospital's robotic ambulation device three times per week. The PT tells Mr. G that she does not recommend this treatment now. Mr. G tells the PT that he understands that using the device may not yet result in functional change, but that he knows it is helping him and he wants to have the feeling of walking again. Mr. G talks to the outpatient supervisor about paying privately for the use of this technology. The PT and her supervisor are concerned—they do not want Mr. G to waste his money on a treatment that may not be clinically beneficial; they do not want to schedule Mr. G to use the device when there are other patients who could benefit from the treatment and may need the appointment slot; they do not want to jeopardize a positive relationship with a prominent person; and they also do not want to diminish Mr. G's motivation by limiting an activity he takes such pleasure in.

Mr. G's therapist consults with colleagues and proposes trial use of a standing wheelchair. With assistance, this device allows Mr. G to rise to a standing position to participate in many daily functional and leisure activities. The PT promised to continue to monitor Mr. G's progress for clinical indications that an additional trial of the robotic ambulation device might be warranted.

Team Conflicts: Goals of Rehabilitation

The biggest lesson I learned that morning was that when it came to my rehabilitation, I was ultimately the one in control of the success or failure of those caring for me. It was my decision to show up or not. I chose to show up for those professionals who brought me energy by connecting with me, touching me gently and appropriately, making direct eye contact with me, and speaking to me calmly. I responded positively to positive treatment. The professionals who did not connect with me sapped my energy, so I protected myself by ignoring their requests. (1)

The literature has suggested that team-based care, as is the model for rehabilitation, may inherently predispose individuals to conflict (65,66,88). As previously stated, conflicts often arise when a clinician's professional recommendation is at odds with a patient's choice. Sharp (88) delineates an often-experienced process of individuals coming together to form a team. She indicates that the way people come together and begin to make joint decisions may not be smooth. Often, groups test each other before they trust the judgment and recommendations of other group members. Teams then ideally reach a place where they can challenge one another safely and reach consensus for the best approach to a particular patient. Dowdy and his colleagues (89) demonstrated that challenging issues are predictable in certain clinical contexts and that use of a preemptive ethical consultation aided team members in feeling that they were each involved in the process of decision making. Bringing clinical teams, patients, and families together to discuss problems and issues is often a very effective means of navigating and resolving conflict (65,66,90,91).

The patient and family (2) are part of this team as well. They face adjustment challenges to team interaction and communication similar to those faced by clinicians. However, at the end of the day, the patient and, in many cases, the family have the most at stake in any scenario. Having direct conversations with patients to learn and focus on their specific goals can aid interdisciplinary teams in avoiding unnecessary discord and in allowing patients' wishes to direct the plan of care to the greatest degree possible.

SUMMARY

I think that one of the problems with stroke is that, as a condition, it offers a moving target. Compared to, say, cancer, stroke is not a degenerative condition. If you survive the initial crisis you are—with luck—constantly and imperceptibly getting better. I had to learn to adjust, and also to wait. (38)

Ethical issues are common in the clinical care of persons who survive a stroke, in part because different individuals in an interdisciplinary team, including patients and families, can experience conflicting values; and in part because the experience and sequelae of stroke may change a person's abilities and concept of himself or herself. This shift in perspective

that stroke survivors commonly experience may require a period of reflection and redefinition for the stroke survivor to clarify his or her new vantage point. Stroke can result in cognitive and communication impairments that affect a survivor's ability to participate in both the routine and the complex decisions about medical care faced in the first hours, days, and even years following the event. Additionally, some potentially life-threatening medical conditions, such as dysphagia, require balanced consideration of the risks and benefits of common and sometimes invasive interventions.

This chapter has presented an overview of the kinds of ethical issues faced by health care providers, patients, and families in the care of stroke survivors. Understanding and use of ethical paradigms and principles will guide clinicians and clinical teams in identifying ethically acceptable options in difficult circumstances. Keeping the wishes of the patient paramount and supporting participation of patients who demonstrate significant communication impairment are critical in reaching optimal outcomes.

Illness can create defining moments in one's life. Clinicians have a role in fostering and facilitating self-actualized choices for the stroke survivor. In the face of great change (either temporary or lasting), patients can still maintain dignity and self-fulfillment with a considered and ethical approach to patient interaction and care.

As Marc Black Sings in "When You Get Back," ". . . you never get back to where you've been, always get back to where you're going on down the line" (92).

Stroke and the Family

Tamilyn Bakas and Lisa Scarton

Families are an integral part of stroke recovery and rehabilitation. A family caregiver can be a relative, partner, personal friend, or neighbor who provides assistance to an older person or adult with a chronic or disabling condition (1). Roughly 68% to 74% of stroke survivors are discharged home under the care of family members (2,3). Stroke is different from other chronic conditions in that stroke caregivers must suddenly assume the caregiving role after a stroke event, whereas, for example, dementia caregivers typically assume the caregiving role gradually over time (4). Family caregivers must quickly learn how to help stroke survivors live with a variety of stroke-related impairments (i.e., motor, sensory, visual, language, cognitive, and affective impairments) (5,6) while also trying to adapt to the changes in their own lives that have resulted from providing care (7–11). Studies have shown that family caregivers are at risk for depression, psychosocial impairments, and mortality as a result of providing care (12–14). To make matters worse, family caregivers of stroke survivors are commonly neglected by health care providers in the practice setting (7,13). In a study of 116 stroke caregivers, 11.7% reported that communication with health professionals was very or extremely difficult (15). Stroke affects the entire family, not just the stroke survivor and his or her caregiver. The survivor's children, siblings, parents, extended family, and friends are also affected. The purpose of this chapter is to provide a general overview of the impact of stroke on the family and to explore existing literature regarding stroke caregiver interventions, which are designed to support families of stroke survivors through recovery and rehabilitation.

IMPACT OF STROKE ON FAMILY MEMBERS

Family caregivers have a variety of needs and concerns related to stroke care and also experience negative outcomes such as depression, declining health, and other life changes such as social and financial problems. Other family members may experience conflict, psychological distress, and other negative outcomes. The literature regarding these topics is reviewed in the following sections.

Caregiver Needs and Concerns

The assessment of caregiver needs and concerns from the caregivers' perspective and culture is important across inpatient, outpatient, and community-based settings (1,7,16–20). The caregiver needs and concerns checklist (CNCC) is one instrument with which health care providers can assess caregivers in the context of stroke care (Figure 47.1) (7). The CNCC, originally developed based on qualitative comments from stroke caregivers, addresses five main areas of needs and concerns:

1. Information
2. Emotions and behaviors
3. Physical care
4. Instrumental care
5. Personal responses to caregiving

Information

Finding information about stroke is especially important for families because spouses and other family members are commonly the initiators of emergency care for stroke survivors (21). Of the estimated 700,000 strokes that occur each year in the United States, 200,000 are recurrent strokes (5). Moreover, 14% of persons experiencing a stroke or a transient ischemic attack (TIA) for the first time will have a reoccurrence within 1 year (5). Family caregivers of stroke survivors have expressed concerns about whether they would be able to recognize a second stroke, and they want more information from health professionals about stroke warning signs (7,22). For example, one caregiver reported that she thought her father was drunk when he was actually suffering a stroke. She was concerned that she might not be able to recognize signs of another stroke (7). Stroke warning signs can be difficult to distinguish from other conditions, particularly when a stroke survivor already has some residual deficits from the initial stroke. It is imperative that health professionals assess and reinforce knowledge of stroke warning signs in both patients and caregivers during follow-up visits.

Stroke caregivers also have needs and concerns about recommended lifestyle changes and risk factors for recurrent stroke. One caregiver reported that she had only received

Information: At this time, I would like more infomation about . . .
(Check all that apply.)
- ☐ the warning signs of another stroke.
- ☐ recommended lifestyle changes after stroke (e.g., eating a healthy diet, being physically active, stopping smoking, getting regular checkups).
- ☐ risk factors for stroke (e.g., controlling high blood pressure, diabetes).
- ☐ the stroke survivor's medications (e.g., drug name, what it's for, dosage, possible side effects).
- ☐ the stroke survivor's condition or what to expect before going home.
- ☐ how to manage specific problems the stroke survivor may have (e.g., constipation, bowel or bladder incontinence, dizziness, fatigue, pain).
- ☐ which health professionals to call for advice (e.g., doctor, nurse, physical therapist, occupational therapist, speech therapist, social worker).
- ☐ where to find books or written materials, support groups, or organizations that can help.
- ☐ where I can go for my health care needs.

Emotions and behaviors: At this time, I need help . . .
(Check all that apply.)
- ☐ dealing with the stroke survivor's emotions (e.g., mood fluctuations, anxiety, nervousness, anger, depression, poor future outlook).
- ☐ dealing with the stroke survivor's feelings about himself or herself (e.g., feelings of dependency, feelings of being a burden on others, worthlessness).
- ☐ keeping the stroke survivor socially active (e.g., keeping in touch with friends, holding an interest in others, finding someone to talk to who's had a stroke).
- ☐ communicating with the stroke survivor (e.g., trying to understand him or her, getting him or her to understand me, using the telephone, dealing with the frustration of communication).
- ☐ dealing with the stroke survivor's changed personality from the stroke.
- ☐ dealing with the stroke survivor's problems with thinking (e.g., loses or forgets things, has poor judgment, can't make decisions, confusion).
- ☐ dealing with the stroke survivor's difficult behaviors (e.g., cries easily, acts childlike, loses temper, uses foul language, waits for others to do things, doesn't appreciate caregiver).

Physical care: At this time, I need help . . .
(Check all that apply.)
- ☐ getting the stroke survivor to take medications on time.
- ☐ getting the stroke survivor to do prescribed exercises.
- ☐ learning how to help the stroke survivor walk, transfer to a wheelchair, move about, or avoid falls.
- ☐ getting the stroke survivor to eat (e.g., forgets to eat, refuses to eat, or has trouble swallowing).
- ☐ assising the stroke survivor with bathing, dressing, or going to the bathroom.

Instrumental care: At this time, I need help . . .
(Check all that apply.)
- ☐ learning how to manage checkbooks, bills, forms, or finances related to the stroke survivor's health care.
- ☐ trying to cover the cost of the stroke survivor's health care (e.g., medications, glasses, adult day care, therapy, services).
- ☐ transporting the stroke survivors places, going public with the wheelchair, or driving.
- ☐ finding care for the stroke survivor while I am away.

Personal responses to caregiving: At this time, I need help . . .
(Check all that apply.)
- ☐ dealing with my own emotions while providing care (e.g., mood fluctuations, anxiety, nervousness, anger, depression, poor future outlook, feelings of loss).
- ☐ with new responsibilities that I am not used to (e.g., taking on unfamiliar household tasks or things the stroke survivor used to do).
- ☐ finding the best way to ask family and friends for help with the stroke survivor's care.
- ☐ dealing with other things in my life (e.g., balancing work with caregiving, caring for other family members).
- ☐ taking care of my own health.
- ☐ keeping my energy level up.
- ☐ keeping my own social life going (e.g., getting out with friends and family, attending church, having free time for myself).

FIGURE 47.1 Caregiver needs and concerns checklist.

Source: From Ref. (7). Bakas T, Austin JK, Okonkwo KF, et al. Needs, concerns, strategies, and advice of stroke caregivers the first six months after discharge. *J Neurosci Nurs.* 2002;34(5):245. Copyright 2002 by American Association of Neuroscience Nurses. Reprinted with permission.

information about her husband's diet and speech therapy and commented that, if he had had a heart attack, she would have received more information on smoking, exercise, and other lifestyle changes (7). Another study reported that only 40% of stroke caregivers remembered receiving any information about stroke prevention (16). Providing information for stroke survivors and families regarding lifestyle changes and risk factors for recurrent stroke is critical for secondary stroke prevention. Current guidelines recommend management of hypertension, diabetes, and cholesterol in stroke survivors, along with counseling to avoid smoking, heavy alcohol consumption, and obesity (17–20,23). Stroke survivors should also undergo a supervised therapeutic exercise regimen that includes a pre-exercise evaluation (17–20,23,24).

Family caregivers need information about these recommendations so they can encourage and reinforce prescribed healthy behaviors and lifestyle changes throughout stroke recovery and rehabilitation.

Additional areas of stroke caregiver informational needs and concerns relate to:

- Medication management
- The survivor's condition and treatment plans
- Management of specific symptoms or problems that the survivor may have (for example, constipation, bowel or bladder incontinence, dizziness, fatigue, and pain)
- Which health professionals to call for advice
- Where to find books or written materials, support groups, or organizations that can help (7,17–20)

Stroke organizations, such as the American Stroke Association (www.strokeassociation.org; 1-888-478-7653), the National Stroke Association (www.stroke.org; 1-800-787-6537), or the National Institute for Neurological Disorders and Stroke (http://www.ninds.nih.gov/disorders/stroke/stroke.htm; 1-800-352-9424), can be valuable resources for stroke survivors and their families. They offer written information on a variety of stroke-related topics, monthly magazine subscriptions addressing the latest issues in stroke care, websites for stroke survivors and caregivers, and lists of stroke support groups for specific geographical areas. Informational needs may not be the same for each caregiver, so individualization is often indicated. This can be challenging given the limited time that health professionals usually have with family members. In fact, caregivers often report that health professionals ignore them (7,13). Nevertheless, caregivers recommend trying to get as much information as possible before the survivor is discharged home; asking for names of health professionals they can call for advice; attending therapy sessions; talking with other stroke survivors and caregivers; and looking for books or written materials, stroke support groups, home health care, financial counseling, and other resources that may assist them in providing care (7,16–20).

Emotions and Behaviors

Managing emotional and behavioral reactions of the stroke survivor are among the most stressful aspects of providing care for family caregivers (5,10,15,16,19,25–30). Gonzalez and Bakas (30) found that male stroke survivors exhibited significantly more bothersome behaviors as identified by their family caregivers. This finding could be attributed to female caregivers being more likely to provide care for more impaired male family members (31). After controlling for survivor gender, 35% of difficult or bothersome behaviors were explained by the family caregiver's depressive symptoms, task difficulty, life changes, and threat appraisal (30). Some studies have also described caregiver unawareness that difficult behaviors might be stroke related and therefore responded with either anger or excessive sympathy (32,33). Emotional and behavioral problems experienced by stroke survivors that caregivers typically face include depressive symptoms and other emotional reactions to stroke, changed personality or cognitive impairment resulting in disruptive behaviors, and communication deficits, including aphasia.

Studies have documented that approximately one-third of ischemic stroke survivors suffer from poststroke depression, a condition that is often misdiagnosed, undertreated, and associated with poor outcomes and increased mortality (34–37). Dealing with poststroke depression is a primary concern for family caregivers, particularly because, although physical deficits are usually recognized in the hospital environment, cognitive behavioral deficits may not become apparent until after discharge (4). Clark and colleagues (26) reported that 74% of their sample of 130 stroke caregivers indicated that their survivor appeared sad or depressed, and this was the most frequent memory or behavior change found in their study. Pierce and Steiner (38) reported in their qualitative study that male caregivers were most concerned about how to deal with their wives' depression and irritability. Although screening for depressive symptoms in stroke survivors using the PHQ-9 Depression Severity Scale is gaining attention in the literature (19,39), information provided to stroke caregivers on how to screen and seek treatment for poststroke depressive symptoms is lacking (19). Caregiver communication with health care providers regarding survivor depressive symptoms can be challenging at times. For example, one caregiver reported that during a clinic visit she tried to inform the physician about her spouse's feelings of worthlessness and negative attitudes, but the survivor displayed a more positive attitude in the presence of doctors, making assessment and treatment for the depression difficult (7).

Additional survivor emotions and behaviors that are troublesome for stroke caregivers to manage include such things as (7,10,15,26,28,29,33,38,40,41):

- Feelings of worthlessness or being a burden on others
- Moodiness or irritability
- Anger, frustration, loss of temper, or negative interpersonal exchanges
- Cognitive difficulties, memory loss, or confusion
- Personality changes or emotional dependency
- Indifference or inertia
- Waiting for others to do things the survivor can do
- Lack of participation in social activities
- Communication difficulties

Providing care to a stroke survivor who has aphasia has been associated with more negative caregiver outcomes and difficulties with tasks compared with caregivers of nonaphasic stroke survivors (10). In a sample of 42 family caregivers of aphasic stroke survivors, communication with the survivor, closely followed by managing behaviors, were rated as the most difficult tasks caregivers faced (10). The challenges that caregivers have in communicating with aphasic survivors have been found in other studies as well (42,43). Helping aphasic survivors and their family caregivers develop effective communication techniques prior to discharge and across the care continuum is strongly recommended by current patient care guidelines (19,20). One stroke caregiver intervention

found in the literature focused on improving communication in the context of aphasia (44). Caregivers receiving the intervention had significant reductions in stress; however, these results were not maintained at three-month follow-up (44). There were no significant effects on communication skills or burden.

Unfortunately, no reported stroke caregiver intervention studies have specifically addressed how to help caregivers manage the emotional and behavioral reactions displayed by stroke survivors, other than the Telephone Assessment and Skill-Building Kit (TASK) (45,46). Stroke caregivers in the TASK program, who identify managing emotions and behaviors as a priority need, are trained how to assess the survivor for depressive symptoms and how to intervene using skill-building strategies that focus on stress management, problem solving, and communicating with health professionals (45). Not all caregivers have to deal with the same types of survivor emotions and behaviors; therefore, there is no one-size-fits-all solution to this problem. Nevertheless, supporting caregivers in their role of managing these difficult emotions and behaviors is paramount. Including the family caregiver in the assessment of stroke survivor depressive symptoms and other emotions and behaviors is a starting point where health professionals may begin to quickly identify areas for treatment or referral (17–20). Simply asking family caregivers about the emotions and behaviors they are dealing with and how they are communicating with the survivor may uncover serious barriers to stroke recovery and rehabilitation that may be amenable to treatment or psychological counseling for the survivor and his or her caregiver.

Physical Care

Physical care provided by stroke caregivers may include such things as assisting the survivor with bathing, toileting, getting dressed, walking, mobility, exercises, meals, managing symptoms and deficits, and medication management. Studies have shown that caregivers do have concerns about managing stroke-related symptoms and deficits as well as providing basic stroke care (7,15,17–20,29). Although the provision of personal care (i.e., bathing, toileting, getting dressed, and feeding) and assisting with mobility and exercises were not among the most difficult tasks on average in a sample of 116 stroke caregivers, 9.1% found personal care to be very or extremely difficult, and 14.3% found assisting with mobility to be very or extremely difficult (15). In a qualitative study of 14 stroke caregivers within 6 months after discharge, getting survivors to take their medications and exercise were major concerns, as were getting survivors to eat; assisting with bathing, dressing, or toileting; and avoiding falls (7). Caregivers suggested such things as using pill boxes for medications, taking the survivor to the mall for exercise, avoiding clutter to prevent falls, taking advantage of resources like Meals on Wheels, following a bladder and bowel regimen, and encouraging the survivor to do as much self-care as possible (7). Health professionals are encouraged to assist caregivers in providing personal care by encouraging them to attend therapy sessions with the survivor to learn transfer techniques and how to assist with activities of daily living (19,20). Medication instruction for stroke survivors should also include the family caregiver, especially if the stroke survivor has trouble reading or has poor sensory perception or cognitive deficits (47). Health professionals should encourage caregivers to ask questions about the survivor's medications, symptoms, and other stroke-related care issues (17–20,47).

Instrumental Care

Instrumental care provided by stroke caregivers include such things as dealing with financial issues, providing transportation, assisting with household tasks (i.e., laundry, cooking, cleaning, yard work, and home repairs), shopping, running errands, managing services and resources, as well as finding someone to care for the survivor while away. In one study of 116 stroke caregivers, household tasks and managing finances were among the top four most difficult tasks, with approximately 17% to 18% finding these activities to be very or extremely difficult (15). Providing transportation (14.2%), finding respite care while away (15.3%), and finding resources (9.1%) were rated as very or extremely difficult as well (15). In another study, six caregivers shared their concerns regarding finances, with one caregiver fearing she would run out of money, which would result in institutionalization of the stroke survivor. Financial management was also a concern for caregivers in another study across all time periods up to two years after stroke (16). These are only a few examples of the needs and concerns that family caregivers have in providing instrumental care. Referral of stroke caregivers to a social worker to assist them in dealing with financial problems and finding appropriate community resources are clearly areas where health professionals may better serve families of stroke survivors (17–20).

Personal Responses to Caregiving

Caregivers will often share their needs and concerns about their stroke survivors before they will share their own personal needs and concerns (7). However, in one qualitative study, caregivers reported needs and concerns about their own emotions while providing care, shouldering new responsibilities, balancing caregiving with existing responsibilities (i.e., employment and care of other family members), asking friends and family members for help, keeping their own social life going, as well as keeping their energy level up and taking care of their own health (7). It was evident from the findings of this study that caregivers experienced great stress while providing care (7). One caregiver stated she would cry late at night at home, but would try to hold up for her sister. Another caregiver mentioned how she and the survivor used to have frequent gatherings and cookouts, but that had stopped since the stroke. Another caregiver was assertive enough to ask the doctor why everyone always asked how her husband was doing, but never asked her how she was doing. This caregiver felt neglected by the health professionals involved in her husband's care and was reaching out for help. In a similar study (16), a wife indicated she wanted more attention from health professionals and they did not have anything for caregivers. In a more recent

intervention study, a caregiver stated, "I was a superwoman and I was going to do it even if it killed me . . . and it almost killed me . . . What I like about it is that you not only deal with the issues of the person with stroke, but you also deal with the health issues and things of the caregiver" (45, p. 372). The most difficult times for caregivers have been reported to occur during hospitalization and the first few months after the patient is discharged home, which underscores the need for early caregiver assessment followed by individualized caregiver interventions during these critical time periods following stroke (16,45). The next section provides a review of literature about negative caregiver outcomes, including depression, poor health, decreased social functioning, and other negative outcomes of providing care.

Caregiver Outcomes

Caregiver Depression

Studies have explored caregiver psychological distress and depression as well as the many factors associated with these outcomes. Estimates of the prevalence of depression in stroke caregivers have ranged between 30% and 52% (12,40,48), with poorest mental health when the stroke survivors were discharged home early (49). In fact, some studies have reported higher depression rates in caregivers than in the stroke survivors for whom they provided care (48,50). The treatment of stroke caregiver depression is important because caregiver stress has been found to be a leading cause of long-term institutionalization of stroke survivors (12). In one landmark prospective study, family caregivers experiencing strain had a 63% higher risk of mortality compared with noncaregiving controls (14).

Factors directly associated with caregiver psychological distress and depression have included:

- Difficulty with caregiving tasks (15,51)
- Burden (52)
- Lack of social support (50,52,53)
- Poorer family functioning (50)
- Concern for future care (54,55)
- Negative caregiver appraisal of the situation (51,56)
- Lower life satisfaction (53)
- Self-losses (53)

Positive factors that tend to be associated with lower caregiver depression and psychological distress include:

- Hope and meaningfulness (57)
- Optimism (54,55)
- Self-esteem (51,58)
- Resiliency (56)

Survivor characteristics such as stroke severity, physical impairment, depression, and negative personality characteristics have also been associated with caregiver depression (48,53,54,57,59,60). Other studies, interestingly, have found that physical disability of the stroke survivor is often unrelated to caregiver depression (12,13). Some studies have shown that Caucasian caregivers, as opposed to African American caregivers, and those providing care for older stroke survivors were at greater risk for developing depression (48,52). Pinquart and Sorensen (61) conducted a meta-analysis of 228 caregiver studies involving informal caregivers of older adults. They found that care recipient behaviors were more strongly associated with caregiver burden and depression than care recipient physical limitations or cognitive status. Perceived benefits of caregiving, such as feeling useful or feeling closeness with the care recipient, were associated with decreased burden and depression in caregivers. Pinquart and Sorensen (61) recommended that caregiver interventions be focused on reducing care recipient problem behaviors, improving caregiver skills in the management of problem behaviors, and promoting positive perceptions of providing care. Screening for depressive symptoms in stroke survivors using the PHQ-9 Depression Severity Scale has been recommended (19,39); however, the use of the PHQ-9 to screen for depression in stroke caregivers might also help to identify caregivers in need of antidepressant therapy or counseling (10,19).

Caregiver Health

The research agenda for stroke caregiving must move beyond psychological distress and depression to explore the general health of family caregivers (12,13,19). Researchers have noted that attention to the health status and health promotion activities of family caregivers is lacking in both descriptive and intervention studies (62,63). More studies are needed to determine predictors of health outcomes. For example, Bakas and Burgener (51) found that low household income and appraisals of threat were significant predictors of self-perceptions of poorer general health in stroke caregivers. Tooth and colleagues (64) found that only patient characteristics, such as cognitive function and mental health and caregiver employment, were predictive of caregiver SF-36 mental and physical component scores. Many studies have used global health measures in stroke caregivers, such as the SF-36 Health Survey. Some reported scores close to published general population norms (49,65,66), whereas others reported lower scores (64,67,68). Bakas and Champion (8) found that, although stroke caregiver SF-36 general health scores were close to published norms, caregivers perceived that their physical health had changed for the worse as a result of providing care. Other studies have also found that stroke caregiver perceptions of their own health worsen as a result of providing care (58,69). Although more research is needed to identify key indicators of stroke caregiver health, clinicians are urged to ask caregivers about their health, encourage them to seek regular checkups, and practice health promotion activities while providing care (19).

Other Caregiver Outcomes

Quality of life issues associated with providing care other than depression, psychological distress, and health deserve more attention in research studies (13,70). White and colleagues (70) described the lack of clarity regarding the term

quality of life in a review of stroke caregiver literature and asserted that quality of life involved not only health, but such things as participation in social and recreational activities, leisure, social relationships, family life, sexual life, ability to manage self-care, vocation, finances, and satisfaction with life as a whole. In an earlier review of the stroke caregiver literature, Low and colleagues (13) found that only 2 out of 31 studies had focused on the social health of stroke caregivers (40,71), noting that, although social measures were most often used as variables associated with depression or psychological distress, they were rarely explored as outcomes (13).

Bakas and colleagues (8,9) noted that, although a number of generic quality-of-life measures were used in stroke caregivers, there was a need for an instrument that measured changes in caregivers' lives, specifically as a result of providing care. Based on Lazarus and colleagues' (72,74) definition of adaptational outcomes, the Bakas Caregiving Outcomes Scale (BCOS) was developed to measure changes in social functioning, subjective well-being, and health, specifically as a result of providing care (Figure 47.2) (8,9). Extensive psychometric testing of the BCOS has found acceptable evidence for its reliability and validity in stroke caregivers (8,9). Two comprehensive reviews of caregiver measures have recommended the BCOS because of its extensive psychometric testing compared with other measures (75) and because it had the highest rate of agreement among the authors for seven different factors considered to be important for stroke caregivers (76). The BCOS has also been used to describe the impact of stroke caregiving in a population-based study in Auckland, New Zealand (77). The most current 15-item BCOS (9) consists of a comprehensive list of caregiver life changes rated on a scale from –3 (changed for the worst) to +3 (changed for the best), with 0 meaning no change. Life changes relate to such things as time for social and family activities, relationships with family and friends, relationship with the stroke survivor, roles in life, financial well-being, emotional well-being, ability to cope with stress, self-esteem, future outlook, level of energy, physical functioning, and general health. Unlike many other measures, an added benefit for the BCOS is the fact that it allows caregivers to rate these life changes as either negative or positive

This group of questions is about the possible changes in your life from providing care for the stroke survivor. For each possible change listed, circle one number indicating the degree of change. The numbers indicating the degree of change range from **–3 "Changed for the Worst"** to **+3 "Changed for the Best."** The number **0 means "Did Not Change."**

	Changed for the Worst			Did Not Change		Changed for the Best	
As a result of providing care for the stroke survivor:							
1. My self-esteem	–3	–2	–1	0	+1	+2	+3
2. My physical health	–3	–2	–1	0	+1	+2	+3
3. My time for family activities	–3	–2	–1	0	+1	+2	+3
4. My ability to cope with stress	–3	–2	–1	0	+1	+2	+3
5. My relationship with friends	–3	–2	–1	0	+1	+2	+3
6. My future outlook	–3	–2	–1	0	+1	+2	+3
7. My level of energy	–3	–2	–1	0	+1	+2	+3
8. My emotional well-being	–3	–2	–1	0	+1	+2	+3
9. My roles in life	–3	–2	–1	0	+1	+2	+3
10. My time for social activities with friends	–3	–2	–1	0	+1	+2	+3
11. My relationship with my family	–3	–2	–1	0	+1	+2	+3
12. My financial well-being	–3	–2	–1	0	+1	+2	+3
13. My relationship with the stroke survivor	–3	–2	–1	0	+1	+2	+3
14. My physical functioning	–3	–2	–1	0	+1	+2	+3
15. My general health	–3	–2	–1	0	+1	+2	+3
16. In general, how has your life changed as a result of taking care of the stroke survivor?	–3	–2	–1	0	+1	+2	+3
If there are any other changes in your life as a result of providing care for the stroke survivor, please write them below and rate them accordingly.							
17.	–3	–2	–1	0	+1	+2	+3
18.	–3	–2	–1	0	+1	+2	+3
19.	–3	–2	–1	0	+1	+2	+3

FIGURE 47.2 Bakas Caregiving Outcomes Scale (BCOS).

or having no change at all. Stroke caregiver studies using the BCOS have shown that the worst life changes were caregivers' time for family and social activities, relationship with friends, financial well-being, emotional well-being, level of energy, and physical health. Areas that changed for the better on average were relationship with the stroke survivor and self-esteem (8,9). Factors found to be associated with total BCOS scores have included threat appraisal (8,9,51), difficulty with tasks (8,9,15), emotional distress (8,51), or depressive symptoms (9,10). The BCOS has been shown to be a valuable measure in stroke caregiver research (8–10,75,76) and might also serve as an assessment tool to determine deteriorating aspects of caregivers' lives so that individualized interventions or referrals can be made (8–10).

Impact of Stroke on Other Family Members

Although literature regarding the effect of stroke on family caregivers has grown substantially in recent years, very little research has focused on the effects of stroke on other family members such as minor children, spouses of adult child caregivers, siblings, and other relatives who may be involved in the care of stroke survivors (78). Even rarer are studies that document the effect of stroke on parents, most likely because pediatric stroke is an infrequent occurrence (17,18,79). Nevertheless, family caregiver education across the continuum of care is important in the context of both adult and pediatric stroke (17,18). Two studies have focused on the effect of a parent's stroke on minor children (80,81). Visser-Meiley and colleagues (81) interviewed 82 children (ages 4–18; average of 13 years) of 55 parents who had suffered a stroke and were admitted to a rehabilitation center in the Netherlands. Shortly after admission, 54% of the children showed at least one behavioral problem or depression; 21% of those scored in the clinical range. Although these behavior problems and depression significantly improved by two months after discharge ($P < .001$), trends for increasing internalizing behavior problems and decreasing health status in the children were noted between two months and one year after their parent's discharge. Significant predictors of child depression scores at one year were the child's baseline depression scores, child's gender, and physical functioning of the parent at admission. Significant predictors of child's health status at one year were baseline health status, spouse depression, and spouse perception of marital relationship at the time of admission. These findings underscore the need to screen for children's functioning, spouse depression, and the quality of the marital relationship during rehabilitation for a more family-centered approach to care (81). Lackey and Gates (80) conducted a retrospective study of 51 adults who had been 3 to 19 years old at the time of their parent's stroke or diagnosis of other types of chronic conditions such as cancer, cardiovascular disease, amyotrophic lateral sclerosis, respiratory disease, diabetes, or arthritis. Providing personal care was most difficult. Household tasks were most time-consuming, and family life, school, and time with friends were most negatively affected by the caregiving situation.

Palmer and Glass (78) urged researchers and clinicians to consider the entire family system, not just stroke survivor–caregiver dyads, in trying to understand the ripple effect of stroke on families. Family roles, responsibilities, and patterns of emotional support and communication must be reconfigured to accommodate the recovery process for stroke survivors. This reconfiguration can pose challenges to pre-existing family relationships as well as family functioning in general (78). Current research is limited in studying family systems in the context of stroke, largely because of inadequate measures and the complexity of developing and studying family intervention methods. The limited research that exists provides some evidence that family functioning is associated with discharge disposition, treatment adherence, rehospitalization, and poststroke depression (78). Although stroke caregiver intervention research is on the rise, very few studies have focused on psychosocial interventions for whole-family systems (78). The next section provides a review of existing stroke caregiver intervention research, followed by a section on recommendations for future research and practice that urges researchers and clinicians to consider a family systems approach to care.

STROKE CAREGIVER INTERVENTION RESEARCH

According to current stroke rehabilitation clinical practice guidelines (17–20,82), health care providers should involve family caregivers in decision making and treatment planning for survivors, be alert to the stress and support needs of caregivers, and provide information on community resources and services, as well as provide patient and family caregiver education about stroke and potential complications. Despite these recommendations, research has not produced sufficient evidence regarding the effectiveness of stroke caregiver interventions that can be easily incorporated into practice, although several recommendations have been provided (12,13,17–20,83–85).

Stroke Caregiver Clinical Trials

Visser-Meiley and colleagues (85) identified 22 studies from January 1966 to March 2003 (14 from Europe, 5 from the United States, 1 from Australia, 1 from New Zealand, and 1 from Canada). From March 2003 to August 2006, an additional three European studies were found (86–88). There was a broad range of outcomes and measures, making comparison of findings difficult, and many other limitations were identified. Only 10 of the 22 studies reviewed improved on one or more outcomes, meaning that 12 (54.5%) studies found no significant intervention effects (85). Potential reasons for the nonsignificant findings included insufficient interventions, incorrect timing of interventions, the use of measures that lacked sensitivity to detect relevant changes, and samples that included different mixtures of spouse and adult child caregivers (85). Of the 10 studies that reported positive outcomes on one or more measures:

- Two reported reduced depression
- One reduced burden
- Five improved knowledge
- One improved satisfaction with care
- One improved family functioning
- Three improved quality of life
- Two enhanced problem-solving skills
- Three improved social activities and support (85)

Legg and colleagues (89) conducted a more recent systematic review of randomized controlled clinical trials published from January 1950 to August 2010 and found that only eight met their inclusion criteria of nonpharmacological interventions that involved stroke survivors and caregivers randomized as a dyad. Only one single-centre study reported significant improvements in outcomes (86). This study involved 300 stroke caregivers randomized to caregiver training or conventional care during inpatient rehabilitation. Outcomes included lower costs, reduced caregiver burden, lower anxiety and depression scores, and improved quality of life for caregivers in the intervention group one year after the intervention (86). Patients of caregivers in the intervention group also reported less depression and anxiety and improved quality of life (86). The caregiver training in this study consisted of three to five sessions of hands-on caregiver training on:

- How to handle stroke problems and complications
- How to prevent future strokes
- Information about local benefits and services
- Training in lifting and mobility techniques, assistance with activities of daily living, and communication tailored to the needs of the stroke patients (86)

However, these interventions were not tailored to the needs of caregivers (85,86). Caregiver intervention studies that better target the needs and concerns of family caregivers, rather than only the needs of stroke patients, have been strongly recommended (1,7,16,17–20,85).

Bakas and collegues (45,46,90) reported findings from a pilot study that tested content validity, satisfaction, effect sizes, and costs of delivery for the TASK intervention. Using the CNCC (7), the TASK program enabled stroke caregivers to self-identify their own needs and concerns regarding care for the survivor, as well as care for themselves as caregivers. Individualized interventions were then delivered based on caregiver self-identified needs. Content tip sheets were provided in five main areas (45):

- Information about stroke
- Managing emotions and behaviors
- Providing physical care
- Providing instrumental care
- Taking care of oneself as a caregiver

Skill-building tip sheets that addressed the following were also provided (45):

- Strengthening existing skills
- Screening for depressive symptoms
- Maintaining realistic expectations
- Problem solving
- Communicating with health professionals
- Stress management workbook for survivors and caregivers

Compared to an Information, Support, and Referral (ISR) group (n = 19), caregivers in the TASK group (n = 21) had significantly higher satisfaction, higher optimism, lower task difficulty, and lower threat appraisal regarding their future ability to provide care (45,46). Subgroup analyses revealed medium to large effect sizes for depressive symptoms for caregivers who screened positive for at least mild depressive symptoms (PHQ-9 ≥ 5) (91). Estimated costs for the delivery of the TASK intervention, consisting of a notebook mailed to caregivers and 8 weekly calls from a nurse, were only $421 per caregiver (90). These encouraging findings led to further refinements of the TASK intervention, which is now being tested in a large randomized controlled clinical trial (TASK II; R01 NR010388; Clinicaltrials.gov NCT01275495).

Also evident in Visser-Meiley and colleagues' (85) review was the need for studies that document the effects of caregiver interventions on patient outcomes. A total of 17 out of 22 studies reviewed used combined patient and caregiver interventions, making it difficult to determine the effects of caregiver interventions by themselves on patient outcomes. Determining the effect of caregiver interventions on stroke survivor outcomes is recommended and would provide a stronger rationale for implementing caregiver programs in practice (85).

Forester et al. (83) concluded from their review of stroke caregiver intervention studies that the provision of information alone had no effect on mood, perceived health status, or quality of life for stroke patients or caregivers. Another review found similar results, concluding that although knowledge improved with information-only interventions, reduction in depression was small and probably clinically insignificant (88). Other studies that combined education with problem-solving strategies were much more effective than using education alone at improving caregiver knowledge, family functioning, problem-solving strategies, and even patient adjustment (32,92). For example, Grant and colleagues (93) found that theoretically based telephone problem-solving sessions with family caregivers of stroke survivors significantly enhanced caregiver problem-solving skills, improved preparedness, reduced depression, and improved several SF-36 Health Survey scores. These sessions consisted of an initial face-to-face visit, followed by 7 telephone calls over a 12-week period to teach and reinforce caregiver problem-solving skills (93,94). King and colleagues (95) tested a similar problem-solving intervention with 121 stroke caregivers, using a wait list control group design, and found significant improvements in caregiver depression and life changes. Threat appraisal and problem solving were significant mediators in the conceptual model used to evaluate the intervention (95). The advantage of these sessions was that they empowered family caregivers to identify, solve, and evaluate their own problems in providing care (93–95).

Dennis and colleagues (96) found that stroke caregivers randomized to a treatment group receiving home visits by a family care worker had very few significant differences in outcomes compared to a control group; however, training and measurement problems may have biased the findings (97). A similar study by Mant and colleagues (98) found that the use of a trained family support organizer who made one hospital visit, one home visit, and three telephone calls significantly improved several SF-36 Health Survey scores, suggesting the importance of adequate training and adherence to a treatment protocol for interveners. Follow-up data from this study showed that the effect of the family support intervention persisted for up to one year after the intervention (87). There have also been other stroke caregiver intervention programs that show promise within the veteran population that use telehealth or videophone technologies (99,100). The Transition Assistance Program (TAP) was found to reduce caregiver strain and there was a trend toward a reduction in caregiver depression ($P = .07$) (100).

Although most stroke caregiver interventions are delivered face to face or by telephone, there are a few stroke caregiver intervention studies that have reported using web-based interventions (101,102). Pierce and colleagues' (101) "Caring~Web" intervention provided education and online support to 103 users over 1 year. Although there were no significant differences in caregiver well-being, there were significant reductions in emergency room visits and hospital readmissions for stroke survivors (101). Smith and colleagues (102) tested a web-based conferencing and video education intervention in 38 dyads (spouse caregivers of male stroke survivors). Although there were no significant differences in survivor outcomes, caregivers in the intervention group showed significant reductions in depressive symptoms. They also found the intervention to be useful, and would recommend it to others (102). Although there may be current technological barriers for many of today's stroke family caregivers, these web-based interventions show promise for the future as more and more family caregivers develop computer skills over time.

Caregiver Clinical Trials in Other Contexts

Most caregiver intervention research has been conducted in the areas of dementia and older persons. The most widely known intervention program, the Resources for Enhancing Alzheimer's Caregiver Health (REACH), evaluated the effectiveness of multiple caregiver interventions implemented across six sites to provide a comprehensive evidence base for caregiver intervention research (103). Meta-analytic findings from these interventions with 1222 family caregivers showed active interventions to be superior to control interventions (104) and multicomponent interventions targeting multiple domains (knowledge, cognitive skills, behaviors, and affect) to be relatively more effective (105). Meta-analysis has also revealed that tailoring interventions to the individual needs of family caregivers is generally more effective than group interventions (106,107). Other comprehensive reviews of caregiver intervention studies in dementia (108,109) and old age (106,107,110,111) exist. Two reviews emphasized the need to look beyond outcomes to methodological design factors such as intervention integrity and theoretical rationale (109,110). *Treatment fidelity*, defined as strategies to improve the reliability and validity of behavioral interventions and address intervention integrity and theoretical rationale, is being increasingly emphasized in intervention research (109,110,112). Treatment fidelity consists of five components: treatment design, training, delivery of treatment, receipt of treatment, and enactment. Treatment design includes the theoretical model or clinical guidelines for the intervention, provider credentials, and information about the dosage (length, number, content, and duration of contacts) for both intervention and comparison conditions. Training includes detailed descriptions of how providers are trained, standardized, and maintained over time (for example, use of training manuals, role-playing, and audiotaping). Delivery of treatment involves ensuring that treatments are delivered as intended (for example, use of evaluation checklists to track adherence to protocol and need for retraining). Receipt of treatment refers to evidence that the study participants understood the intervention (for example, ability to verbalize what they have been taught, pretest/posttest, and ability to demonstrate skills). Enactment of treatment skills refers to evidence that study participants have incorporated treatment strategies into their everyday lives or that they use the strategies in a variety of settings (112). Although integration of these five components of treatment fidelity into clinical trials can be costly, time-consuming, and difficult to implement in clinical practice (113), rigorous attention to these components is likely to enhance scientific reporting, provide more plausible conclusions as to why interventions did or did not work, and improve treatment replication, making treatments more applicable to a wider variety of clinical practice settings (112).

RESEARCH FRONTIERS

The aging of the population, along with the current shortage of health care professionals to assist with the transition to home care, underscore the urgent need for public policies and programs to support family caregivers (114,115). This is especially true for family caregivers of stroke survivors, because the incidence of stroke is likely to increase as the population ages (5). As detailed earlier in this chapter, caregivers have a variety of needs and concerns about providing care, such as information, managing the survivor's emotions and behaviors, providing physical care, providing instrumental care, and personal responses to caregiving. Caregiver depression, deteriorating health, and other negative caregiver outcomes such as decreased social functioning and financial well-being are common. Family caregivers often feel neglected by health professionals in practice settings. Although there are a few stroke caregiver intervention studies with positive results, this body of research as a whole has not produced sufficient evidence for the effectiveness of stroke caregiver interventions. Clinically tested interventions for family caregivers of stroke survivors are prerequisite to the development of effective

public policies and programs that can be implemented into practice settings for family caregivers. Stroke also affects the entire family system (i.e., parents, minor children, spouses of adult child caregivers, siblings, and other relatives), although research is severely limited in this area. Interventions based on a family systems perspective have been recommended; however, further research is required to develop and clinically test interventions at the family systems level. The following sections summarize recommendations for future research and practice implications pertinent to stroke recovery and rehabilitation for families.

Recommendations for Future Research

1. More research that includes assessment tools to identify problem areas experienced by family caregivers is needed so that individualized caregiver interventions can be delivered (1,7,16–20). For example, further studies using the CNCC (7) to assess caregiver needs and concerns, the Oberst Caregiving Burden Scale (OCBS) (15) to assess difficulty with caregiver tasks, and the BCOS (8,9) to assess negative changes in caregiver lives as a result of providing care are needed (7–10,15,19). The use of the PHQ-9 (33) to screen for caregiver depressive symptoms also warrants further testing (10,19).
2. Quality outcome measures relevant to stroke caregivers that have documented evidence of reliability, validity, and sensitivity to change are needed to evaluate stroke caregiver intervention programs (85).
3. Caregiver intervention research should include interventions that are tailored or individualized to specific caregiver needs and concerns (7,10,12,15,19,20,45,46,85 ,107).
4. Stroke caregiver interventions that specifically address how to help caregivers manage the emotional and behavioral reactions displayed by stroke survivors are especially needed because managing survivor emotions and behaviors is among the most stressful aspects of providing care (5,10,15,16,19,25–30,45).
5. Multicomponent caregiver interventions covering multiple domains (knowledge, cognitive skills, behaviors, and affect) (105) and offering more than just information provision (83,88) should be the focus of future stroke caregiver intervention research.
6. Correct timing for interventions should receive attention when designing stroke caregiver intervention studies (85).
7. Studies that separate spouse data from adult child caregivers during analyses are needed to identify interventions appropriate for each group (85).
8. Studies that document the effects of caregiver interventions on stroke survivor outcomes are needed to provide a stronger rationale for caregiver interventions in practice (85).
9. Studies that look beyond outcomes to methodological design issues, including treatment fidelity, are recommended (109,110,112).
10. Studies that incorporate a theoretical rationale for interventions are recommended (45,46,109,110,112).
11. More research from a family systems perspective is needed to document the impact of stroke on entire families, as well as to develop and evaluate interventions at the family systems level (17,18,78).

Practice Implications

1. Because of the wide variety of needs, concerns, and negative outcomes experienced by family caregivers of stroke survivors, detailed assessment from the caregivers' perspective using tools such as the CNCC (7) is recommended so that individualized caregiver interventions or referrals can be provided (1,7,16–20,45,46,85).
2. Health professionals should assess and reinforce both patient and caregiver knowledge of stroke warning signs, lifestyle changes (i.e., diet, exercise, smoking, heavy alcohol consumption, and obesity), and risk factors for secondary stroke prevention (i.e., management of hypertension, diabetes, and cholesterol) throughout stroke recovery and rehabilitation (7,16–20,23,24,82).
3. Family caregivers should be asked about the stroke survivor's depressive symptoms and emotions, and how they are communicating with the survivor, to identify possible barriers to stroke recovery and rehabilitation that may be amenable to treatment, therapy, or psychological counseling (7,10,17–20,26,42,43,82).
4. Family caregivers should be encouraged to attend therapy sessions and ask questions about the survivor's medications, symptoms, and other stroke-related care issues (7,17–20,47,82).
5. Family caregivers should be referred to a social worker as needed to assist in dealing with financial problems and finding appropriate community resources (7,15,16,19,20,82).
6. Stroke organizations, such as the American Stroke Association (www.strokeassociation.org; 1-888-478-7653), the National Stroke Association (www.stroke.org; 1-800-787-6537), or the National Institute for Neurological Disorders and Stroke (http://www.ninds.nih.gov/disorders/stroke/stroke.htm; 1-800-352-9424), can be valuable resources for stroke survivors and their families (72).
7. Family caregivers should be asked how they are doing (7,10,16,19,82), particularly about their depressive symptoms and health. Refer them for treatment and/or psychological counseling as needed. Encourage them to seek regular checkups and to practice health promotion activities while providing care.
8. The entire family system should be considered during recovery and rehabilitation, not just the stroke survivor–caregiver dyad (17–19,78). Ask the stroke survivor and his or her family caregiver how other family members are dealing with the stroke, including any minor children, and refer them for treatment and/or counseling when appropriate.

CONCLUSION

Providing care for a family member with stroke can be difficult and can lead to negative consequences not only for the family caregiver, but also for the entire family. Researchers and clinicians are urged to explore ways to better support families in providing care for stroke survivors during stroke recovery and rehabilitation. Research regarding the needs and concerns, depressive symptoms, poor health, and other negative outcomes experienced by family caregivers has been reviewed, along with stroke caregiver intervention research and the need for a family systems perspective in helping families adjust after stroke. Perhaps with attention to the several recommendations for future research and practice outlined in this chapter, families may receive better care and support from health professionals in the future.

Driving After Stroke

Hillel M. Finestone and Arthur M. Gershkoff

Cerebrovascular disease can cause physical, visuospatial and/or cognitive symptoms that can lead to unsafe driving. Careful assessment of cognition, insight, and judgment, as well as gathering a thorough history and performing a complete physical examination, are important in determining potential driving risks. However, clinicians know that returning to driving after stroke can be a very sensitive and emotional issue (1). Many stroke survivors relied on driving before their illness and consider it an essential component of independent living as well as a pleasure and a right of citizenship. Stroke survivors who are able to resume driving are better integrated into the community than nondrivers (2,3). But the fact that "driving is a privilege and not a right" must sometimes be compassionately conveyed to the patient with stroke.

Health care providers who draw attention to patients' physical, cognitive, and/or visuospatial deficits may thus threaten stroke survivors' image of themselves. However, attention to driving safely is a necessary part of the overall rehabilitation plan for virtually all stroke survivors. The issue must be addressed from several points of view:

- *Societal*: Although many stroke survivors safely return to driving, society must be protected from unsafe drivers, who expose themselves and others to the risk of bodily harm and property damage. Some stroke survivors may deny the severity of their deficits because of anosognosia (denial of illness) or severe impairment of judgment. The need to drive may be so strong that they purposely fail to report symptoms to their physicians, such as seizures or episodic loss of consciousness that would lead to mandatory loss of driving privileges (4). Society therefore has an obligation to create pathways to return to driving following stroke and administer careful and thorough driving evaluations that assess the safety of the stroke survivor. Safe and effective transportation is also needed for those who are no longer able to drive.
- *Ethical*: While the public must be protected from unsafe drivers, there is also an obligation to treat stroke patients fairly. It should *not* be assumed from the outset that residual neurologic deficits preclude safe driving (5,6). However, various jurisdictions have different regulations governing when and how a stroke survivor may return to driving.
- *Medicolegal*: The physician's potential liability for damages to others caused by an unsafe driver always lurks in the background. A few U.S. states and most Canadian provinces have clarified physicians' responsibility by legislating mandatory reporting of potentially unsafe drivers. The jurisdiction may then either revoke the license of someone judged unsafe to drive or require the patient to undergo standard or specialized driving assessments.

Though we are now more aware of driver safety following stroke, rehabilitation programs may not always address this issue. Of the approximately 78% of people who survive an acute stroke, 50% to 70% regain functional independence. A substantial proportion of these have the potential to return to safe driving but often must overcome or adapt to residual deficits. Some deficits, especially those that impair judgment or awareness of deficits, preclude safe driving, whereas others do not. A 1997 survey of 290 stroke survivors 3 months to 6 years after stroke showed that only 30% of subjects who drove before their illness resumed driving after the stroke. A total of 48% had not received advice about driving, and 87% had not received any type of evaluation of driver fitness before returning to driving (7). In another British study, published in 2008, very few patients recalled receiving any driving advice from their referring doctor while awaiting assessment for their transient ischemic attack (TIA) or minor stroke (8).

CONCEPTUAL DRIVING MODELS

Driving requires multiple skills, and models have been developed to conceptualize the types of skill interactions that occur. Michon described three levels of driving-related decision making: strategic, tactical, and operational (9). Strategic decision making, the highest level, refers to trip planning, such as the route that will be taken and determining whether the weather or time of day or night is appropriate. Tactical decision making refers to the driver's vehicle-handling decisions, such as how fast or slow to drive, whether to tailgate, and when to pass appropriately. Finally, operational decision making refers to basic driving actions, such as braking, steering, and reaction to a sudden possibly dangerous event. Galski et al. developed a more dynamic model that incorporated sensory

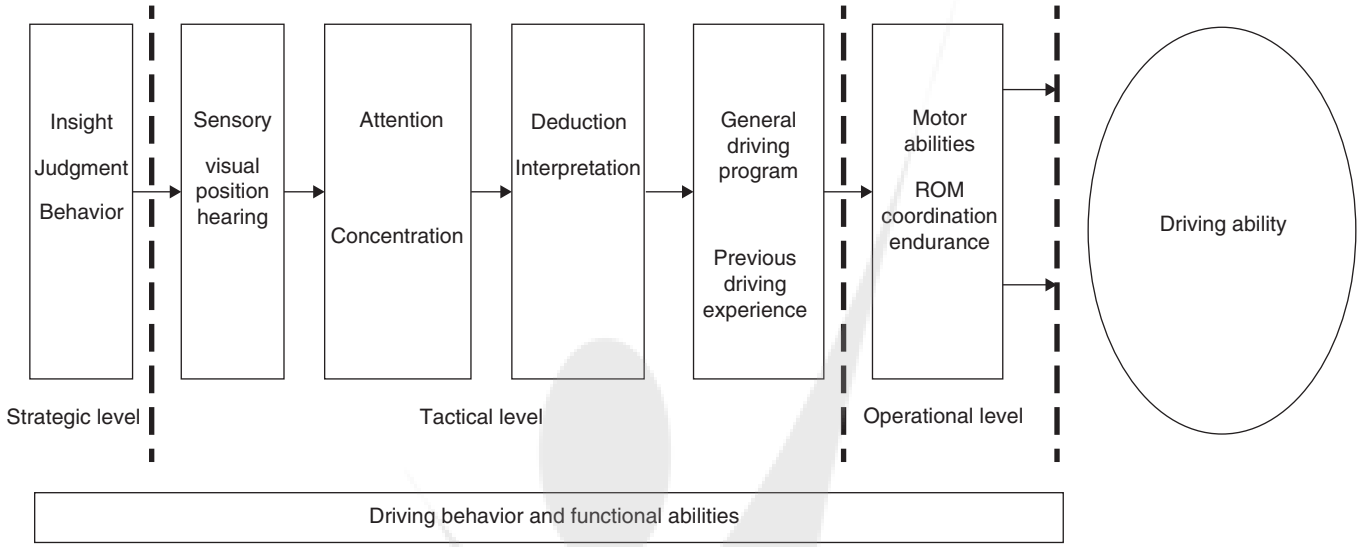

FIGURE 48.1 Model demonstrating the complexity of driving performance and how the physical, perceptual, and cognitive deficits that result from stroke may impede this performance at many levels.

Source: Reprinted with permission from Ref. (11). Marshall SC, Molnar F, Man-Son-Hing M, et al. Predictors of driving ability following stroke: a systematic review. *Top Stroke Rehabil.* 2007;14(1):98–114.

input, information processing, driving experience, and motor output skills (10). Marshall et al. combined the two models, as shown in Figure 48.1 (11). The figure amply demonstrates the complexity of driving performance and how the physical, perceptual, and cognitive deficits that result from stroke may impede this performance at many levels.

NEUROLOGIC DISORDERS AND CRASH RISK

In a review on the risk of vehicle crashes or traffic citations among patients with various diagnoses, it is of note that five of the seven studies show that drivers who have had a stroke have an increased risk of crashing compared to their counterparts without stroke (12). Diller et al. examined crash risk for Utah drivers based on medical conditions identified through a mandatory medical questionnaire at the time of licensure, followed by more extensive health screening (13). For each condition, the authors compared drivers having restricted licenses with drivers who were unrestricted. Neurologic conditions included a wide variety of diseases, but stroke was not separated out. Subjects with epilepsy in the absence of other neurologic disease were excluded. The data were linked to Utah Department of Transportation crash files. Among unrestricted drivers, those with neurologic conditions had 1.62 times the overall crash risk compared with a comparison group of 1773 unrestricted drivers without medical conditions matched for age, sex, and county of residence; the relative risk for at-fault crashes was 2.20. Subjects with neurologic conditions and restricted licenses had an increased relative risk of crashes, but this did not reach statistical significance. Separate analysis of drivers with epilepsy and episodic disorders of consciousness showed a significantly increased overall and at-fault crash risk for both restricted and unrestricted drivers (13). (It should be kept in mind that discrepancies in accident and infraction rates may exist between patient self-report and transportation authority records (14)).

However, a retrospective study of 1910 stroke patients indicated that the crash risk per person-year of driving for stroke survivors who return to driving is *not* higher than that for presumably healthy control subjects matched for age, sex, and zip code (15). The authors did not consider licensed drivers who voluntarily ceased driving or changed their driving exposure (16,17). Reduction of driving exposure has been noted with increasing age (18). The crash risk per mile driven rises substantially for drivers over age 65 (18); as the incidence of stroke increases substantially with aging, the crash risk per mile driven is therefore likely to be higher for stroke survivors as a group, regardless of neurologic deficits.

Nevertheless, specific neurologic deficits likely to be present following stroke play a role in driver performance and crash risk. In a study of visual impairments and their relationship to crash risk in 294 drivers aged 55 to 87 years, the most important deficit was restriction in useful field of view (UFOV), the visual field area within which a person can use rapidly presented visual information without moving the head or eyes (19). UFOV testing is different from visual field testing, which assesses visual sensitivity only. After adjustment for age, sex, race, chronic medical conditions, mental status, and number of days driven per week, impairment of UFOV of 40% or greater was associated with a 2.2-fold increased crash risk during 3 years of follow-up. Subcomponents of UFOV include processing speed, divided attention, and selective attention. Divided attention, which is frequently impaired following stroke, was associated with a 2.3-fold increased crash risk; the other subcomponents were not significantly associated with increased risk. Other vision parameters (visual acuity, contrast

sensitivity, stereo-acuity, visual field sensitivity [central and peripheral], and disability glare) were not significantly associated with increased crash risk (19). In another study, elderly drivers with substantial UFOV deficits had 15.6 times the crash rate at intersections compared with elderly drivers with normal UFOV (20). A meta-analysis by Clay et al. confirmed the significant relationship in older adults between UFOV and driving performance (21). In contrast to studies on UFOV, studies that examine the effect of visual field loss on driving have generally not shown a relationship between the loss and crash risk (16); however, stroke patients were not examined separately in these studies.

STROKE-RELATED DEFICITS AND DRIVING

Fisk et al. studied UFOV, visual acuity, peripheral vision, contrast sensitivity, and behavioral attention in 50 community-dwelling stroke survivors and a control group of 105 older adults without neurologic or visual impairment (17). They compared performance on these measures with a questionnaire of driving habits. Stroke survivors as a group demonstrated more impairment in UFOV, contrast sensitivity, and peripheral vision than controls, whereas stroke survivors who were drivers had less impairment of attention than those who were nondrivers. Stroke survivors who drove reported difficulty with challenging driving conditions and drove less than controls (17).

In general, the greater the severity of deficits, physical or cognitive, the lower the likelihood that the patient will return to driving. It has been estimated that every one-point increase in composite Functional Independence Measure score at discharge raises the likelihood that a stroke patient will return to driving by 5% (7). Smith-Arena et al. studied retrospectively the neurologic status at the time of admission to the rehabilitation hospital of 45 stroke patients referred to occupational therapy for driver prescreening (22). The 29 patients who passed the prescreening—23 of whom eventually passed an on-road assessment (ORA)—were significantly more likely than those who failed the prescreening to have intact visual fields and higher Mini Mental Status Examination (MMSE) and Motricity scores.

Aphasia presents a challenge to driving. In a 1980 study, 20 aphasic subjects (10 who had chosen to return to driving and 10 who had not) were evaluated as functional or nonfunctional to drive by a team including a physiatrist, driving instructor (off-road screening tests), occupational therapist, and speech therapist (23). The team's assessments of driving-related sensorimotor and cognitive domains were strongly predictive of the subject's decision whether or not to continue driving. Performance in spatial relationships was the most important variable that differentiated between those who chose to drive and those who did not, and between subjects who were judged as functional and those who were judged as nonfunctional to drive. The severity of aphasia had a significant effect on the subject's decision to drive but not on the team's rating. All aphasic patients who chose to drive were judged functional by the team (23).

Few studies have explored anatomic factors in driver performance following stroke. Using a driving simulator, Kotterba et al. studied 32 stroke survivors and found that patients with middle cerebral artery strokes performed more poorly than those with vertebral artery territory damage (24). This makes sense, given that middle cerebral artery strokes are likely to be larger in volume than vertebral artery strokes and are more likely to involve structures that affect cognition, vision, and perception. Patients with right-brain lesions are more likely than those with left-brain lesions to score poorly on visual and perceptual tests that are predictive of driving outcome (25). Akinwuntan et al. analyzed specific deficit areas in the ORA of 68 stroke survivors and found that subjects with attributes of visual neglect consistently drifted toward one side of the road and lacked adequate vision and perception during complex driving conditions (26).

Lastly, stroke patients may have a limited awareness of their disability (27) and thus tend to overestimate their driving ability (28). Losing the ability to drive has been documented to be unexpected, arousing strong feelings and reactions (29). It is no wonder that clinicians often consider the discussion of driving after a stroke such a difficult part of their practices.

DETERMINING FITNESS TO DRIVE

Numerous articles have attempted to outline the key factors that predict stroke survivors' ability to return to driving safely. Patient age and amount of disability (30,31), performance on cognitive tests (11,32), measures of strength and motor activity (33), normal visual fields (22), performance on a specialized driving track (34), and functions such as divided and/or selective attention and speed of processing (35) have been identified as important pieces of information for the clinician to consider. The majority of stroke survivors interested in return to driving will likely require an ORA, which remains the gold standard for determining driver safety. However, it must be emphasized that the physician's interview, examination, and assessment are vital components of the evaluation process. For the patient with apparent complete neurologic recovery, the physician may feel comfortable clearing the patient to return to driving, in which case the neuropsychological tests, closed-course driving tests, and driving simulator performance described in this chapter can provide helpful corroboration of the validity of this decision. If the patient has residual deficits, these screening tools can assist the clinician in determining if the ORA is necessary and when it should take place.

The On-Road Assessment

The ORA can take place in the patient's own vehicle, with a trained driving instructor sitting in the front passenger seat assessing performance. More often, and especially in cases in which safety is unknown or a true concern, the instructor will require a dual-control vehicle in which both driver and instructor have control over the brakes. Most dual-control vehicles have automatic transmissions. For standard-transmission

vehicles with a manual clutch, the instructor may have control over a second clutch; however, such vehicles are rarely, if ever, used or recommended for stroke patients.

Ideally, the instructor will be a driver rehabilitation specialist (DRS—see discussion following) or at least have experience with stroke patients. In the province of Ontario, Canada, provincial law mandates that, for a specialized ORA for a disabled individual, an occupational therapist must ride in the vehicle and evaluate performance as well. However, many areas of North America lack driving instructors with such expertise, and the physician may have to (or be required to) send the patient for an ORA by the state or provincial license certifying agency. The experience of the agency's instructors in working with stroke survivors and other disabled people may vary considerably.

The overall failure rate on the ORA by stroke survivors is 26% to 83% (16). Such a wide variability in failure rate attests to the wide variation in testing methods for the ORA. The method of assessing on-the-road driving performance may be highly structured but often differs between centers. In addition, different instructors may score a structured assessment differently. For example, the validity and reliability of a particular structured 10-mile ORA were evaluated in a Belgian study involving 39 stroke survivors (36). The results of this study demonstrated a significant variability in the pass rate between driving instructors. The state-registered evaluator failed seven of nine patients who had been passed by a driving instructor who had had more experience working with patients with strokes and other disabling conditions (36). The findings indicate a need for stroke survivors to work with instructors who are skilled in evaluating disabled people.

The ORA can be costly, and failure can lead to the serious consequences of loss or inability to re-obtain a license to drive. Regaining the license may entail overcoming considerable bureaucratic hurdles (even to obtain a training or learner's permit) and substantial expense in driving lessons. When the ORA is necessary, the physician can play a key role in determining when it should be scheduled to present the maximum likelihood that the patient will pass.

Predriving Cognitive and Neuropsychological Testing

A variety of studies have involved batteries of neuropsychological tests and correlated the results with ORAs (11,16,37). These studies show significant relationships between a number of psychometric tests and fitness to drive as measured by the ORA. They suffer from tremendous variability in the kinds of tests administered and the timing of testing following stroke. In most cases small numbers of patients were studied. The exact locations and extent of cerebral damage are generally not identified (16).

Engum et al. developed the Cognitive Behavioral Driver's Inventory (CBDI), which consists of brief neuropsychological tests with 27 individual scoring items. These tests evaluate the following domains of driver-related cognitive functioning: attention, concentration, rapid decision making, stimulus discrimination/response differentiation, visual scanning and acuity, and attention shifting (38). A summary score is average of the 27 items and is classified as pass, fail, or borderline. The CBDI has high internal consistency and validity based on correlations with the ORA. In a double-blind study of 81 patients, clearly passing the CBDI was 94% predictive of passing the ORA, and clearly failing the CBDI was 100% predictive of failing the ORA (39). The CBDI was further validated and shown to be sensitive in discriminating among 109 brain-injured subjects who passed the ORA, 54 brain-injured subjects who failed the ORA, and 41 nonbrain-injured control subjects (40). In a recent retrospective study of 172 patients, including 28 with left-brain stroke, 20 with right-brain stroke, and 58 with traumatic brain injury, the CBDI was found to be a significant predictor of pass or fail on the ORA for patients with right-brain stroke and traumatic brain injury but not for those with left-brain stroke (41).

Klavora et al. found the CBDI alone to be only 66% accurate in predicting success or failure on the ORA in 56 stroke survivors (42). These authors also evaluated the accuracy of the Dynavision Performance Assessment Battery, which uses a computerized apparatus to test and train visual scanning, peripheral visual awareness, visual attention, and visuomotor reaction time, and found the accuracy of the battery and subtests to be 66% to 77%. Some of the subtests of the Dynavision battery that take 5 to 10 minutes or less matched the predictive accuracy of the CBDI, which takes 60 to 90 minutes. Combining the CBDI and Dynavision battery yielded 100% accuracy (42).

In a study involving 23 subjects with stroke and 14 subjects with traumatic brain injury, Galski et al. compared 21 neuropsychological tests of attention, concentration, reaction time, memory, visual acuity, and visuospatial skills against a structured ORA consisting of 26 tasks (43). A driver evaluator converted the neuropsychological tests into a pass or fail score. Neither the pass/fail score nor any of the individual neuropsychological tests predicted the ORA outcome. The authors concluded that predriving evaluations should focus on screening out patients who are unsafe drivers rather than trying to predict reliably which patients are safe to drive (43). In a Swedish study, none of the neuropsychological tests offered was able to predict driving outcome (44).

In a study in Great Britain, 39 subjects who had had a stroke more than 6 weeks earlier were given a cognitive assessment by a psychologist and the ORA by the British School of Motoring (45). Significant relationships were noted for cube copy (spatial ability), dot cancellations time and misses (visual inattention, spatial ability, and memory), Rey figure recall (visual inattention), "What else is in the square?" (a children's game that tests reasoning ability), pursuit rotor (eye–hand coordination), road sign recognition (visual comprehension), and hazard recognition (visual recognition from videotape of an open-road drive). Using these, the authors developed a model for predicting driving

competency during the ORA; the model predicted pass or fail accurately for 95% of subjects. Complex reasoning skills seemed especially important (45).

A follow-up study, however, failed to validate the model in 40 stroke survivors (20 with left and 20 with right hemiparesis) (46), possibly because of a change in the ORA and the driving evaluator used. A new model was developed using dot cancellation, square matrices (based on "What else is in the square?"), and road sign recognition; this model predicted performance on the ORA with 79% to 82% accuracy and was eventually developed into the Stroke Drivers Screening Assessment. Two later studies involving a total of 66 patients showed this tool to be 80% to 81% accurate in predicting performance on the ORA (36,47). The instrument has shown excellent concurrent validity with more extensive neuropsychological measures of attention and executive functioning (48).

Other studies using multivariate statistical analysis have shown a significant correlation between various tests, including the Motor Free Visual Perception Test (MVPT) (25,49), single-letter cancellation test (25), Trail Making Test B (25), and figure of Rey complex drawing task (50), and subsequent performance on the ORA. In a multicenter trial of 269 patients, lower scores on the MVPT, increased age, and right-brain lesions were significantly associated with failure on the ORA, but the MVPT alone was insufficient to serve as the sole screening instrument for determining readiness for the ORA (49).

In a systematic review, Marshall et al. examined the predictors of driving ability following stroke (9). They noted useful screening tests, such as Trail Making Test A and B. Cognitive tests that assessed "multiple cognitive domains relevant to driving" were deemed to have the best reproducibility in predicting fitness to drive (11). A recent meta-analysis by Devos et al. of 27 studies encompassing 1728 stroke survivors confirmed the utility of the Compass Trail Making Test B, and road sign recognition tests; each test individually was 80% to 85% accurate in predicting potentially unsafe drivers, that is, those who failed the ORA (51).

Thus, cognitive testing in a variety of domains can be helpful in identifying potentially unsafe drivers. However, no single test or battery of tests predicts this absolutely. If the physician believes the patient to be unsafe, that too has some validity; there is a significant correlation between the objective driving score derived from standardized ORA and the global subjective evaluation of fitness to drive (52). In general, regardless of the predriving screening method used, the threshold for requesting (or insisting) that the patient undergo an ORA should, in the opinion of the authors, remain low.

Driving Simulators and Closed-Course Driving Tests

Traditionally, driving simulation involved watching films or videos of a car being driven through traffic and watching or tabulating the patient's reactions on mock driving controls, often adapted from an actual vehicle. Such simulation is noninteractive. Advances in computer simulation, video technology, and gaming have enabled development of highly realistic, interactive scenarios in which the video monitors wrap almost around the patient and the computer routine can change in response to the patient's actions. The computer can also monitor and record reaction time, errors, and appropriate or inappropriate use of steering and other controls (9).

Off-road, closed-course driving tests are recommended to evaluate vehicle operation skills and readiness for an in-traffic ORA (52). However, one small study showed no significant correlation between measures of driving on a closed course and performance on an ORA (53). A closed course thus may require a different set of skills than those required on an open-road ORA, and some stroke survivors may perform better in open-road driving—which may be an over-learned skill—than in a novel, off-road closed-circuit test.

Szlyk et al. found decreased performance on a driving simulator in patients with hemianopsia associated primarily with occipital lobe damage from stroke compared with a control group of similar age (54). In a Belgian study, 83 stroke survivors were assigned to simulator-based driver training (experimental group) or driving-related cognitive tasks (control group) (55). The subjects trained for one hour three times weekly for five weeks. The simulator consisted of the controls from an actual vehicle, with adaptive equipment as needed and with large-screen video and audio that simulated a 13.5-kilometer (8.4-mile) course under varied driving conditions. Visual and neuropsychological performance improved in both groups. The experimental group improved significantly more than the control group only in a road sign recognition test. Before training, only 27% of either group was judged fit to drive based on the ORA. After training, improvements in the classification of fitness to drive favored the experimental group. Ultimately, 73% of the experimental group and 42% of the control group were legally permitted to resume driving. Akinwuntan et al. noted in 2012 that driving simulators were improving and could potentially overcome "the problems currently faced in the evaluation and rehabilitation of driving after stroke" (56).

Galski et al. found that neuropsychological test results explained only 64% of the variance in ORA performance, while performance on the Doron simulator (a realistic but noninteractive driving simulator) predicted 63% (57). Together, the neuropsychological test and the simulator test explained 69% of the variance. The subjects' driving skills in a parking lot were also examined. The ability to follow directions, the presence of slow response, inattention and distractibility, and an index of overall observed behavior added 23% to the predictability, for a total of 92% of the variance. A factor analysis of the testing protocol identified five independent factors that predict performance on the Doron simulator: higher-order visuospatial abilities, basic visual recognition and ability to respond, anticipatory braking, defensive steering, and behavioral manifestations of complex attention (57).

In a study of 30 stroke survivors and 30 matched controls, a regression model was developed that included performance characteristics on a driving simulator and 3 psychological domains: attentional processing, executive capacity, and cognitive processing (58). A model based on performance variables on the simulator correctly predicted pass or fail on the ORA with 85% accuracy, whereas a model based on the psychological variables was 83% accurate.

A driving simulator has been noted to potentially improve stroke patients' "self-awareness" (59) and driving performance in "subacute stroke patients with mild deficits" (60) after six months but not five years later (61). A driving simulator may therefore serve as a driving trainer for the stroke patient. Similarly, the simulation of driving may also be used for educational purposes; that is, poor performance on the driving simulator may be more persuasive than paper-and-pencil neuropsychological test results to convince a patently unsafe patient to postpone the ORA and avoid driving. In this way, it may provide a safer alternative to the ORA for evaluating the driving potential of a stroke survivor who is likely unsafe but who insists on being tested. However, to prove or disprove driver safety, there is still no perfect substitute for the ORA administered by competent and experienced personnel.

Other Screening Instruments Not Specifically Tested in Stroke Survivors

Clock drawing, which evaluates memory, visuoconstructional ability, and executive functioning, can be a quick, useful, and simple screening tool. Failure on the clock-drawing test was found to be 90% accurate in predicting failure on an ORA in 100 adults aged 65 years or more (62). Clock drawing also correlated highly with performance on a driving simulator in 119 community-dwelling, active older Virginia drivers (63).

General screening tools for dementia, such as the Clinical Dementia Rating Scale and Folstein MMSE, have been studied in older adult drivers. Dubinsky et al. reviewed controlled studies of Alzheimer's disease and driving (64). Driving was found to be mildly impaired in drivers with probable Alzheimer's disease (Clinical Dementia Rating of 0.5, roughly equivalent to an MMSE score of 25, indicating only slight limitation in functional areas). The driving impairment was no different from that tolerated legally in other segments of the population (drivers aged 16–21 or drivers under the influence of alcohol with legal blood levels of less than 0.08%). Drivers with a Clinical Dementia Rating of 1 (roughly equivalent to an MMSE score of 19 to 24, indicating moderate limitation in memory and cognition that interferes with daily activities) had a significantly increased crash risk and performed more poorly on driving performance measurements. Stroke patients with cognitive deficits that correspond globally to these impairment levels probably share the respective levels of driving disability and crash risk.

The Assessment of Driving-Related Skills

The assessment of driving-related skills (ADReS) is the formal assessment tool developed by a consensus panel for the American Medical Association (AMA) (18). It was designed for assessing older drivers but is applicable to a wide variety of conditions, including stroke. For several of the subtests, there is evidence linking poor performance with increased risk of adverse driving events (18). The ADReS consists of the following subtests:

- Visual field testing by confrontation
- Visual acuity using a Snellen chart
- Rapid pace walk
- Manual test of range of motion, including neck rotation, finger curl, shoulder and elbow flexion, and ankle plantarflexion and dorsiflexion
- Motor strength (standard manual muscle test scored from 0 to 5) of shoulder abduction, adduction and flexion, wrist flexion and extension, hand grip, hip flexion and extension, and ankle dorsiflexion and plantarflexion
- Trail Making Test B
- Clock-drawing test (Freund method of scoring) (63)

If the patient fails any element of the ADReS, an ORA is recommended. Note that for stroke patients, significant hemiparesis will make it difficult for the patient to pass the motor strength screening (all muscles 4/5 or better in both upper extremities and the right lower extremity) and rapid pace walk test (10 feet and back in 9.0 seconds or less). Dominant upper-extremity involvement will affect handwriting and may affect performance on the trail-making and clock-drawing tests.

The ADReS has good inter-rater reliability among nursing, medical, and occupational therapy professionals (65). In a study of 50 licensed adults aged 65 or older, McCarthy and Mann found the instrument to be 100% sensitive in identifying subjects who subsequently failed an ORA (66). However, it was only 38% specific, meaning that many safe drivers (those who passed the ORA) failed the ADReS. A major reason for the high false prediction of failure on the ORA was failure of the clock-drawing test. To pass this test, the patient must draw the clock without error by the Freund scoring method. The authors noted that lowering the cut-off scores for passing the clock-drawing test from 8/8 to 6/8 would not reduce the sensitivity but would improve the specificity to 62% (66).

In McCarthy and Mann's sample, which did not include any stroke survivors, only 16% of patients failed the ORA. The high sensitivity and specificity of the ADReS may be different in a stroke population, in which the likelihood of failing the ORA is much higher (26%–83%) (16). However, the battery of tests is useful because it is a quick screening tool (15–20 minutes) that incorporates elements of the functional examination that the rehabilitation clinician will likely perform.

RETURN TO DRIVING (OR OTHER SAFE COMMUNITY TRANSPORTATION)

Adaptive Equipment to Aid in Safe Driving

For stroke survivors with significant weakness of the hemiparetic arm, a spinner knob attached to the steering wheel is required (Figure 48.2); this enables adequate control of the

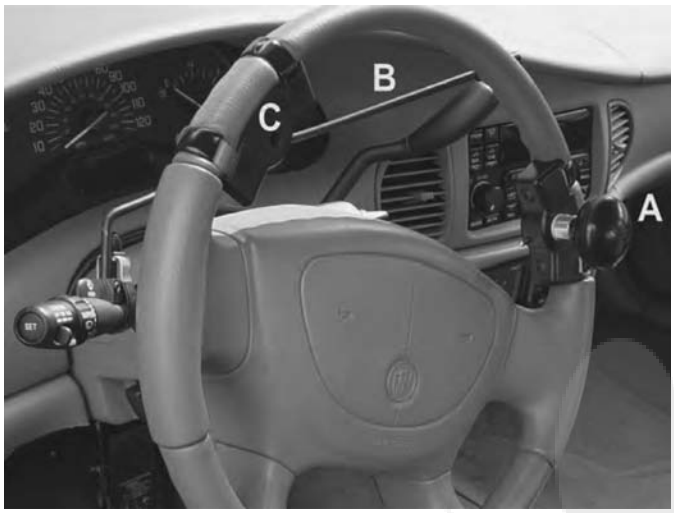

FIGURE 48.2 Adaptive equipment for hemiparetic drivers. (A) Spinner knob to be used at all times with the right hand for driver with left hemiparesis. (B) Left-to-right turn signal control. (C) Note that spinner knob can be placed on the left side for a driver with right hemiparesis.

Equipment available from Mobility Products & Design, PO Box 306, 144 South 100 West, Winamac, IN 46996.

steering wheel and must be used at all times during operation of the vehicle. Spinner knobs are now also available with switches to make it possible for the driver to control, without removing his or her hand from the knob, the turn signals, windshield wipers, horn, and high beams (Figure 48.3). If the person cannot control his or her right ankle, a right-to-left accelerator pedal converter may be needed (Figure 48.4) (67).

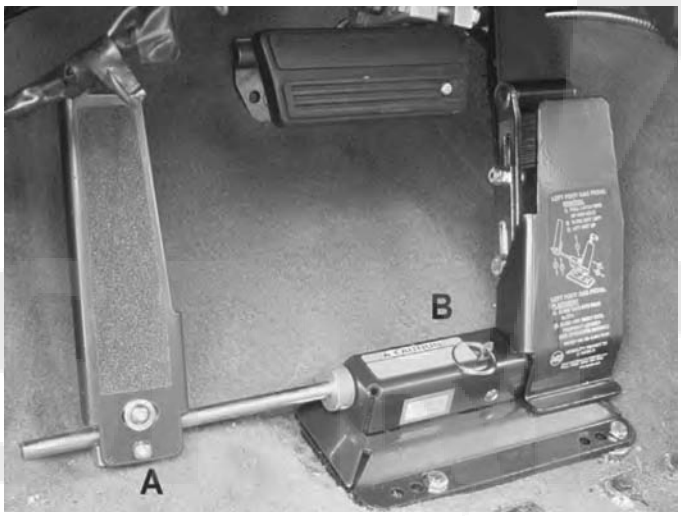

FIGURE 48.4 (A) Right-to-left foot control for accelerator pedal for a driver with right hemiparesis. (B) Note the pin for easy removal, so that the vehicle can also be used by an able-bodied driver.

Equipment available from Mobility Products & Design, PO Box 306, 144 South 100 West, Winamac, IN 46996.

Similarly, for a stroke patient with left hemiparesis, controls on the left, such as a turn signal, will require left-to-right conversion (Figure 48.2). For all of these, the control is usually designed to be easily removed, so that the vehicle can be used by an able-bodied person as well (67).

The Driver Rehabilitation Specialist

A DRS is a driving instructor who "plans, develops, coordinates and implements driver rehabilitation services for individuals with disabilities" (68,69). A DRS generally undergoes a certification process through the Association for DRSs (formerly the Association for Driver Educators for the Disabled [ADED]). Certification requirements include education, work experience, and passing a written examination. However, in most states and provinces there is no absolute requirement for certification to work as a DRS in adaptive driving instruction or administration of ORAs for people with disabilities. A DRS usually has certification or training in another discipline, most often occupational therapy but also physical therapy, kinesiotherapy, speech therapy, or recreational therapy. A driving instructor without training in another discipline (e.g., a driving school instructor or state driver licensing bureau examiner) can qualify for the examination with three years of full-time work experience in the field of driver rehabilitation (68).

The Association for DRSs has several categories of membership in addition to individual members: mobility equipment dealers, businesses involved in manufacturing and distributing products used by a DRS and by individuals with disabilities, and facilities and businesses that implement or administrate driver rehabilitation services. The association organizes and administers the examination for certification, has developed best-practice standards for delivery of driver

rehabilitation services, and has established ethical standards of practice. Thus, it serves as a major resource for all professionals involved in driver rehabilitation (68).

Adaptive driving programs are available in a variety of settings. Many comprehensive rehabilitation hospitals and programs offer driving schools for the disabled. A few programs are located within universities and are often connected to research facilities that are federally funded. Some are sponsored by local affiliates of national nonprofit organizations that serve the disabled, such as United Cerebral Palsy. Some private commercial driving schools have developed the expertise to advise on adaptive equipment and provide evaluation and training of stroke survivors. A few state vocational rehabilitation programs also offer such training, but most provide funding for patients to participate in adaptive driving programs in other settings (67).

The DRS performs a clinical evaluation of the patient, including medical and driving history, vision examination, assessment of selected physical aspects, cognitive assessment, and ORA. The medical history includes determining current medical status and stability to undergo further testing, reviewing medications for their potential deleterious effect on driving, assessing the patient's current communication status, reviewing the driving history, determining the license status (to determine whether an ORA can be performed legally), and assessing the availability of a suitable vehicle for the ORA. The DRS must also establish that the patient is actually medically cleared for an ORA and that performance of the ORA, given the medical condition, does not violate state or provincial regulations (70).

If the stroke survivor has had a seizure within the state-mandated period during which driving is not permitted, the DRS cannot perform an ORA, even if requested by a physician. In several states the mandated period of driving abstention can be overruled by the medical board of the state licensing agency if appropriate medical documentation is provided.

If a patient lacks a legal license but is cleared medically for the ORA, the DRS can facilitate the patient's obtaining a temporary license from the state authorizing the evaluation in a dual-control vehicle. This is required of the patient whose license is revoked because of a stroke and its sequelae but who recovers sufficiently to be evaluated.

For driving prescreening, the DRS performs an extensive functional and driving-oriented vision examination using assessment tools and clinical observation. Physical capacities required to control a motor vehicle are evaluated: strength, range of motion, grip strength, sensation, proprioception, coordination, and muscle tone. The level of cognitive impairment and self-awareness is also scrutinized, often with neuropsychological tests. Reaction time is usually measured objectively, especially movement of the foot from the accelerator to the brake pedal; this can now be tested with portable equipment in the patient's own vehicle. The DRS also evaluates the patient's assistive devices and orthotics needed for ambulation and must determine whether these will interfere with driving (70). Spastic talipes equinovarus, foot drop, and the use of an ankle–foot orthotic to block right ankle motion will usually impair control of the accelerator or brake pedal; the DRS can establish whether modification of the vehicle with adaptive equipment is indicated.

In a 2003 survey of driving evaluation practices of DRSs, more than 70% used a brake reaction timer, 70% the trail-making test part A or B, and 65% the motor-free visual perceptual test. In addition, 30% used the MMSE, and about 25% the letter cancellation test. Other measures of vision, perception, and cognition were used by 15% or less (71).

At the start of the ORA, the DRS assesses the patient's ability to enter and exit the vehicle and determines whether specialized equipment is needed (70). Rarely, stroke patients require a specialized wheelchair lift to access the vehicle independently. The patient's sitting posture and position with respect to the steering wheel and controls are evaluated. A major component of the evaluation is the patient's ability to operate controls while the vehicle is stationary or moving. If the vehicle already has adaptive equipment, the DRS evaluates its condition and appropriateness for the patient (70).

Out on the road, the DRS assesses the patient's driving performance in increasingly complex traffic conditions. The purpose of the examination is to observe the patient in road settings, traffic density, and weather conditions that approximate as closely as possible those likely to be encountered normally (70). For patients with suspected deficits that might interfere with safe driving, the DRS should design the ORA to emphasize driver actions that stress those deficit areas, for example, frequent left turns and performance at intersections with moderate to high degrees of traffic flow for patients with suspected left hemineglect (67). Some patients may be cleared for limited licenses, for example, to drive only during daylight hours. For most patients it is necessary to demonstrate satisfactory performance of all usual driving maneuvers required of able-bodied drivers seeking licensure.

At the end of the evaluation the DRS indicates to the patient—and the referring clinician—whether the patient is safe or unsafe to drive. If the patient is deemed unsafe to drive, the DRS recommends whether further training would help achieve safe driving or whether the patient should retire from driving. If adaptive equipment is required, the DRS trains and tests the patient to assure competence in its use while driving. If further training is likely to benefit the patient, the DRS can develop a program of goal-oriented driving lessons, with the ultimate purpose of passing a second ORA (70).

Stroke survivors who possess a valid license, require no special adaptive equipment, and are judged safe to drive by the DRS can generally return to driving. If new adaptive equipment is required, usually the patient must also be retested and certified by the state using that equipment. In most cases drivers seeking commercial certification must also be retested by the state to resume commercial occupations legally.

Evaluation and training by a DRS is expensive, generally costing $80 to $120 or more per hour. Some insurance companies may pay for this, but most do not. Federal and

state vocational rehabilitation offices often pay for an ORA if it can be shown that return to driving will facilitate return to work.

The Physician's Approach to the Patient

Stroke patients vary considerably in their potential to be unsafe drivers, and physicians need to individualize their approach for each individual patient, depending on the severity of the stroke, the specific impairments involved, and associated comorbidities. Patients with moderate to severe deficits will be clearly unable to drive, either temporarily or permanently. Objective tests that characterize cerebral damage (computed tomography or magnetic resonance imaging) and quantify the impairments can help in developing a prognosis, but poststroke functional ability and driving performance will ultimately determine the potential to resume driving.

Patients with severe impairments and disabilities may need counseling to avoid driving and to seek alternative forms of transportation. Patients who deny or are unaware of their neurologic deficits (including many with right-brain infarcts and anosognosia) and those with cognitive deficits who may impulsively decide to drive present a particular problem. In many, but not all, states and provinces the physician is legally obligated to report all potentially unsafe drivers to driver licensing agencies. Family members may have to be counseled to take measures to prevent the unsafe driver from driving (e.g., lock the car, hide the keys). Family members may also have the right to report the likelihood of unsafe driving practices to the driver licensing agency, and the threat of this may add weight to the physician's insistence that the patient cease driving. Patients who insist on an ORA may need counseling to postpone the assessment until further recovery has taken place.

Those with milder deficits and those who have recovered should be assessed using the ADReS or another objective, quantifiable test. Cognitive testing with the MMSE or other instrument is also useful. Patients who recover full motor, sensory, perceptual, and visual function, who lack cognitive deficits by testing, and who pass the ADReS are probably safe to drive. However, reaction time may still be affected and should be measured if possible. If there is *any* question that residual (or premorbid) visual, sensorimotor, or cognitive deficits exist, the patient should be referred for an ORA. Patients with hemiparesis severe enough to prevent bimanual grip of a steering wheel or regular use of brake and gas pedals must be referred to a DRS for adaptive equipment or modification of the vehicle before the ORA.

Aphasic patients may recover in other neurologic domains to the point at which safe operation of a motor vehicle is feasible, but may have difficulty completing written or oral examinations and following the driving instructor's verbal instructions during an ORA. The physician or therapist should anticipate such problems during testing and urge the testing or licensing agency to make accommodations for the patient's needs. This may include waiving the written test. If a written test cannot be avoided, patients with aphasia may benefit from extra time and the use of multiple-choice questions rather than prose or essay responses. Those with alexia or anomia may require someone to read the questions and choices for answers. Multiple-choice tests designed using pictures instead of words will also help the aphasic patient. Some with severe deficits may fail because they are untestable or because the agency cannot provide the necessary accommodations.

Physicians often encounter patients who have recovered from stroke but who present with new weakness. Even if the patient seems to have recovered fully, as with a TIA, driving should be avoided until a full medical evaluation has been completed. Persistent (for more than 24 hours) new weakness warrants cessation of driving until completion of not only a medical reevaluation but also the ADReS, cognitive tests, and if appropriate, another ORA. A patient previously judged competent to use adaptive equipment—whether related to deficits from a prior stroke or from another disabling disease—may need reevaluation and training to use the equipment safely again. Repeated unpredictable TIAs, syncope, or seizures require definitive medical treatment before driving can be resumed. If the medical condition can be controlled perfectly or is always preceded by adequate warning symptoms, return to safe driving may be possible. The physician should adhere to state or provincial regulations for reporting such transient neurologic changes. Most jurisdictions support the decision that the patient stop driving and require a period of freedom from episodes of altered consciousness before a license can be restored. The Canadian Medical Association recommends that the stroke survivor wait at least one month after the stroke before resuming driving (72), but this is a guideline and not a law.

Patients who have undergone cerebrovascular or intracranial surgery should not drive until they are judged fully stable, free of postsurgical symptoms, and cleared by a neurosurgeon. Residual neurologic deficits should be addressed in the same way as persistent deficits following a stroke. Arteriovenous malformations and subarachnoid hemorrhage should be treated similarly; the risk of future bleeding/re-bleeding of arteriovenous malformations and aneurysms must be assessed. If the risk is low and residual neurologic deficits are stable and mild, return to driving can be considered. However, driving is contraindicated if the medical condition remains unstable or at high risk of recurrence (18).

Pre-existing comorbidities may influence driver safety in stroke patients who may previously have been safe drivers. The presence of arthritis, mild Parkinsonism, visual acuity problems, deafness, mild dementia, or other disorders of aging may not in themselves preclude safe driving, yet when combined with even mild neurologic deficits after stroke, they may adversely affect driver safety. Thus, driver rehabilitation may require the physician to evaluate and treat such secondary comorbidities.

Regardless of state or provincial reporting requirements, *it remains of paramount importance that the physician tell the patient, who is potentially unsafe, not to drive, until further*

TABLE 48.1 Tips to Reinforce Driving Cessation for Stroke Survivors Likely to Be Unsafe Drivers

1. Write on a prescription pad, "Do not drive." This emphasizes the strength of the message and can serve as a visual reminder to the patient.
2. Ask whether the patient wishes to risk an accident in which injury could occur. The patient, his or her family, or an innocent party could be injured. How would the patient feel if someone else were injured as a result of causing an accident?
3. Point out that an accident will very likely raise insurance premiums.
4. Owning, insuring, fueling, and maintaining an automobile can be very expensive. If the patient retires from driving and sells the vehicle, how much money could be saved?
5. Ask how much lower the cost would be to take taxis or public conveyances.
6. Develop a plan for alternative transportation with family members. Present that plan to the patient.
7. If the patient lacks a valid license or is not qualified to drive because of the medical condition, point out the legal risks of driving without a license.

Source: Adapted from Ref. (18). Carr DB, Schwartzberg JG, Manning L, Sempek J. *Physician's Guide to Assessing and Counseling Older Drivers*. 2nd ed. Washington, DC: National Highway Traffic Safety Administration; 2010.

recovery takes place or until the patient undergoes a definitive ORA. The physician may be found negligent if the patient is not counseled in this way and subsequently drives and has an accident. To protect the physician, it is important to document in the medical record that this counseling took place.

It is important to offer support and counseling to patients who are unsafe to drive or who resist giving up driving or being tested. A list of tips to reinforce driving cessation is given in Table 48.1 (18). Referral to social services will help the patient to identify, apply for, and ultimately qualify for alternative community-based or subsidized transportation. The stroke survivor may require door-to-door public van service, which may require medical justification; the physician should expect requests for documentation when patients apply for such services.

AMA Physician's Guide to Assessing and Counseling Older Drivers

A useful resource to assist physicians and other rehabilitation personnel in addressing driver safety is the *Physician's Guide to Assessing and Counseling Older Drivers* (18). This was a cooperative effort between the AMA and the U.S. National Highway Traffic Safety Administration. It was developed by consensus of an advisory panel of clinicians, researchers, and representatives of medical specialty societies and organizations that serve the elderly. The primary goal of the guide was to educate physicians and provide them with assessment and management tools to address driving in elderly populations, but overall it is also of value to physicians and therapists who work with stroke survivors of any legal driving age. The AMA guide is divided into chapters, many of which include specialized resources for evaluating and managing driver safety issues (Table 48.2).

The AMA guide lists a series of "red flags" for medically impaired driving that should alert the physician to potential driver safety issues. Those particularly applicable to stroke include concerns about the patient's driving expressed by family members, the presence of multiple chronic medical conditions, polypharmacy (especially use of medications with potential sedative effects), and a history of episodic or unpredictable events, such as hypoglycemia, cataplexy, angina, or syncope. Family members should be queried about recent crashes, near misses, traffic tickets, unexpected or unexplained episodes of becoming lost, and forgetfulness. The presence of any of these should trigger a formal evaluation of driver safety as outlined earlier.

COMMON PROBLEMS AND MEDICAL DECISION MAKING

Your patient has sustained a stroke. The following is a series of questions and answers concerning reporting, testing, and medical responsibility.

1. Do physicians have to report to "the authorities" that their patient sustained a stroke?

The answer to this varies according to the patient's residence, the type of stroke sustained, and the sequelae of the stroke itself. States and provinces have different responsibilities. Most provinces and a few states have mandatory reporting, which means that the physician must report the patient to the state or provincial motor vehicle licensing authority if the stroke has caused any type of physical, cognitive, psychological, or other abnormality that could affect the ability to drive. It does *not* mean that every patient with the diagnosis of stroke must be reported, as is the case in Belgium, where it is mandatory for physicians to report all acute stroke patients, who must then refrain from driving for six months.

There are stroke survivors without residual neurologic deficits who do not need to be reported; but it is the physician's responsibility to establish that fact with objective tests and examination. If the physician is uncertain about the apparent full recovery, reporting the patient may relieve the physician of potential liability for negligence or damages, if the patient is subsequently involved in an accident (see discussion following). Not reporting the patient in a state with mandatory

reporting may leave the physician in violation of civil law and may make defending a lawsuit for damages more difficult.

In some states and provinces, reporting potentially unsafe drivers is encouraged but not required. In that case, before the physician sends any driving-related information to the state or provincial authority, he or she should obtain the patient's consent to do so. Liability for reporting confidential information without the patient's permission (technically a breach of confidentiality) and immunity from prosecution or lawsuits arising out of such reporting vary from state to state.

For example, the state of Illinois, which has no mandatory reporting for physicians, legally obligates *drivers* to declare at the time of license application or renewal whether they have "any mental or physical condition that might interfere with driving," among other topics. Drivers are also supposed to notify the motor vehicle department of any medical conditions that may cause a loss of consciousness or affect safe operation of a motor vehicle within 10 days of becoming aware of the condition. The driver is thereafter obligated to produce a "physician's statement, a medical agreement, and/or the appropriate court documentation." The physician, however, is neither legally obligated to submit information regarding the medical condition of a patient nor can be held liable for providing this information. A specific form that provides medical documentation related to the patient's ability to drive safely has a corresponding patient section that must be completed as well. The physician can request that any or all of the three components of a driving test (written, vision, and road) be performed. The state Medical Review Board may also compel the patient to take any or all of these tests (4).

In contrast, in Pennsylvania "all physicians and other persons authorized to diagnose or treat disorders and disabilities must report to The Pennsylvania Department of Transportation any patient 15 years of age or older, who has been diagnosed as having a condition that could impair his ability to safely operate a motor vehicle." Reporting is confidential. Physicians who report are granted immunity from breach of confidentiality, and are immune from civil or criminal liability related to a patient driving and becoming involved in an accident. Failure to report leaves the physician open to possible conviction of a summary criminal offense (for not reporting) and to possible liability in case the patient has a motor vehicle accident (73).

While the patient–physician relationship is usually built on trust, noncompliance with physician recommendations and treatment occurs frequently. The incidence of noncompliance with medical recommendations not to drive has not been studied in stroke survivors, but it has been studied in people with seizures. Salinsky et al. gave an anonymous questionnaire to 158 outpatients in an epilepsy clinic and found that if the patients were required by law to report seizures to the department of motor vehicles (but the physicians were not so required), 96% would tell their physicians if they had breakthrough seizures, but only 56% would report this to their department of motor vehicles (74). Under mandatory physician reporting, only 84% would inform their physician. A total of 17% endorsed that they would

inform the physician but continue to drive, despite advice from the physician not to drive and despite the automatic license suspension from the state after being reported (74). Extrapolating to stroke patients, it cannot be assumed that just because the physician tells the stroke survivor not to drive, the patient will automatically comply.

2. Does my patient with a stroke have to stop driving? To return to driving, is it necessary to undergo an ORA?

According to the Canadian Medical Association (72), patients who have had a stroke "should not drive for at least 1 month. During this time they require assessment by their regular physician. They may resume driving if functionally able, if a neurologic assessment discloses no obvious risk of sudden recurrences, and if all underlying causes have been addressed with appropriate treatment. When there is a residual loss of motor power, a road test may be required." While there is no absolute, evidence-based foundation for the one-month restriction, many provincial legislative bodies agree with this decision. Delaying return to driving to give the patient time to recover more fully, regain stability, or undergo testing makes sense medically.

3. What is the liability of the physician if a reported patient is involved in a motor vehicle accident?

Most, but not all, states and provinces protect the physician from at least some liability (damages or breach of confidentiality) if a patient has been reported for medical reasons to driving authorities. If a stroke patient who is not reported is personally involved in an accident (whether at fault or not), the physician could be sued for negligence and for damages resulting from the accident (18). The case against the physician would likely be strengthened if the plaintiffs can prove the physician was legally obligated to report the patient to state or provincial authorities or if the physician failed to counsel the patient not to drive. For example, if a poststroke seizure is not reported and the patient is not instructed to stop driving, the physician could be held liable if the patient is involved in an accident.

4. Do certain strokes require different types of reporting or attention by the physician?

In general, there is no specific type of stroke that absolutely requires a report to a driving authority. However, the Canadian Medical Association guide indicates that "untreated cerebral aneurysms" are an absolute barrier to driving any class of vehicle, and a waiting period of three months for a private driver and six months for a commercial driver is required (72). A recent "medical expert panel" reviewed guidelines for commercial motor vehicle drivers and recommended driving cessation for one year after a TIA or stroke (75). These recommendations have face validity but are based on somewhat limited scientific studies focusing on stroke and/or epilepsy risk following a TIA or stroke. They make medical sense but are quite empirically based and reflect how every case must be approached on an individual basis.

5. Can I restrict the type of driving that my patient performs?

A restricted driving license—meaning a license indicating that the person cannot drive at night, at certain speeds, or on certain roads—is available in only a few states and provinces in North America. In Utah, for example, the Utah Driver License Division indicates that a restricted license with speed and/or area restrictions may be issued if there are moderate impairments. The province of Saskatchewan has a restricted license as well. Marshall et al. studied whether people with restricted licenses were involved in more vehicle infractions or accidents than those without restricted licensing. The available data did not indicate a significant difference, but because of the use of provincial records, the driving patterns of the study subjects could not be ascertained (76). As a group, stroke patients appear to self-restrict when, where, and how much they drive (31). Older patients are known to self-restrict as well, for example, not driving as frequently in the dark or in inclement weather (31).

6. Can my patient with isolated homonymous hemianopsia return to safe driving?

Homonymous hemianopsia can affect safe operation of a motor vehicle, especially if the patient has associated perceptual deficits. In many, but not all, states, patients with homonymous hemianopsia fail to meet visual field licensing criteria (usually 110) (18). In Canada, however, hemianopsia alone is not an absolute contraindication to driving. A person with congenital homonymous hemianopsia took his case to the Supreme Court of Canada, where it was decided that if hemianopsia did not affect driving performance, it was not an absolute criterion preventing an individual from driving (77). Blindness of one eye also does not, by itself, make driving unsafe.

7. When should the physician inform the patient about the decision to report to driving authorities?

This issue should preferably be discussed as soon as the decision is made. In a state or province with mandatory reporting, the situation is made much easier. The physician emphasizes the legal obligations and necessity to report a person who may have impairments that could affect driving safety.

In jurisdictions without mandatory reporting laws, the physician reporting a patient without first obtaining consent risks liability for breach of confidentiality. However, even when reporting is mandatory and anonymous, it is ethically appropriate to share with the patient the physician's legal obligation to report. The physician should limit information in the report to the minimum needed for the state to process the report appropriately. Being open with the patient is important to maintaining the patient–physician relationship. It may also help the patient accept the reality that driving may not be safe. The physician should also obtain the patient's permission before speaking to family members and caregivers (18), unless the patient lacks the capacity.

8. What therapy is available to improve my patient's potential to drive safely?

In general, there are no specific therapies that have been shown to speed up the recovery process to enable earlier return to safe driving. The physician should address stroke-related disabilities with appropriate therapies, including strengthening, conditioning, and coordinating visuoperceptual training. The study by Akinwuntan et al. suggests that training with a computerized driving simulator may be helpful in preparing some patients to be safe drivers (55). Training in UFOV may also be of benefit for patients with right-brain lesions (78).

CONCLUSION

Driving after a stroke is possible, and clinicians are encouraged to work within the enacted legislations to enable their patients/clients to drive. However, evaluation of the patient who has sustained a stroke must take into account any possible residual physical, cognitive, and perceptual impairments that may impede safe driving. The authors have identified the imperfect but relevant research on driving after stroke, as well as the physician responsibilities and requirements to report unsafe drivers. In general, if there is uncertainty about the stroke survivor's ability to drive, a formal driving evaluation, including an on-road assessment, should be done. This may not always happen, but the authors believe that this is a principle that society should mandate. Future research should focus on the effects of specific neurologic deficits on driving, the consequences of driving cessation after stroke, better screening tools to identify unsafe drivers, and alternate systems of community transportation to support stroke survivors.

Sports and Recreation

Amy X. Yin, Cheri A. Blauwet, and David M. Crandell

There is more to life than putting on your pants (1).
—Mary Vining Radomski

Sports and recreation can play an important role in stroke recovery and rehabilitation. The World Health Organization (WHO) defines *recreation* as engaging in programs of physical fitness, organized play, and sports (2). The WHO further defines *sports* as engaging in games or athletic events, performed individually or in a group. Sports need not be formal or competitive to be enjoyed. Participation in sports and recreation can be rooted in the context of specific rehabilitation goals of increased flexibility, strength, endurance, balance, and coordination. With the adoption of the Convention on the Rights of Persons with Disabilities, the United Nations has acknowledged sports, among other areas, as a human right for persons with disabilities (3). This includes the encouragement and promotion of participation, to the fullest extent possible, of persons with disabilities in sporting and recreational activities.

> Participation in disability sports rebuilds lives. When your life has been turned upside down by a disability, you need successes and you need accomplishments and you need them immediately. Participating in sports rebuilds. It's both a rehab tool and a lifestyle tool available to everyone (4).
>
> —Kirk Bauer, Executive Director, Disabled Sports USA (DSUSA)

Every individual, with or without a disability, requires access to opportunities in sports and recreation to ensure full participation in the community as well as functional independence. Sports and recreation can be powerful tools to enhance the abilities of stroke survivors, rather than focusing on the impairments or functional loss incurred at the time of injury.

The origin of sports and recreation for individuals with disabilities in the United States can be traced to informal games at veterans' hospitals in the 1940s. Many veterans from World War II returned home with newly acquired physical disabilities and emotional trauma from their experiences. By playing wheelchair basketball, veterans with disabilities rediscovered the joy of participating in sports. The first documented game of wheelchair basketball took place in California in 1946 (5). By the late 1940s, intrahospital games had led to state and national competitions in the United States.

Around this time, Dr. Ludwig Guttman, a neurosurgeon working on the spinal injuries unit at Stoke Mandeville Hospital in England, introduced sports and recreation as part of the standard rehabilitation program for his patients. In 1948, Dr. Guttmann organized an archery competition for 16 servicemen and women with disabilities called the Stoke Mandeville Games. These games were held to coincide with the opening ceremony of the 1948 London Summer Olympics. Today, the Stoke Mandeville Games are considered to be the precursor to the modern Paralympic Games (6).

> By restoring activity of mind and body, by instilling self-respect, self-discipline, a competitive spirit and comradeship, sport develops mental attitudes that are essential for social reintegration (7).
>
> —Dr. Ludwig Guttman

In 1960, the first official Paralympic Games took place in Rome, Italy, featuring 400 athletes from 23 countries. By 1976, sport categories for amputee and blind athletes had been added to the Summer Paralympic Games in Toronto. In 1980, athletes with cerebral palsy were also added to the roster (6). As of 2012, there are 10 impairment types eligible for participation in competitions. Athletes with impairments such as reduced muscle power or range of motion, hypertonia, ataxia, athetosis, visual impairment, and intellectual impairment may qualify to compete in the Paralympic Games. Individuals who have sustained a stroke may certainly experience any number of these impairments (8).

As the Paralympic movement evolved, it became clear that a focus on grassroots programs was necessary to create equal access to disability sports opportunities in the United States. At the 1996 Summer Paralympic Games, the Atlanta Paralympic Organizing Committee developed a legacy program to nurture community-based adaptive sports. BlazeSports Georgia was founded and named after the Atlanta Paralympic Games' mascot, "Blaze." Initially a local

program, this evolved into a national organization in 2002. By that time, BlazeSports America was in partnership with programs and teams in at least 60 communities and 29 states in the country. In 2006, the organization became international, expanding programming into low-resource settings such as Egypt, South Africa, Iran, and Haiti. Today, BlazeSports is recognized by the United States Olympic Committee as the national coordinating body for competitive youth sports for individuals with disabilities, including cerebral palsy, traumatic brain injury, and survivors of stroke (9).

The 2012 London Paralympic Games reached new heights of sports competition participation and coverage. A total of 4250 athletes from 164 countries competed in 20 sports and 503 medal events. 251 world records were broken. Media coverage expanded to include more than 100 countries and territories. The London Games were also the first to emphasize social and online media, with 1.9 million visitors to the official website of the Paralympic Movement (www.paralympics.org) and more than 9 million views of sporting action on the International Paralympic Committee (IPC) YouTube channel (10,11). While this was a breakthrough Games in terms of global expansion, it was exceeded by the recent 2014 Sochi Paralympic Games. The Sochi Games was record-breaking in terms of athletic performances, ticket sales, and media coverage. In fact, it attracted a record cumulative global TV audience of nearly 2.1 billion people (12).

THE ROLE OF SPORT IN STROKE REHABILITATION

Cardiovascular Fitness and Secondary Stroke Prevention

Therapeutic exercise is a mainstay of stroke rehabilitation. It may lead to improvements in physical function as well as flexibility, range of motion, muscle tone, strength, and coordination. Regular exercise has been shown to have a broad impact in individuals with disabilities. Some of these effects include improvements in restorative sleep, maintenance of bone density, improvement in weight control, and impact on preventing secondary disabling conditions (13). Specific to the stroke population, there is growing evidence that exercise may play a role in secondary stroke prevention and mitigation of cardiovascular complications (14). A decline in aerobic fitness resulting from physical inactivity may increase the risk of cardiovascular disease and subsequent strokes or myocardial infarctions (15). In a study of 33 stroke survivors, Baert and colleagues noted that those most at risk for aerobic deconditioning after stroke were individuals who were premorbidly diabetic, premorbidly less active in work or sport activities, and/or initially more severely impaired by the stroke (16). These patients would likely most benefit from aerobic conditioning. However, the cardiovascular effect of a contemporary stroke rehabilitation program is often too low to induce a positive aerobic training effect (17). In this setting, it is useful to consider the role of vigorous or intensive adaptive sports participation as a tool for improved cardiovascular fitness and with it, secondary stoke prevention.

Studies also implicate cardiovascular exercises in improving cerebral blood flow after stroke. In a study by Ivey et al., 38 participants, all more than 6 months after stroke, were randomized into a treadmill training group versus a nonaerobic stretching group. Transcranial Doppler studies were performed both before and after the intervention. Findings revealed a statistically significant improvement in ipsilesional and contralesional cerebral vasomotor reactivity in the treadmill training group. Additionally, the treadmill training group displayed a 19% increase in peak oxygen update (VO_2 max) as compared to the nonaerobic stretching group (18).

Furthermore, recent evidence reveals that physical activity can impact both cardiovascular health and several functional parameters after stroke. Michael et al. conducted a pilot intervention study using adaptive physical activity in stroke survivors (19). The intervention produced improvements in balance, six-minute walk time, and peak exercise capacity. Exercising in group sessions also promoted self-worth and reinforced behavioral change for improved daily function. Stoller et al. performed a meta-analysis of prospective controlled studies utilizing cardiovascular or aerobically based training strategies within six weeks of stroke. Across these studies (n = 11), improvements were found in peak oxygen uptake (VO_2 max) and walking distance (20). These findings were supported by a 2009 Cochrane Review on physical fitness training for individuals with stroke. In this systematic review of 24 randomized controlled trials with a total of 1147 subjects, cardiorespiratory training involving walking-based activities (e.g., treadmill training) was found to improve both walking endurance and walking speed. Although this supported the use of cardiorespiratory interventions in stroke rehabilitation for functional gains, the authors could not determine the effects of these training programs on death, overall level of dependence, and degree of disability (21).

Prior to engaging in vigorous physical activity, stroke survivors must be aware of the inherent risks and benefits of participation. To date, evidence supports the overall safety of exercise as an intervention in this population (22–24). Duncan et al. reported no major adverse outcomes such as cardiac events or death during a series of aerobic exercise sessions for stroke survivors. Although subjects involved in the study did experience a total of three recurrent strokes, no strokes occurred during an exercise treatment session or at a time clearly correlated with bouts of exercise (24). A subsequent meta-analysis of aerobic exercise training in individuals with stroke found very few adverse events, and investigators concluded that it would be unlikely for exercise training to contribute to stroke recurrence (15). In sum, evidence supports the use of vigorous physical activity as safe and effective in improving both aerobic fitness and functional parameters after stroke.

Neurorecovery and the Use of Gaming Technology

Another key aspect of stroke rehabilitation is the facilitation of neurorecovery. Earlier and more aggressive rehabilitation takes advantage of neural plasticity and brain remodeling to regain function (25). Starting therapy with higher-level activities soon after stroke can improve functional outcomes even in individuals with severe cognitive and motor impairments (26,27). A study by Horn and colleagues (28) indicated a strong and consistent association between improvement in outcomes and activities that challenge individuals beyond their current functional level. In this cohort of 830 people, participants practiced upper-extremity functional activities as rehabilitation exercises rather than focusing on trunk strengthening alone. Results revealed a relative increase in trunk strength as a secondary outcome of the upper-extremity activities. The authors concluded that there may be many benefits to attempting high-level activities that otherwise would seem excessively challenging according to common clinical practice. Thus, sports and recreation for stroke survivors may be an important component of a comprehensive stroke rehabilitation program (29) and can encourage patients to push themselves beyond their own expectations.

Specifically, gaming has become an increasingly utilized recreational activity to help stroke recovery. Studies on stroke rehabilitation point to task repetition as a way to enhance brain remodeling and maintain long-term function (30). Effective therapy for motor learning after stroke includes progressively challenging, high-repetition, goal-oriented, skilled movement tasks (31). These interventions target neural plasticity for lasting change, but it is difficult to achieve the high frequency and intensity of movement needed in any given therapy session. Patients are also often unable or unwilling to adhere to the prescribed home exercises. Novel recreational activities using robotics and virtual reality (VR) gaming technology may assist individuals in achieving the specific task-related training needed to capitalize on early neuroplasticity.

Several small studies have demonstrated that interactive gaming and VR technology combined with conventional therapy may yield increased functional gains. A meta-analysis by Saposnik et al. evaluated the use of computer-based VR technology for upper-extremity motor recovery after stroke in 195 individuals (32). The authors analyzed data amassed from both randomized controlled trials and observational studies. The pooled data from 5 randomized controlled trials indicated that the VR group was 4.89 times more likely to achieve motor improvement compared to the control group. The 7 observational studies showed a 20.1% improvement in motor function in the VR group as measured by the Wolf Motor Function Test, Box and Block Test, and Jebson-Taylor Hand Function Test. This study was supported by a Cochrane review of 19 studies with 565 total patients in which VR and interactive gaming were shown to be more effective than conventional therapy in improving both upper-limb function and activities of daily living (33). Other studies also suggest that interactive gaming and VR may have a role in cognition as well as lower-extremity function and dynamic balance (34,35).

Gaming and VR systems may vary from intricate robotics or complete immersion systems to low-cost commercial gaming products that are readily available. Regardless of the complexity of the system, these recreational technologies have the potential to keep people on track in their rehabilitation and recovery. Gaming strategies may reinforce sensorimotor components of neural plasticity through the use of sensory input for repetitive and demanding goal-oriented movements and postures (36). It is clear that recreational gaming may be an underutilized tool in furthering the functional recovery of individuals with stroke.

Performing Arts and Sports Alternatives as Novel Rehabilitation Strategies

Recreational activities such as listening to or performing music, dancing, and participating in tai chi or yoga should also be considered as potential strategies in the rehabilitation of stroke survivors. Clinicians need to remember that individuals with stroke have diverse interests. For those who are not sports inclined, there are many alternative forms of recreation or leisure that can keep anyone engaged.

Tai chi is an ancient exercise that is beneficial and exceptionally suitable for today's stroke survivor. Taylor-Pillae and Coull enrolled 28 individuals who were at least 3 months after stroke in a 12-week pilot study (37). Participants in this study performed 150 minutes or more per week of tai chi, which aligns well with national physical activity recommendations for individuals with disabilities. The study demonstrated that tai chi exercises are safe and lead to improvements in balance in stroke survivors. It was also well tolerated by study participants and resulted in high patient satisfaction. Additionally, modified and/or adapted yoga can lead to significant changes in poststroke balance as well. In a pilot study by Schmid et al., clinically meaningful improvements in balance and balance self-efficacy were found among yoga-based rehabilitation participants (38). In postintervention interviews, study participants reported improved confidence in maintaining their balance and were more willing to attempt new activities in different and challenging environments. Even as further randomized studies are needed to determine the full spectrum of functional benefits of tai chi and yoga, the evidence remains promising.

Music and performing arts may optimize rehabilitation learning by creating a multisensory environment (39). A study by Sarkamo et al. suggested that individuals with stroke who listen to music on a daily basis may experience structural gray-matter changes as well as improved auditory and verbal memory, focused attention, and mood early after stroke (40). Although the mechanism for this was unclear, the authors put forth several theories. Cognitive arousal and emotions from music may biochemically modulate the dopaminergic mesolimbic system or enhance glutamatergic

neurotransmission. Other possible mechanisms involve neural plasticity. Music may provide environmental enrichment that increases brain remodeling, or it may decrease poststroke stress and cortisol levels, which are maladaptive. Although the mechanism by which multisensory stimulation from music and performing arts may not be well understood, there appears to be little harm and potentially much to gain with its use.

Beyond the potential for music to affect cognition and neuroplasticity, it may also have a direct impact on functional skills. Several studies have used music-movement therapy or music-supported therapy with musical instruments for rehabilitation (41,42). Rodriguez-Fornells et al. described the use of musical instruments such as the piano or drums for stroke rehabilitation (42). There are many possible reasons why music-supported therapy can be advantageous. The use of musical instruments may once again promote neuroplasticity because of the high number of repetitions that are required to play or practice with an instrument. Furthermore, music-supported therapy can shape the complexity of the movements based on function and progress. Another advantage is the immediate audio-motor coupling, whereby each movement is reinforced by auditory feedback from the instrument. Lastly, music-supported therapy may feed into emotional–motivational effects. Music can improve general mood as well as decrease anxiety and depression (42,43).

Though dance therapy is a commonly used strategy within other fields of rehabilitation, little has been published regarding its use in the stroke population. One case report did use adaptive dance, specifically the tango, as therapeutic treatment in a stroke survivor who reported great interest and enjoyment (44). More study is needed to evaluate the potential functional and rehabilitative benefits of dance therapy in stroke survivors.

Stroke survivors may choose from a wide assortment of recreational and leisure activities in order to stay active. Whether it is performing tai chi or yoga, listening to or playing music, or dancing, all these activities are fun and may aid individuals with stroke in their recovery.

Social Integration and Quality of Life

For those who wish to pursue active lifestyles after a stroke, the potential for sport and recreation to improve mental health outcomes and quality of life (QOL) is profound (45,46). A preponderance of evidence has demonstrated the positive impact of community sports participation on confidence, self-efficacy, community integration, and socialization in stroke survivors. Several recent studies illustrate this concept well. Stuart et al. randomized 78 adults who were at least 8 months after stroke into either a progressive, community-based exercise regimen at a local gym or "usual care" in an outpatient physical therapy setting within a rehabilitation facility (47). Participants engaged in a community-based exercise regimen had significant improvement in social participation domains of the Stroke Impairment Scale (SIS). This improvement was greater than that of participants who engaged in usual care. Another study by Rand et al. evaluated the association between physical activity and health-related QOL (48). Those with a higher level of daily physical activity (as measured by accelerometers) scored higher on the Medical Outcomes Study Short-Form 36 (SF-36) physical component section.

In and of itself, social participation is positively associated with a high QOL after stroke (49–51). Leisure satisfaction has been found to correlate highly with overall life satisfaction (52), and the failure of stroke survivors to resume prestroke leisure activities can interfere with poststroke functioning (49). Bhogal et al. found that a reduction in social and leisure activities both in and outside the home led to increased rates of depression, ineffective coping, and difficulties in social integration in stroke survivors. These findings were more common in those who were young at the time of their stroke (49). Even if stroke survivors regained their physical independence, they frequently did not return to the typical social activities that they had enjoyed prior to acquiring a disability (51). Kwok et al. found that the presence of depression had greater adverse effects on QOL than deficits in basic functional disabilities. Additionally, it was noted that group exercises promoted socialization and community reintegration, thus lessening the negative effects of depressive symptoms (53).

Given this positive association between physical activity, sports participation, and QOL after stroke, it is important that opportunities be available for individuals to engage in community programs within various settings. Here we offer two examples: sports participation in a clinical rehabilitation setting and sports participation within a university-based educational system.

The Spaulding Adaptive Sports Center (SASC), an initiative of Spaulding Rehabilitation Hospital, focuses on creating an innovative and exciting adaptive sports and recreation program. Taking advantage of Spaulding's unique location on the banks of the Charles River in Boston, SASC's flagship program offers a variety of water- and land-based activities. Participants represent a wide spectrum of rehabilitation diagnoses and include both inpatient and outpatient stroke survivors. SASC program staff represent the multidisciplinary construct of rehabilitation. The team consists of professionals trained in therapeutic recreation, physical therapy, and occupational therapy as well as volunteers from the nursing and medical staff. Recruitment is achieved from our inpatient rehabilitation programs, outpatient therapies within the Spaulding network, and the community. Seasonal sporting activities currently include downhill skiing, cycling, windsurfing, outrigger canoeing, kayaking, rowing, paddle boating, and wall climbing, among others. One component of the program specifically designed for stroke survivors is the use of modified hand cycle and windsurf equipment for participants with hemiparesis (Figures 49.1 and 49.2).

The emergence of organized sports programs within collegiate sports departments has also offered the opportunity for individuals with disabilities, including stroke

FIGURE 49.1 Adapted windsurfing.

or cerebral palsy, to engage in sports while also attending university. In one study, college students with disabilities were offered the opportunity to engage in sports such as swimming, horseback riding, racquetball, fitness, bowling, tennis, tai chi, walking, and/or weightlifting. Students who engaged in the activity for 5 to 24 weeks reported that their perceptions of social self were expanded by the experience, and that they initiated more social activities (46). Participants indicated that the program got them out of the house, gave them opportunities to meet new people, and offered opportunities for increased interaction with persons both with and without disabilities (46).

Participation in adaptive sport and recreation represents the desire of stroke survivors to have typical athletic experiences and to reach their optimum level of physical fitness, skill, enjoyment, and life satisfaction. The goal of comprehensive rehabilitation for stroke survivors is the attainment of an optimal level of independent living and QOL. Combining the two components into a "game plan" can promote healthy lifestyles and reduce the effects of impairment and disability. For many, adaptive sports and recreation is an integral part of stroke recovery and serves to increase enjoyment in leisure activities, enhance the sense of self-confidence and achievement, and ensure community access and social integration.

CASE HISTORIES: EXAMPLES OF THE "DIDS" AND "DID-NOTS"

To understand sports and recreation as a rehabilitation tool for stroke survivors, it is important to appreciate the individual's own concept of these topics before and after stroke. We characterize two major prestroke categories as the "dids" and the "did-nots." The "dids" are those individuals who participated actively in either recreational or competitive sports prior to their stroke. The "did nots" are those individuals who, like many sedentary adults, did not participate actively in any sports or recreation program. It is useful to examine the stroke survivor's self-concept of sports participation to best understand what strategies may be the most appropriate for him or her.

"Dids"

Case One

A 37-year-old engineer experienced a cardioembolic stroke as a consequence of aortic valve replacement surgery. Sequelae included a mild left-sided hemiparesis and mild left visuospatial neglect. Prior to his stroke, he was physically active, working in construction and playing regularly in an

FIGURE 49.2 Adapted cycling.

adult hockey league. He had also played college hockey at a competitive Division I program and was the coach of his young son's hockey team.

Two of his rehabilitation goals were to return to skating and to continue to coach his son's team. He did well in acute rehabilitation, went home, and continued to attend outpatient therapy. During his initial follow-up appointment, he reported that he was happy to be back at the hockey rink, coaching his young son. During his next follow-up, he reported that he was now also skating with his son.

After several months, he was back to playing hockey himself. His comment was that although he had "lost a step" and had some difficulty up against the boards, he was still able to play competitively and safely. Most importantly, he was still having fun. He joked that he had always been better than his younger brother at hockey, but the situation was reversed after his stroke. Despite this, he was not deterred and was determined to improve and get back to beating his brother. His participation in sports offered a healthy outlet for his drive to compete, an inherent part of his personality that was not affected by experiencing a stroke. This drive motivated him to push his rehabilitation efforts even further, and make substantial progress in only a brief period of time.

Case Two

A 34-year-old psychologist experienced a brainstem hemorrhagic stroke caused by an arteriovenous malformation at 38 weeks of her first pregnancy. She remained hospitalized and delivered her child via a cesarean section. She and her new son did quite well; her residual deficits included mild left hemiplegia, intermittent double vision, and right facial hemisensory deficit.

Six months after her stroke, she expressed frustration with her ongoing standard outpatient physical and occupational therapy program, especially with the rate and level of her functional recovery. Prior to her stroke, she was an accomplished athlete, competing in singles tennis at a Division I university. She was also the age-group winner in several local triathlons. Even well into her pregnancy, she was running and biking up to 30 miles per week. During her rehabilitation program, she had developed left patellar tendonitis and had also exacerbated back and shoulder problems from prior sports injuries.

At the time of outpatient follow-up, her rehabilitation program was refocused on her goals of wanting to walk at typical speeds without asymmetry, and also to run again. She was referred to a local sports therapy program that was experienced in working with elite athletes and utilized aquatic therapy. For her, it was an excellent fit because the treatment approach matched her identification as an athlete, not as a stroke survivor. She was used to pushing herself, and her therapist was able to raise the effort to a level and intensity that she could relate to. She was not willing to settle for any goals that did not include running again and, with time, was able to achieve this goal.

These two examples of "dids" show the importance of sports in these individuals' lives, which intuitively did not change in the setting of having experienced a stroke. In these cases, setting sport-specific goals was no different from establishing other short-term rehabilitation goals. Returning to sports helped each individual reach the highest functional level possible and continued to be a positive driving force in their rehabilitation.

"Did-Nots"

Case Three

A 54-year-old bus driver experienced a pontine stroke thought to be related to poor adherence to his prescribed antihypertensive medications. His impairments included a mild dysphagia, right-sided weakness, and poor sitting and standing balance. His family related that, prior to his stroke, he was not physically active. They described his daily activity level as "sitting behind the wheel . . . followed by sitting on the couch."

Immediately after his stroke, he was admitted to an inpatient rehabilitation facility where he made only very slow progress during his initial weeks of hospitalization. His interdisciplinary care team attributed this limited improvement in part to low motivation and discussed strategies to move him forward in his recovery. Recreational therapy and adaptive sports were recommended.

When the therapist discussed with him the different activities that were available, he couldn't believe what he was hearing. He incredulously replied, "You want me to go *windsurfing*?"

Despite his initial reluctance, he acquiesced. He was escorted to the dock by the adaptive sports staff and went for his first sail with a tandem windsurfer designed for individuals with hemiplegia. After his session, his family immediately noticed his improved vigor and spirit when he returned to the patient floor. He couldn't stop relating his positive experience to the other patients. His performance in therapy also gained some momentum. Feedback at subsequent interdisciplinary meetings was very positive, and the team consensus on his prognosis changed to believing he would likely meet his inpatient rehabilitation goals. Both the patient and his family also came to realize that if he could windsurf after his stroke, then many of the hurdles they had envisioned could be overcome with time and a proactive attitude.

Case Four

A 58-year-old senior accountant experienced an intracerebral hemorrhage as a complication of anticoagulation therapy for a deep vein thrombosis. This required an emergent right-sided craniotomy and resulted in a seizure disorder, which was managed during a series of acute and rehabilitation hospitalizations over the course of a year. The patient had a significant left-sided hemiparesis and impairments in attention, memory, and motivation. He was also clinically depressed. Despite his employer's promise that "you'll have your job when you return," he found himself unemployed with little prospect for a new job during a severe economic recession. This contributed to his ongoing frustration with his recovery.

His wife described her husband as a "nonadventurous type" who was quite sedentary in his work before the stroke, though he did sing in a choir. As his efforts in sending out resumes remained unfruitful, he related that he was not sure how he could perform in an interview, even if he did get a call back. Shortly thereafter, he was referred to an Adaptive Sports Program. He had always admired the many rowers he had seen over the years on the Charles River not far from his former office, so he selected rowing as his first activity. With a minor adjustment to secure his oar, he was out enjoying his new view of Boston. He was thrilled, as was his wife, and he continued to attend adaptive sessions with improved performance and a buoyed outlook on his abilities. He joined Boston's Community Rowing Program and now rows independently in a modified shell. He has also returned to his choir, which continues to give him a spiritual lift.

He is still working on his ultimate goal of returning to work as an accountant. Despite his inability to find compensated work, he has been quite satisfied in volunteering part-time for a community housing agency. With this, he has learned new skills and has improved his communication while handing out books from a loaner cart and relating his story to medical and physician assistant students throughout the year.

These two cases of the "did-nots" illustrate the need for stroke survivors and their families to understand the benefits of sports and recreational participation for recovery. For both the "dids" and "did nots," being an "I do" is an important part of stroke rehabilitation, increasing the use of leisure time, sense of enjoyment and achievement, self-confidence, and community access. Not only can sports and recreation aid physical strengthening and conditioning, they can help reshape the view stroke survivors have of themselves and their abilities.

FUTURE IMPLICATIONS

Advocacy for Exercise Prescription and Community Access

As outlined in this chapter, physical activity, sports, and recreation may greatly affect outcomes related to enhancing secondary stroke prevention, neurorecovery, and QOL. Strong consideration must be given to the routine use of an exercise prescription when recommending rehabilitative tools for stroke survivors. Whether at the time of hospital discharge, in the outpatient clinic setting, or as a component of community reintegration strategies, the concept of "Exercise is Medicine" (54) is aptly suited to this population.

Currently, at the time of discharge from inpatient stroke rehabilitation, patients are connected with either home-based or outpatient-based physical, occupational, and speech therapy services. Given that these services are typically offered through a well-established structured rehabilitation program, this transition is quite fluid. Patients are ensured continuity in establishing a schedule, finding location for therapies, and recruiting appropriate professionals for the provision of rehabilitation services. It is important to reinforce the importance of exercise and physical activity throughout this process. Furthermore, as stroke survivors undergo the stepwise transition from home or outpatient-based services to greater independence, sports and recreation are even more vital in helping patients attain long-term maintenance of an active lifestyle. Indeed, this is where many stroke survivors fail to engage in programs, such as adaptive sports or community-based exercise (e.g., local gyms), that may ensure ongoing cardiovascular fitness, previously achieved level of mobility, and health-related QOL. Physicians and rehabilitation professionals can play a critical role in supporting the success of this more complex transition from structured rehabilitation to a program based on community independence.

The achievement of this goal requires a multifaceted strategy aimed at decreasing barriers related to public access of fitness facilities and sports programs. Additionally, negative attitudes that propagate misconceptions about the willingness of individuals with physical and/or cognitive disabilities to engage in sports and exercise must be changed. In a 2008 survey of 83 adults with unilateral

stroke, the 5 most commonly perceived barriers to exercise were: (a) cost of the program (61%), (b) lack of awareness of an accessible fitness center in the area (57%), (c) no means of transportation to a fitness center (57%), (d) no knowledge of how to exercise (46%), and (e) no knowledge of where to exercise (44%). Conversely, the least common barriers from the perspective of stroke survivors were (a) lack of interest (16%), (b) lack of time (11%), and (c) concern that exercise would worsen their condition (1%) (55). From the standpoint of structural barriers, needs analyses are required to establish the gaps in community resources. Areas for investigation include accessible fitness facilities, fitness programs appropriate for individuals with mobility impairments, and adaptive sports programs serving the needs of both developmental and elite athletes (56). Regarding attitudinal barriers, there is an overwhelming need to provide further educational programs to professionals outside the scope of traditional rehabilitation (e.g., athletic trainers, fitness class instructors, coaches) to ensure that these individuals have the appropriate skill set to work with the unique population of stroke survivors. Finally, the creation of direct referral services from rehabilitation-based settings to community-based settings can serve to transition stroke survivors at the completion of structured therapies.

Rehabilitation professionals, including physiatrists, therapists, nurses, case managers, and social workers, are uniquely suited to be the drivers of change on this critical topic. Through a multidisciplinary approach, ongoing advocacy initiatives will push our communities, as well as stroke survivors themselves, to a more comprehensive understanding of the need for engagement in physical activity, sports, and recreation.

Final Quips: "The Bruschi Effect"

On February 18, 2005, public health officials in Boston, Massachusetts, reported a significant increase in neurologic and stroke-like complaints in emergency departments around the city. An unusually large number of young men came in complaining of headache, blurred vision, and unilateral weakness. The greatest increase (25%) in these visits was found among young men ages 20 to 49. There was no geographical clustering and no known toxic exposure or unusual illness reported (57). This phenomenon was termed the "Bruschi Effect" (Figure 49.3) and occurred after the media broke the story that New England Patriots professional football player Tedy Bruschi had suffered a mild stroke and was hospitalized at the Massachusetts General Hospital. Even though there had been a significant increase in stroke-related complaints, public health officials did not detect any corresponding increase in the actual diagnosis of stroke. A compensatory decrease in the number of stroke-related visits was observed the following week.

> When there is heightened media coverage of a particular illness—in this case, stroke—it is not unusual for the public to react. (57)
>
> —Dr. John Rich, Medical Director of the Boston Public Health Department

In 2005, Tedy Bruschi was a 31-year-old defensive linebacker and 9-year NFL veteran at the top of his game. He was a pivotal player in the Patriots' 2005 Super Bowl victory with a key fourth-quarter interception. It was just 10 days later that he was taken urgently via ambulance to the hospital after complaining of left arm and leg numbness,

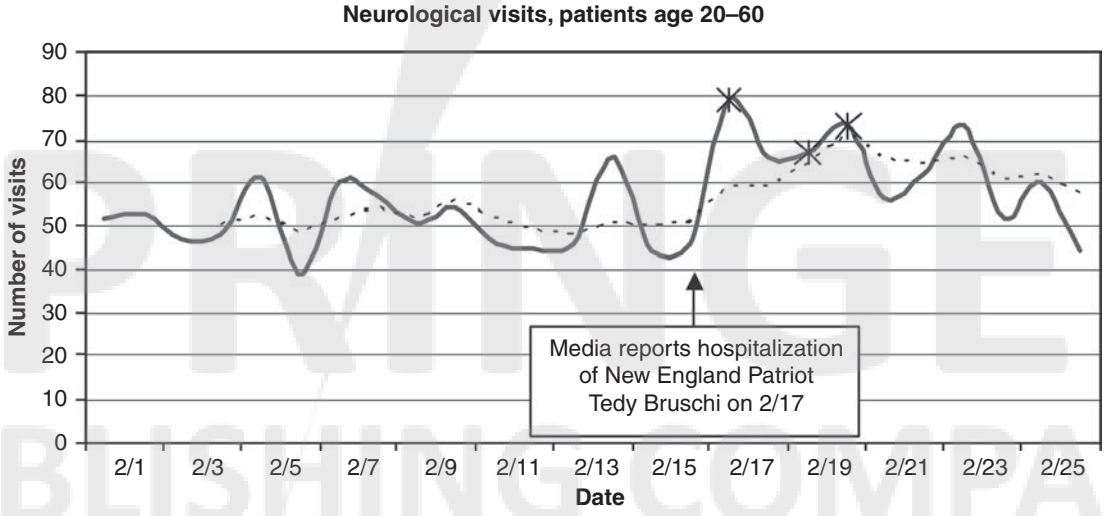

FIGURE 49.3 "Bruschi Effect."

blurred vision, and headache. He had experienced a small right-sided stroke, and an echocardiogram revealed a patent foramen ovale (PFO). He did well with his rehabilitation and the PFO was subsequently closed. After only eight months, Bruschi returned to playing football professionally.

His stroke and return to play resulted in a secondary and more lasting "Bruschi Effect," in which there continues to be an overwhelming emotional response to his unprecedented comeback. Bruschi has received thousands of letters from stroke survivors, noting that his personal story of stroke recovery has been inspirational, offering hope and an optimistic perspective to individuals around the country who have also experienced stroke.

> I don't think America knows very much about strokes, that you can get back to your life after you have a stroke. There can be a full recovery. If your normal life after a stroke is just getting back to work, maybe your normal life is playing professional football. That was my normal life. That's what I wanted to get back to. I was fortunate enough that I was able to rehabilitate myself 100% and get back to playing football again. (*USA Today*)
>
> —Tedy Bruschi

For Bruschi, returning to playing football was living his life his way. He has used his experience to raise awareness about stroke through the American Heart Association. He has been a popular and successful spokesman both on and off the field and has inspired many stroke survivors to return to sports and recreation.

Sexuality After Stroke

Monika V. Shah and Marni G. Hillinger

The importance of sexuality in the scope of human experience is profound. Sexuality is more than sexual intercourse alone. It is a complex, multidimensional phenomenon that incorporates biologic, psychological, interpersonal, and behavioral dimensions. The ability to form and sustain an intimate relationship is a fundamental aspect of human life. The impact of sexuality on quality of life after stroke and other neurologic diseases is even more powerful. Unfortunately, studies on quality of life in general and on sexual life specifically after stroke are relatively few. Although stroke is the leading cause of long-term disability worldwide, few epidemiological data are available on sexual functioning and sexual satisfaction after stroke.

The goal of this chapter is to highlight the potential challenges related to sexuality, sexual function, and intimacy that arise after stroke from a rehabilitation perspective. Because there is a higher incidence of stroke in the elderly population, the effects of aging and medical comorbidities are also reviewed. For the purpose of clinical practice, there is also a discussion of the general evaluation and management of sexuality in the poststroke population.

PHYSIOLOGY OF SEXUAL FUNCTION

Our understanding of sexuality has its foundation in the work of Masters and Johnson published in 1966 (1). It is from their work that the sexual response cycle was categorized into four phases: excitement, plateau, orgasm, and resolution (Figure 50.1). This classification provided a means by which health care professionals could more clearly identify and treat sexual dysfunction. Later, in 1974, Kaplan simplified this into three phases: desire, excitement, and orgasm (2). Regardless of the model used, it was clearly understood that sexual function relies on a complex network of both central and peripheral neural pathways.

Sexuality involves the integration of sexual interest, physiological functioning, and sexual satisfaction (Figure 50.2). The cerebral cortex represents only one level of sexual functioning at which the brain influences human sexual arousal and response. Subcortical structures, including the limbic system and parts of the hypothalamus, also play an important role in the integration and control of reproductive and sexual functions. Sexual interest may arise from thoughts, emotions, and memories, which are all mediated through complex cerebral mechanisms. Thus, sexual arousal can occur without any sensory stimulation. Sexual satisfaction is achieved not just by processes of physical arousal, but is also influenced by the feeling of intimacy as well as the health of one's own self-image. These additional aspects of psychological health can operate on both a conscious and subconscious level. By understanding the physiological, cognitive, and emotional aspects of sexuality, clinicians can better understand the impact of stroke-related disability on human sexuality.

Prevalence of Sexual Dysfunction

In the General Population

Sexual dysfunction is defined as any of a group of sexual disorders characterized by disturbance either of sexual desire or of the psychophysiological changes that usually characterize sexual response. Accurate estimates of prevalence are important in understanding the true burden of male and female sexual dysfunction as well as identifying risk factors for prevention efforts. Most studies of prevalence figures are quite variable, as they depend on case definition, characteristics of the study population, and time frame of the prevalence estimates. The paucity of information led to a gathering of 200 multidisciplinary experts from 60 countries, including members of major urology and sexual medicine associations, who attempted to provide accurate estimates of prevalence, epidemiology, and risk factors. This international consortium described a prevalence of about 40% to 45% of adult women and 20% to 30% of adult men having at least one manifest sexual dysfunction. There was a consensus that the incidence increases as men and women age. Common risk factor categories associated with sexual dysfunction include individual general health status, psychiatric and psychological disorders, and sociodemographic conditions (3). Most studies also confirm these rates of prevalence and find that, although many men and women experience sexual dysfunctions, few seek medical care to address them (4). Recent evidence also suggests that patients are more likely to seek medical care related to sexual dysfunction if their physician inquires about sexual concerns on a routine visit (5).

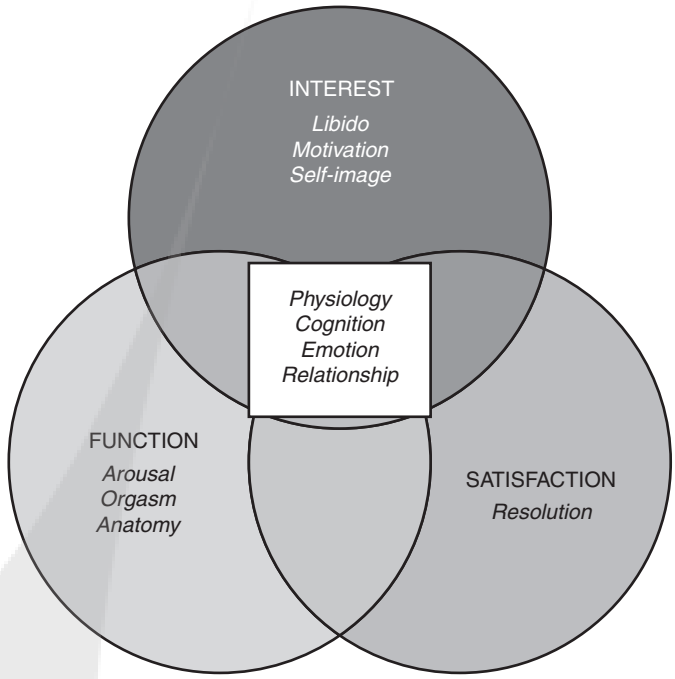

FIGURE 50.2 Concepts in sexuality and sexual functioning.

In the Stroke Population

Studies on the prevalence of sexual dysfunction after stroke are sparse compared with studies of the general population. Most poststroke studies include a small sample size of subjects with a median age of 50 years. In general, the prevalence of sexual problems after stroke or any other neurologic disability is consistently higher than in the general population, with a range of 57% to 75% (6). As the incidence of stroke itself includes a much wider age group, it becomes even more important to include both extremes of age in studying prevalence, risk factors, and treatment of problems related to sexuality.

Some studies on sexuality after stroke emphasize the importance of psychological factors in poststroke sexual functioning (7). Korpelainen and Monga suggested in separate reviews that sexual problems following stroke are never a consequence of stroke alone; rather, they may be caused by a variety of associated medical conditions and psychosocial factors (8,9). Most studies focus on sexual interest and physiological aspects of sexual ability following stroke, and there still remain few studies that address the psychosocial or intimacy issues among stroke patients and their partners.

Classification of Sexual Dysfunction

As described earlier, Masters and Johnson classified their findings into a linear sexual response cycle of excitement, plateau, orgasm, and resolution (Figure 50.1). Men and women were described as having similar physiologic characteristics. More recent research suggests that women do not always fit into this model and that their sexual experience follows a more complex pattern that extends beyond achieving adequate vaginal lubrication and having an orgasm. Thus, it is a challenge to formulate a single model that can adequately represent a single population or group. Indeed, the sexual experience in stroke survivors encompasses the impact of changes in self-esteem, body image, relationship and intimacy, pleasure, and satisfaction, in addition to the severity of disability, pain, weakness, spasticity, and many other physical variables.

Therefore, many approaches to the classification of sexual dysfunction have emerged since the time of Masters and Johnson. One modification of the Masters and Johnson model, described by Helen Kaplan Singer, adds desire as an initial response; Kaplan includes the role of subjective feeling, which involves interpersonal and psychological as well as biologic factors.

The most common classification system used by clinicians for the diagnosis and treatment of sexual dysfunction is the *DSM-5* criteria, which is also adapted from older models previously described. Table 50.1 lists the classification system for both males and females. Because of the complexity of female sexual dysfunction, the American Foundation for Urologic Disease developed another system, a consensus-based classification (Table 50.2). Although these classification systems have been revised over time to include psychological causes in addition to the organic causes of sexual dysfunction, with a particular emphasis on problems in women, there remain other important limitations. For example, disease-specific issues that can affect sexuality and sexual functioning should be assessed during comprehensive evaluation, but they are not well addressed by these classification systems.

Psychosocial Factors in Sexual Dysfunction

Korpelainen reported that psychosocial factors play a large role in determining sexual drive, activity, and satisfaction

TABLE 50.1 *DSM-5* Classification of Sexual Dysfunction

Male

- Delayed ejaculation
- Erectile disorder
- Male hypoactive sexual desire disorder
- Premature (early) ejaculation

Female

- Female orgasmic disorder
- Female sexual interest/arousal disorder
- Genito-pelvic pain/penetration disorder

Affecting both males and females

- Substance/medication-induced sexual dysfunction
- Other specified sexual dysfunction
- Unspecified sexual dysfunction

following stroke (8). Bodrini and colleagues also highlighted the crucial role that psychological and interpersonal factors play in sexuality following stroke (10). Along with common psychiatric problems seen after stroke, such as depression, anxiety, or posttraumatic stress disorder, impairment of social dimensions, such as lack of a partner or loss of job, may also play a significant role in sexuality issues after stroke.

Dependency in ADLs

It has been suggested that the degree of dependence in ADLs is a strong predictor of a decrease in sex frequency (11,12). This dependency can cause feelings of embarrassment and vulnerability as one's privacy is compromised. This may be particularly problematic when the sexual partner also provides personal care, and this is consistent with the finding that sexual dysfunction is also common in sexual partners of stroke survivors (8). This shift in role from caregiver to partner or patient to partner can have a negative effect on sexual identity. One solution is to have some aspects of care, such as toileting, carried out by a nonfamily caregiver whenever possible.

Role Shift Within the Family

The profound role shift within a family after stroke may present as anger and frustration on the part of the patient and spouse. Loss of previous roles results in a serious change in the quality and style of the interpersonal relationship, and it takes time and patience to rediscover a loving partnership. Recognizing and anticipating such changes early after stroke and providing opportunities for counseling can allow better adjustment to role changes in a partnership. Thompson and Ryan (2009) found that poststroke spousal relationships were significantly different in the realms of sexuality, sexual desire, and sexual functioning (13).

TABLE 50.2 American Foundation for Urologic Disease Classification for Female Sexual Dysfunction

Altered Body Image and Self-Esteem

Across the spectrum of medical diseases and disability, changes in self-image can have a profound impact on quality of life and satisfaction (14). Specifically, neuromuscular changes that affect movement, the use of assistive devices or adaptive equipment, and changes in bodily function can result in feelings of decreased attractiveness and self-esteem, followed by shame, frustration, and even depressed mood. There may be real or perceived fear of rejection, betrayal, and/or abandonment by the partner, resulting in loneliness or isolation and avoidance of social or sexual situations.

Lack of Sexual Partner

Because stroke survivors are often of advanced age, many have survived their sexual partner. For those who are not in a relationship, it is often assumed that sexuality is not an issue. But lack of a sexual partner does not erase a person's concern about attractiveness, sexual functioning, and potentially finding a partner in the future. Unfortunately, social opportunities for meeting others and finding potential sexual partners are often limited after stroke, which reduces the likelihood of engaging in sexual activity. It is important to provide reassurance that sexual functioning and intimacy are still possible and to assist patients in full reintegration to the community through comprehensive rehabilitation.

Fears, Myths, and Unrealistic Expectations

There are certain fears and myths around sexuality and sexual performance that are common among stroke survivors. Most commonly, the fear of a recurrent stroke can result in reduced sexual activity, decreased libido, and sexual dissatisfaction (15). Monga and others interviewed patients with stroke and their spouses about sexuality. The most common factor identified as causing a decline in sexual activity was the fear by both partners that having sex might adversely affect blood pressure and cause another stroke (9); similar fears have been described in patients with coronary artery disease (CAD) (16). In reality, the cardiac response associated with sexual activity is equivalent to climbing two flights of stairs at a brisk rate (17). The

energy expenditure is equivalent to 2 to 3 metabolic equivalents of task (METS) during the preorgasmic phase and 3 to 4 METS in the orgasmic phase (18). This level of exertion, though significant for some patients with stroke, is unlikely to overly stress cardiac function or result in a dangerous rise in blood pressure. Therefore, education, reassurance, and a focus on general physical fitness may be appropriate in certain stroke patients.

Unrealistic expectations of what constitutes a normal sex life may lay a foundation for failure. Normal sexuality is unique to each couple, as is their unique relationship. A healthy couple's perception of normalcy should align more with their personal life expectations than that of society or the media. It may be useful to discuss these misconceptions early with both patients and their partners. The recognition of unrealistic expectations, fear, and myths can serve as an educational opportunity.

Physiological Factors

Neuromuscular changes, including fatigue, weakness, and spasticity, can play a role in sexual function after stroke. Neuroendocrine factors also play a role in normal sexual function.

Neuroendocrine Abnormalities

Any brain lesion, as occurs during stroke onset, can affect the neuroendocrine system and produce an imbalance of hormone production and release, leading to erectile dysfunction, decreased arousal, and/or infertility. From a strictly physiological standpoint, normal sexual functioning involves the interaction of libido and potency. In males, erectile dysfunction (ED) is the most commonly cited complaint in able-bodied patients as well as those with disability. It is well known that testosterone levels steadily decrease with advanced age; however, hormonal replacement has shown limited success in resolving erectile dysfunction. In females, low sexual desire and reduced coital frequency are most often reported. These symptoms tend to correlate with reduced estrogen levels. The female reproductive system and menstrual cycle are controlled by the interplay of hormones and endocrine organs. In general, other physiological changes may include decreased vaginal lubrication, anorgasmia or delayed orgasm, priapism, retarded or premature ejaculation, retrograde ejaculation, breast hyperplasia, gynecomastia, and others.

Location of Stroke

It is likely that the location of the stroke-related brain injury is related to sexual dysfunction. A lesion located in deeper structures of the brain that regulate sexual function, such as the pituitary gland or hypothalamus, may result in disrupted neuroendocrine and hormonal functioning. Specifically, subarachnoid hemorrhage is commonly associated with neuroendocrine dysfunction (19). Disturbance of sexual functioning is related to severity of neurologic impairment, but no specific pattern has been detected. Early reports suggested that frontal strokes and strokes in the left hemisphere are more strongly associated with depression, which can impair sexuality, but other studies have disagreed. A systematic review by Carson and others in 2000 concluded that there is no evidence for an association of left hemisphere or frontal lobe stroke with depression (20,21). Jung et al. (2008) noted that lesions in the right cerebellum were associated with disorders of ejaculation, whereas patients with left basal ganglia lesions demonstrated decreased sexual desire (22).

TABLE 50.3 Non-PDE5i Options for the Management of Erectile Dysfunction

1. Intracavernous injection therapy—alprostadil, papaverine, phentolamine
2. Vacuum tumescence
3. Hormonal therapy
4. Penile prosthesis

Erectile Dysfunction

ED is the inability to achieve or maintain sufficient erection for satisfactory sexual functioning. ED is the most common cause of sexual dysfunction in the general male population (23). It is estimated that 50% of men over the age of 40 have experienced some degree of ED. It is likely that the incidence in male stroke survivors is even higher given the multifactorial nature of this problem. Atherosclerosis, an important risk factor for stroke, may cause reduction of blood flow that affects end organs, including genitalia. In males, this may reduce the success and effectiveness of erection. In females, there may similarly be a reduction in vulvar lubrication and engorgement. In addition, medications used to manage stroke risk factors and prevent secondary stroke may contribute further to ED. With the advent of phosphodiesterase 5 inhibitors (PDE5i), a group that includes sildenafil, tadalafil, vardenafil, and the newer udenafil and avanafil, there is medical treatment for ED; however, these medications are not a panacea. It is important to identify any underlying psychological factors that may significantly contribute to ED. Table 50.3 includes alternative forms of treatment for ED.

Decreased Libido

Low sexual desire is the most prominent sexual finding in females with or without a disability. Disorders of tactile sensation and disturbed lubrication are found to have some relation to a decline in desire. Moreover, disability-related physical limitations as well as altered body image appear to be the most cited reasons for low sexual desire and reduced sexual activity. Coexistent medical issues and medication side effects will also contribute to physiological changes similar to ED in men. Other reasons for low sexual drive include underlying psychological factors such as fear of rejection by a partner, anger in the relationship, or other interpersonal conflicts. Treatment will depend on the underlying cause.

Fatigue

Fatigue is a common sequela of stroke, impacting daily activities as well as psychological well-being. Fatigue can limit sexual activity and cause a reduction in libido in both men and women. As many as two-thirds of patients experience some level of poststroke fatigue (24). The cause of fatigue after stroke is unclear and may be a result of multiple factors; Choi-Kwon et al. (2005) demonstrated that prestroke fatigue, a high score on the modified Rankin scale, and poststroke depression may be possible risk factors (25). The increase in energy output that patients with stroke require to complete usual daily activities such as transfers, walking, bathing, toileting, and dressing may cause fatigue. Fatigue may also be a consequence of altered sleep–wake cycles. Various medications that are used for secondary stroke prevention or to treat stroke-related symptoms might have sedative effects. Treatment of fatigue may include management of insomnia and the sleep–wake cycle, use of neurostimulant medications, change in medications, or change in timing of medication administration. Counseling on timing and flexibility with sexual activity is also an important strategy for managing the effects of fatigue.

Weakness

Of the various neurological impairments following stroke, weakness is perhaps the most common (26). The pattern and severity of weakness after stroke need not prevent sexual activity if there is effective communication with the partner. Alteration in usual sexual positioning will often compensate for weakness quite effectively and increase sexual satisfaction. In patients who do not have severe paralysis, there may still be some evidence of weakness in relation to poststroke fatigue that can impact sexual performance and vary from day to day. It is important to include resistive training for both upper and lower limbs in a comprehensive rehabilitation program, as it can produce significant strength gains for patients even after six months after stroke. Training patients and their partners with illustrations of sex positions appropriate for patients with weakness and hemiplegia can be helpful.

Spasticity

Besides the challenges of mobility and positioning during sex, spasticity may prevent a couple from returning to sexual activity because of the unpredictability of dystonic movements and muscle spasm during sexual intercourse. Significant spasticity may preclude certain usual sexual positions when the patient assumes dystonic postures, so communication with the sexual partner is important. Discussion of sexual functioning should be included in comprehensive spasticity evaluation. In females, the presence of adductor spasms may require targeted treatment. Focal chemodenervation or motor point blocks of the hip adductors may be effective. The use of intrathecal baclofen has been studied in patients with spinal cord lesions from multiple sclerosis and spinal cord injury. Although intrathecal baclofen can reduce severe adductor spasticity, it may compromise both erection and ejaculation (27). This may be reversible, but patients should be informed of this side effect. Adjustment of the intrathecal baclofen dose may also help resolve these problems.

TABLE 50.4 Tips for Poststroke Patients With Neurogenic Bladder

1. Empty bladder shortly before sexual activity.
2. Indwelling catheter may be temporarily removed and replaced under the direction of the physician.
3. In females, catheter may be taped to one side.
4. Reduce fluid intake 4 hours prior to sexual activity.
5. Plastic covering may be used on the bed to protect covering.
6. Cleaning supplies should be kept close to bedroom or bed.
7. Avoid positions that may put pressure on the bladder.

Poststroke Pain

Although stroke sequelae may often produce decreased sensation, there may be other areas of the body with heightened or even painful sensation. In the case of dysesthesia, proper diagnosis is necessary to differentiate central poststroke pain, complex regional pain syndrome type 1, diabetic peripheral neuropathy, or other causes of tactile pain. Appropriate treatment can be provided if the correct diagnosis is made. Although rare after stroke, vaginismus and vulvodynia of muscular or noninflammatory origin can occur. Some studies suggest that botulinum toxin can be effective in treating these conditions by effectively blocking nociception (28,29).

Neurogenic Bladder

Neurogenic bladder after stroke can include detrusor hyperreflexia, or, simply, incontinence from uninhibited bladder. This may be a source of fear or embarrassment in patients who wish to resume sexual activity. Avoidance of sexual activity is commonly reported in patients with urinary incontinence. Education on timed voiding and voiding before sex can minimize frequency of incontinence. For patients using a chronic indwelling catheter, it is important to provide information on catheter management during sexual intercourse (Table 50.4).

Chronic Medical Conditions and Medications

Chronic medical conditions that coexist with stroke can cause sexual difficulties either directly or indirectly. Specifically, mood disorders such as depression are commonly observed after a stroke, and frequently affect sexual relationships. Also, common risk factors for stroke, such as hypertension and diabetes, are important contributors to sexual dysfunction. For example, vascular disease associated with diabetes can impact arousal, and cardiovascular disease may

inhibit intercourse because of dyspnea or fatigue. Secondary effects of stroke such as urinary incontinence may also cause sexual dysfunction or decreased sexual activity because of embarrassment and fear of having an accident. Medications used to treat many medical conditions are often associated with changes in sexual functioning. Unfortunately, the sexual side effects of chronic medical conditions and the medications used to treat them are often underreported and underdiagnosed. Therefore, it is important for the clinician to recognize and inquire about these effects and address any issues around sexuality for patients with stroke.

Poststroke Depression

The prevalence of major depression after stroke is reported to range from 16% to 40% within the first year (30–32). Although underreported, it is well known that sexual dysfunction is common among individuals with major depressive disorder (MDD) (33–35). In a study by Kennedy and colleagues, 40% of men and 50% of women with major depression reported decreased sexual interest and reduced arousal (36). Mood and sexual function have an interactive association such that anxiety or depression may adversely affect sexual function and sexual dysfunction may lead to depression.

The changes in mood may be related to the severity of neurologic deficit (9,10); it has also been reported that younger age, greater stroke-related disability, and inability to work at three months might relate to persistent depression (32). Together, these lead to a general loss of self-esteem. Although sexual dysfunction is not considered a direct symptom of MDD, it may represent depression-related anhedonia. However, in contrast to patients with mild stroke, those with more severe physical impairments are at risk for developing emotional disorders and a consequent decrease of sexual intercourse and perceived sexual dysfunction. The treatment of poststroke depression has been examined in several placebo-controlled, randomized clinical trials that show efficacy with drugs such as nortriptyline and citalopram (37–39). Studies also support early treatment with antidepressants, which can significantly increase the survival of both depressed and nondepressed patients (40). It is important to recognize that treatment of depression may improve sexual functioning, but use of antidepressant medication may also cause sexual dysfunction (41,42). As an alternative, enhanced social support when possible may have a positive influence on poststroke depression, improving the patient's esteem and sexual identity. With appropriate treatment, the progression of recovery following stroke can be altered, including improved recovery in ADLs and cognitive impairment.

Antidepressants

Selective serotonin reuptake inhibitors (SSRIs) are typically considered the medication of choice for the treatment of poststroke depression. They are popular in part because of their good safety profile and relatively benign adverse effects, especially compared with the older tricyclic antidepressants and monoamine oxidase inhibitors (MAOIs). However, many of the antidepressant classes are not free of treatment-emergent adverse events. Specifically, one of the most prominent adverse effects seen with antidepressants is sexual dysfunction.

In particular, the SSRIs have been shown to cause sexual dysfunction in 30% to 70% of patients treated for depression (43). The clinical implication is that compliance rates of antidepressant therapy may decrease with the recognition of sexual side effects. Therefore, it is important for clinicians to monitor and recognize sexual side effects when starting empiric antidepressant therapy.

Several strategies can be employed to manage antidepressant-induced sexual dysfunction (Table 50.5). Although some patients develop a tolerance to antidepressant side effects over time, it is usually only a small number of patients. If tolerance does not occur, other strategies include reduction of dose, addition of agents that may counteract sexual side effects, direct treatment of sexual side effect using drug holidays, or other techniques. Although antidotes such as yohimbine, amantadine, and buspirone have been suggested, they have not been shown to be effective in clinical trials. Some practitioners continue to support the use of these agents as an option in their patients. There are significant data showing that some classes of antidepressants and certain specific agents have had success in treating depression without a severe impact on sexuality. Bupropion, mirtazapine, and nefazadone have been well studied and have shown the least risk of inducing sexual dysfunction (44–46). Studies have also shown lower rates of sexual dysfunction with venlafaxine, a serotonin–norepinephrine reuptake inhibitor (SNRI), compared with SSRIs (42).

TABLE 50.5 Antidepressant Therapy: Recommendations to Reduce Sexual Dysfunction

1. Reduce dose: It may be possible to reduce dose to minimize sexual side effects while still maintaining therapeutic efficacy.
2. Schedule dose after sexual activity: The drug concentration may be at its lowest if the dose is scheduled after usual time for engaging in sexual activity.
3. Treat sexual dysfunction: There are pharmacological and nonpharmacological methods that may be useful in the case of erectile dysfunction.
4. Augment with a drug that may reduce dysfunction: Some studies suggest that there are medications that may counteract sexual dysfunction, such as dextroamphetamine, amantadine, buspirone, and so forth. These may be taken prior to sexual activity.
5. Change to another antidepressant: Certain antidepressants, such as nefazadone and bupropion, have been shown to have less effect on sexual functioning.
6. Take a drug holiday: It may be appropriate to provide a weaning schedule depending on the agent and length of treatment.

Diabetes

Diabetes is a multisystem disorder that includes a high prevalence of sexual dysfunction in both men and women. Studies by Kolodny in the 1970s and McCullogh in the 1980s describe the natural history and prevalence rates of sexual dysfunction as it relates to diabetes (47,48). Reports of dysfunction in diabetic men range from 27% to 75% (49–51) ED; ejaculatory dysfunction, and sometimes decreased libido, are commonly cited in men with history of diabetes. It is typically the combination of neuropathy and vasculopathy rather than hormonal changes that cause ED in diabetic men. In addition to diabetes, there is also mounting evidence that truncal obesity may be an independent risk factor for the development of ED (52).

Treatment of diabetes-related sexual dysfunction is similar to treatment of ED in general. Most studies suggest that PDE5i drugs are 70% to 80% efficacious in this population (53,54). Currently, there are no prophylactic measures available to prevent diabetic ED. Tight control of blood sugar should be the initial treatment, followed by treatment of malnutrition and general physical condition. Hormonal therapy can be considered in addition to the use of medication for ED. A referral to a urologist can be made to consider intracavernous injection therapy, vacuum therapy, or penile prosthesis.

Studies of sexual dysfunction in diabetic women are limited, but have consistently reported decreased orgasmic response (55,56). Other symptoms reported include decreased libido, reduced vaginal lubrication, dyspareunia, and vaginal infections. The pathogenesis of diabetic sexual dysfunction in women is complex and multifactorial, as are its evaluation and treatment. The cornerstone of treatment begins with education of the woman and her partner that decreased sexual desire and responsiveness may be caused by diabetes and challenges in the partner's relationship. As in men, nutritional and medical status should be optimized, including a thorough review of medication use. Counseling may be appropriate if no other reversible cause is found.

Coronary Artery Disease

It is now well documented that several of the risk factors for CAD are risk factors for ED. These may include hypertension, diabetes, dyslipidemia, and smoking. The incidence of ED has been reported to be as high as two-thirds of patients with myocardial infarction. Recent studies suggest that ED is an early symptom of cardiovascular disease and may precede CAD by two to three years in a majority of patients. Both of these conditions, ED and CAD, have shared risk factors that contribute to endothelial dysfunction and impede the ability of the arteries to dilate appropriately in response to stimuli (57).

The Princeton Consensus Conference developed guidelines for the safe management of cardiac patients with varying degrees of coronary risk regarding sexual activity and the treatment of ED. It reports that the PDE5i drugs are effective in treating ED in patients with CAD. Low-risk patients can usually receive PDE5i drugs without additional cardiac workup. In high-risk, unstable cardiac patients, the workup for sexual dysfunction should be deferred until the cardiac problem has been corrected or stabilized. Generally, this class of medication is considered safe in patients with stable CAD and does not pose any additional risk for ischemia. In contrast, the use of nitrate medications or alpha-blockers in combination with PDE5i is contraindicated. The American College of Cardiology/American Heart Association consensus position on medications such as sildenafil is that it is safe for patients with stable CAD who are not taking nitrates (58).

Antihypertensives

Hypertension is the major independent risk factor for stroke, so it should be treated aggressively to provide adequate blood pressure control. Unfortunately, sexual dysfunction has been associated with many of the antihypertensive medications (Table 50.6) (59,60). It is important to understand the sexual side-effect profile of various classes of antihypertensives, as this will affect not only compliance, but also a patient's quality of life.

TABLE 50.6 Sexual Side Effects Associated With Antihypertensive Classes

ANTIHYPERTENSIVE CLASS	ERECTILE DYSFUNCTION	DECREASED LIBIDO	IMPAIRED EJACULATION	PRIAPISM	GYNECOMASTIA
Beta-blockers	+	–	–	–	+
Diuretics					
Spironolactone	+	+	–	–	+
Thiazides	+	+	+	–	–
Antiadrenergics					
Central	+	+	+	–	–
Peripheral	+	–	+	+	+
Calcium channel blockers	–	–	+	–	+
ACE inhibitors	–	–	–	–	–
Angiotensin II blockers	–	–	–	–	–
Vasodilators	+	–	–	+	–

Many studies have reported ED in male subjects related to treatment with antihypertensive medications. Certain medication classes tend to show a higher prevalence of sexual dysfunction than others. In general, diuretics and beta-blockers have the most negative effects on sexual performance. Beta-blockers, such as propanolol, with high lipophilicity and nonselective beta blockade, are associated with ED. Thiazide diuretics are essentially devoid of central or autonomic nervous system activity, yet they are associated with ED, possibly because of fluid and zinc depletion (61), even though the definitive pathogenetic role of zinc in ED remains unclear. Spironolactone can cause ED as well as gynecomastia and a decrease in libido. As an alternative to these medications, ACE inhibitors and angiotensin II antagonists have minimal sexual side effects and are often better tolerated by patients. In fact, some studies report a positive impact on sexuality and quality of life with the use of medications such as losartan, an angiotensin II antagonist. There are several reports suggesting that drugs that inhibit the renin-angiotensin system exert favorable actions on erectile function (62–66). It is important for practitioners to communicate openly with patients and work with them closely to minimize the sexual side effects of antihypertensive agents while maintaining antihypertensive efficacy. In addition, PDE5i drugs may be used effectively in this population, even when they are taking concomitant antihypertensive medications (67,68).

Seizures

Seizures are a common complication after stroke, with a reported incidence up to 10% (69–71). Some patients who experience a first seizure go on to develop epilepsy, especially those with late-onset seizures that occur beyond two weeks following stroke onset. In general, patients with epilepsy have hyposexuality. In males, there may be decreased sexual desire or ED. Men with epilepsy have a 57% increased risk of ED versus 3% to 9% in the general population (72–74). In females, epilepsy is associated with menstrual irregularities or reproductive dysfunction. Estrogens lower seizure threshold, so seizure frequency may increase during menses or pregnancy.

Sexual disorders are distinguished by a temporal relationship with seizure activity. There are two categories:

- Those directly related to the epileptic discharge period (ictal)
- Those unrelated in time to seizure occurrence (interictal)

Hyposexuality has been linked to interictal seizure activity, whereas hypersexuality has been reported in the setting of ictal seizure activity (75–77). Monga et al. described three case reports of patients who demonstrated a hypersexuality and deviant sexual behavior after stroke (78). In all three cases, temporal lobe lesions were noted on cranial computed tomography, and all had a history of poststroke seizure activity.

The association between diminished sexuality and chronic anticonvulsant use is well established. Antiseizure medications, such as phenytoin and carbamazepine, are commonly associated with sexual dysfunction. In males, they can decrease the testosterone level, which, in turn, reduces sexual desire. Antiepileptic drugs alter the serum concentrations of sex hormones and the regulatory feedback loop of the hypothalamic–pituitary–gonadal axis. Rattya et al. examined the effects of carbamazepine, oxcarbemazepine, and valproate in epileptic men and suggested that oxcarbemazepine may be the best choice of anticonvulsant in epileptic patients suffering from hyposexuality (79).

Cognitive Impairments

Cognitive changes after stroke can cause memory problems and difficulty expressing emotions, which may influence intimacy and sexual activity. Cognitive deterioration relating to dementing disorders can include disinhibition, agitation, or depressed mood, which can cause interpersonal difficulties and negatively impact a couple's sexual relationship (80,81). These behaviors may be seen in basotemporal and orbitofrontal lesions (78,82). For example, a patient may make socially inappropriate verbal comments of a sexual nature in public whereas prestroke the person would have suppressed this verbal output. Disinhibited syndromes in brain injury as a whole have been a frequently described phenomenon and can involve disinhibited behavior in multiple realms, such as motor disinhibitions (e.g., aggressive outbursts) and emotional disinhibition (e.g., emotional lability) in addition to sexual disinhibition (82). Infrequently, hypersexuality can be seen following a stroke. It has been described in lacunar strokes, which affect the frontolimbic system, and in thalamic infarctions; some literature has compared this symptomatology to Kluver–Bucy syndrome (83,84). It has been proposed that hypersexuality following stroke may relate to dysfunction in the fronto-subcortical circuits secondary to thalamic infarctions (83). Coping with disinhibited behaviors and hypersexuality following a stroke can be challenging. Reducing external distractions during intimacy and using verbal and nonverbal communication for sexual expression may aid in managing these symptoms. In addition, optimizing sleep–wake cycles may minimize the cognitive impairments experienced by some patients after stroke.

Aging and Sexual Dysfunction

There is a notable and sharp decline in sexual activity with age. Pfeiffer et al. studied sexual interest and activity as people age; in their study, 50% of individuals aged 60 to 65 were still sexually active in comparison to 20% in the 78 to 83 age group (85). For those who care for patients with stroke, it is important to understand the normal age-related changes that impact sexual functioning in the elderly. Proper understanding of sexuality and aging can also minimize the myths and misconceptions that many clinicians have about sexuality in the elderly. This section discusses the physiological and psychological changes commonly seen in the older adult and older stroke survivors.

Physiological Changes in Elderly

In the aging male, the most common changes in sexual physiology occur in both erectile function and ejaculation (80,87). Stein et al. reported that 40% of men aged 70 to 79 and 60% of men over 80 experience ED (86). For example, men tend to show increased time required to produce a full erection, an increase in the time that erections can be maintained prior to ejaculation, a decrease in the force of ejaculation, and an increase in the duration of the refractory phase (80). The high prevalence of diabetes, CAD, hypertension, depression, and the use of various medications also contribute to these changes in sexual functioning.

In older women, the physiological effects of aging on sexual function are primarily caused by decreased amounts of circulating estrogen after menopause. Lower estrogen levels not only contribute to a decline in sexual interest and coital frequency, but also reduce vaginal lubrication, resulting in painful intercourse and less pleasurable sex. However, other studies have suggested that many women experience an intensification of sexual desire during menopause. In these cases, the negative effects of menopause are more than offset by the freedom to explore and enjoy sexual activity without the worry of becoming pregnant (87).

Psychological Attitudes in the Elderly

In our modern culture, there is often still an expectation that older people are, or ought to be, asexual (87). Although sex roles have changed and there has been more freedom of sexual expression since the 1960s, the stereotypes that older people are physically unattractive, uninterested in sex, and incapable of achieving sexual arousal are still widely held (88).

Modern Western society has generally viewed sexuality in older adults in a very restrictive manner. Studies of nursing staff in extended care facilities have identified significant staff discomfort about sexual expression among the elderly residents. Older residents who display any form of sexual expression are often regarded by staff as having a behavioral problem and may even be tranquilized (89). Staff attitudes toward masturbation or sexual activity between unmarried residents are often disapproving and repressive, and adult children may complain of permissive institutional attitudes toward their parents' sexual expression (90,91).

It is still quite common for society to consider sexual expression or activity to be unnatural or unacceptable in the aging population. Clearly, educational intervention is needed to dispel negative myths, stereotypes, and self-fulfilling attitudes in older people and to promote the perception that full sexual expression is part of the entire extent of adulthood.

Opportunity for Elderly

Opportunities for sexual contact are greatly reduced in those with advanced age. Gender differences in life expectancy may impact the sexual experiences in older adults. For example, demographic data indicate that there are many more women than men over the age of 65. If marital status or living with a partner is a measure of increased opportunity structures for sex, elderly heterosexual women have a limited opportunity for sexual expression. In contrast, decline in sexual activity for men is less likely to be due to the lack of a partner (87). A physiological change, such as ED, is likely the reason for reduced sexual activity in men. The lack of privacy in nursing homes is a major obstacle to sexual expression. Not surprisingly, older residents report that, because of a lack of privacy and inhibiting staff attitudes, they have little opportunity to experience intimacy.

Because many types of professionals are involved in the provision of health services to older people, staff-wide education about the importance of sexuality in the promotion of mental and physical health for older adults is important and should lead to more positive attitudes. Greater knowledge and acceptance of older adult sexuality and sexual functioning are important goals for all sex educators, counselors, and therapists trying to meet the needs of older adults (92).

Management of Sexual Dysfunction

Comprehensive medical evaluation should precede any treatment intervention for sexuality dysfunction after stroke. Early referral to the appropriate health care professional is a key strategy. Physician specialists involved in evaluation and management of sexual dysfunction include physiatrists, urologists, gynecologists, primary care practitioners, or neurologists. A thorough evaluation includes review of sexual, medical, and psychosocial history followed by medical and neurologic examination and laboratory testing. Medical risk factors for sexual dysfunction include hypertension, diabetes mellitus, depression, and cardiovascular disease. Medications should be reviewed to identify those that cause sexual side effects. Lab studies should include hormonal evaluation to exclude a diagnosis of hypogonadism (testosterone and prolactin levels) and testing to screen for diabetes. Social history should be elicited to discuss other risk factors, including obesity, tobacco, alcohol, and illicit drug use. It is also important to distinguish disease processes from the normal physiologic aging process. Other specialists vital to the management of sexual dysfunction after stroke include rehabilitation nursing, physical, occupational, and speech therapists, as well as social workers and psychologists. Referral to physical or occupational therapists may be appropriate in situations where positioning or energy conservation techniques would be warranted. A rehabilitation physician can provide spasticity management, including oral medications, focal chemodenervation, and other methods to reduce spastic dystonia or painful spasms that interfere with sexual functioning. Sexuality counseling is the responsibility of all involved in the care of adults with neurologic disability.

Sexuality Counseling

In 1976, Annon described the PLISSIT model for approaching sexual dysfunction and intimacy problems. PLISSIT stands for

TABLE 50.7 PLISSIT Model

P = Permission
LI = Limited information
SS = Specific suggestions
IT = Intensive therapy

permission, limited information, specific suggestions, and intensive therapy (Table 50.7) (93). Though this is not stroke specific, it does provide some valuable guidance. Permission involves offering both the patient and the partner, who often assumes a caregiver role, a chance to discuss issues related to sexuality. It may also validate the patient or partner to include healthy sexual functioning as part of the overall goals of rehabilitation.

Premorbid sexual knowledge may be variable depending on familial, religious, or cultural backgrounds; therefore, it is helpful to provide basic information regarding sexual issues. Some patients may require more specific suggestions to ameliorate problems related to their sexuality, such as methods of communicating with a partner to allow for intimacy or an explanation of a medication's effect on sexual functioning. There will certainly be areas that fall out of the realm of the clinician's expertise; therefore, in specific cases a referral for intensive therapy may be beneficial. It is also important to reassure patients that it is safe to participate in sexual activities. The timing of receipt of information regarding sexual function is also important. Receiving this information prior to discharge from acute rehabilitation is generally preferred by patients (94).

Here is one potential introductory dialogue a physician might use:

> As you prepare to return home, I wanted to briefly discuss some issues that haven't been addressed during your rehabilitation stay, such as resuming sexual activity. Some people are concerned about the safety of having sex after stroke, and I wanted to reassure you that it is perfectly safe to do so, and that this does not increase your risk of having another stroke. Many people are able to resume their sex lives without difficulty after stroke, but others experience some challenges because of the stroke itself, or sometimes due to the medicines prescribed for other problems, such as depression. Please let me know if you have any questions or concerns about sexuality now that I can address. We will also have a chance to review any issues that might arise once you are back at home when I see you in the office in several weeks.

CONCLUSION

Sexual dysfunction after stroke is common and can have a significant impact on the quality of life of the affected patients and partners. Altered sexual activity after stroke may have a medical cause that is often directly or indirectly a result of neurologic changes in libido, sexual behavior, and sexual performance. Comorbidity and general health status, together with psychological factors, are also important determinants of poststroke sexual functioning.

Treating sexual dysfunction is part of the holistic approach to rehabilitation. Counseling should include dispelling stereotypes, myths, and misperceptions, not only for the stroke survivor, but also for the partners and rehabilitation staff members. Counseling stroke survivors on sexual problems is a challenging experience, but it is necessary for improving their quality of life. Education in the field of sexuality and aging is also essential for all health professionals who are in contact with older people, both in institutions and the wider community.

Studies demonstrate that disorders of sexual functions are most significantly associated with various psychosocial factors, such as patients' general attitude toward sexuality, fear of impotence, and ability to discuss sexuality, as well as with the degree of poststroke functional disability. Therefore, providing this opportunity for evaluation and management is paramount. With emerging awareness of the primary importance of quality of life as the critical indicator of good patient management and the advent of more effective treatment of sexual dysfunction, it is no longer acceptable to ignore this very important dimension of life.

Vocational Rehabilitation After Stroke

Mark A. Young, Steven A. Stiens, and Alessandra Hirsch

According to Sigmund Freud, "Love and work are the cornerstones of an individual's humanness." A stroke can threaten to strip a person of that core humanness and of the treasured roles shared with others. In no domain can that issue be more poignant and the financial impact more devastating than in the vocational and work environment. Viewed from within the traditional "impairment-disability-handicap classification" paradigm,[1] an individual who experiences a stroke faces an *impairment*, generally defined as "any loss or abnormality of anatomic structure, physiologic, or psychological function of an organ or system" (1). Examples of impairments resulting from stroke include weakness, sensory deficits, and cognitive and communication deficits. A *disability* is the term used to describe the inability of an individual to complete a routine task as a result of the *impairment*. A *handicap* refers to a disadvantage stemming from an impairment or disability in performing a role in society. An example of a stroke-related "impairment-disability-handicap" adversely impacting work might be a left internal capsular ischemic stroke with right hemiplegia (impairment) that prevents a computer programmer from typing on a computer (disability) and returning to work (handicap). The use of appropriate assistive technology, such as speech recognition software in this case, might allow this individual to return to work, thus overcoming the handicap, while still having an impairment and disability.

[1]The "impairment-disability-handicap" classification system, although somewhat dated, remains a classic and instructive model for conceptualizing the disability spectrum. While its application has more recently been supplanted by the World Health Organization International Classification of Functioning, Disability and Health (see http://www.who.int/classifications/icf/en), the authors of this chapter have elected to utilize the classic system because of its historic significance and relevance to vocational rehabilitation.

The decision to return to work after a stroke can be affected by a number of factors, both physical and mental. The psychological effects of stroke (especially poststroke depression) may have as large an impact as the physical consequences of stroke (2,3). About 40% of stroke survivors experience significant poststroke depression (4). Poststroke depression may be associated with not returning to work, but the cause-and-effect aspects of this association are complex. The causes of poststroke depression are not fully understood, with damage to the brain suspected of precipitating this condition in many cases and the psychosocial stressors of sudden disability also playing an important role in many cases. In any given case, it may be hard to determine whether a patient hesitates to return to work because he or she is depressed or is depressed because of the loss of work in his or her life. It is important to recognize also that, although there are approximately 5.4 million stroke survivors in the United States, there has been only sparse research on the subject of return to work after stroke. Fewer still are studies that examine strategies to improve those rates.

Kirk Douglas (Figure 51.1), the famous actor of *The Bad and the Beautiful* and *Spartacus* suffered a stroke at the age of 80 and wrote a book about his struggles with depression and recovery. In it he describes the depth of his depression, which centered around his own perceived inability to go back to work as an actor: "I was tired of being a big, strong, tough guy. I began to cry. The room seemed to get darker and a big black cloud engulfed me. I cried and cried until my pillow became wet with tears […] I didn't want to see anybody. What good is an actor who can't talk? […] I felt so helpless—so useless. I will never make another movie—I will never write another book. Will I ever talk again?" (5)

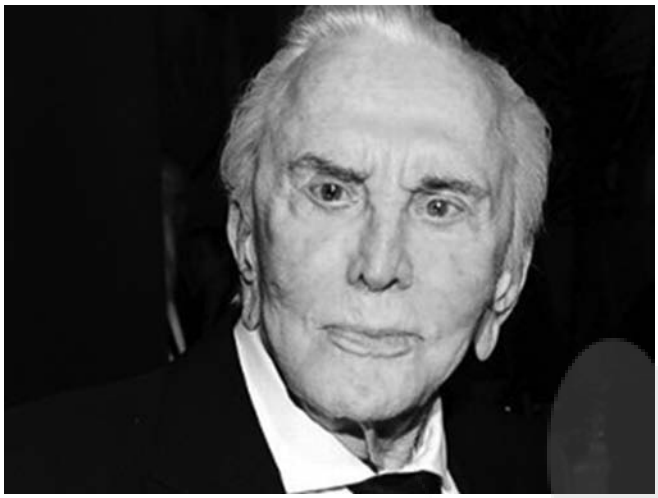

FIGURE 51.1 Kirk Douglas after his stroke.

The preceding excerpt is from Kirk Douglas's book, *A Stroke of Luck.* In it, he describes his own vocational battle with stroke, and emphasizes not only the feelings of helplessness but also the importance of speech and language. Although his story is perhaps unique because of the high-profile nature of his job, his experience is not. Aphasia from stroke can have a profound impact on vocational opportunities and return-to-work (RTW) potential.

Risk Factors: Barriers to Overcome

Depression is only one of many factors affecting stroke survivors and their decisions regarding return to work. The reported range of RTW rate for stroke survivors ranges from 4% to 77% of patients (3). This large variation is due to varying definitions of "RTW" used in different studies. Some studies recognize only paid work, whereas others include persons who do not work outside of the home at baseline and who resume managing their own homes. This also illustrates how individualized a decision to return to work can be for each stroke survivor. In spite of the challenges of defining *work,* there are some factors that consistently appear important in determining RTW rates. They include age; stroke severity; psychological social and societal factors; and cultural and geographical factors.

Age: The Younger the Better

Younger patients are more likely to return to work after stroke. Generally, patients over the age of 65 tend to have a low rate of returning to work, for a number of reasons. Patients who are near retirement age are inclined to see a stroke as a sign to retire (6). Although much of the time this is a reasonable response to circumstances (recognizing both the difficulty in returning to work and, typically, less financial need to do so), a premature and undesired retirement can have a negative impact on a patient's mental health after stroke. As Freud reminds us, many rely on work as a source of purpose as well as joy. Patients who see themselves as forced into early retirement may become depressed despite the fact that they reached an appropriate age to retire by conventional criteria.

Conversely, the very young stroke survivor may also have greater difficulty vocationally. A severe stroke in very young patients who have not yet entered the workforce can often prevent those patients from ever entering the work force in the first place.

Stroke Severity: The Major Predictor of Return to Work

It comes as no surprise that more severe strokes tend to result in lower RTW rates. In fact, stroke severity is the best predictive factor for returning to work (6). Stroke severity tends to be correlated with how long the patient is hospitalized. A more severe stroke typically necessitates a longer hospital stay and also tends to result in more severe long-term neurological and functional impairments impacting ability to work. Irrespective of cognitive or physical limitations, an extended period of absence from work may reduce patient motivation to return and increase the likelihood that the original job will no longer be available. Finally, recurrence of stroke is also a barrier to RTW. A recurrent stroke may lead to additional neurological impairments; it also may discourage the patient from trying to return to work. The fear that another stroke may occur, resulting in another leave from work and additional impairments, is a disincentive for returning to work for both stroke survivor and employer (7). It should be noted, however, that stroke severity can be measured from a variety of perspectives, including motor, cognitive, and behavioral effects. Many studies have revealed that the hemisphere of the brain where the stroke occurs does *not* predict a patient's likelihood of returning to work (8). The behavioral outcomes of these lesions are what really determine perceptions and job options. A stroke that impairs a patient's language abilities, memory, vision, intelligence, and/or socializing skills affects his or her ability to re-enter daily life (9). Like other types of brain injury, stroke survivors can benefit from compensatory techniques and neurobehavioral therapy to optimize vocational and behavioral outcomes.

Psychological Social and Societal Factors: Positive Mood, Family, and Education Can Help

When measuring qualitative factors, there is less of a consensus in the literature. Alcohol use, for example, was identified in some studies as an important barrier to RTW and in others had no effect at all (6). As mentioned earlier, depression is an important factor in returning to work, and is one that both may deter patients from returning to work as well as potentially result from premature retirement. In either case, if a patient is suffering from depression before attempting RTW, the chances of that patient actually doing so are small (2). Marital status has no effect, whereas both a high education level and cohabitatation with someone else increased

RTW rates (6). The type of job previously held by the patient also has an effect on RTW rates. In fact, patients who held white-collar jobs were 37% more likely to return to work than those holding blue-collar jobs (6).

Cultural and Geographical Factors: Traditions, Policies, and Economy

There are variations in RTW rates among different countries. Japanese people are more likely to return to work, perhaps because of a strong cultural emphasis on work, often in spite of the severity of the stroke and its outcomes. The United States has among the lowest RTW rates, with 19% as a low estimate. Germany also has a low RTW rate, with only 14% of its stroke patients returning to work. France, Portugal, and Israel hold some of the highest rates, with 73%, 73%, and 67%, respectively (6). The causes of this variation are not well understood; theories suggest that it is a function of the health care practices and facilities in these countries, or perhaps the cultural role that work occupies in the local culture.

An overall breakdown of RTW among stroke survivors is shown in Figure 51.2. This graph can be interpreted in several ways. With such low RTW rates, there is considerable opportunity for improvement. Vocational rehabilitation is a relatively new field, and longitudinal studies of its effectiveness will require more data. It seems clear that we should work vigorously to help individuals who are of an age when RTW is a priority (generally below age 65 or even younger), who have residual impairments that do not preclude return to the workforce, and whose job environment is conducive to returning to work. For the majority of stroke patients, however, RTW is unlikely as a result of a combination of these factors, and therefore, realistic expectations should be set, and exploration of alternatives to return to full-time employment should be encouraged.

Fluctuations in the economy also affect efforts to return to work. During an economic recession, it is often difficult even for the able-bodied to find jobs and certainly even more difficult for a patient with a visible disability. A cold economic reality may manifest itself in the high association of unemployment and stroke. The limited number of available positions are often filled by younger, able-bodied individuals who may also possess more formal qualifications (albeit possessing less experience). Of course, this should not discourage patients living with stroke from seeking a RTW. Rather, it should remind the stroke survivors and their families as well as their vocational rehabilitation counselors (VRCs), that returning to work or finding a new job may be more difficult today than in the past. A longer period devoted to a job search is now to be expected, but returning to work is by no means impossible in this economy.

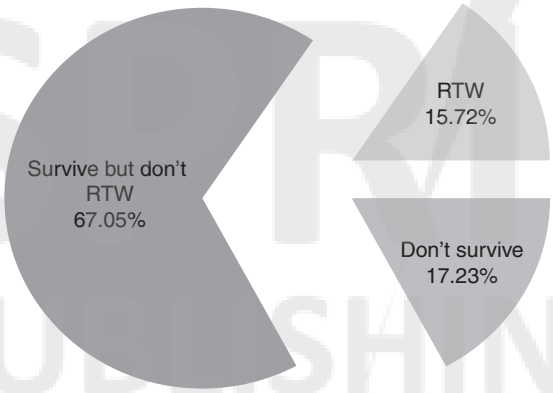

FIGURE 51.2 Stroke patient outcomes.

Defining Employment: Labor to Achieve an End, Livelihood

Perhaps the biggest problem with existing studies on RTW rates is the variable definitions of *work* used by the authors. Some investigators only include patients who return to a paying job in their definition of *work*. Others include students and housewives who return to their studies and housework; some include volunteering. The lack of standardization on this topic accounts for the wide range in reported RTW rates. According to the *Oxford English Dictionary*, *work* is an "action involving effort or exertion directed to a definite end, especially as a means of gaining one's livelihood; labour, toil; [one's] regular occupation or employment" (10). This seems to be an appropriate definition, and one that the authors of this chapter will use. It focuses on a human's livelihood first, which is the essential reason *why* RTW is so important to stroke survivors. One of the earliest mentions of the word *work* comes from Milton's *Paradise Lost*: "Man hath his daily work of body or mind appointed, which declares his dignity" (10). This usage captures the psychosocial impact of work, and explains why many stroke survivors pursue this goal despite the challenges they encounter.

Factors Impacting the Feasibility of Stroke Survivors Returning to Work

Capability and Motivation: Making the Decision to Return to Work

The first step in returning to work is, of course, making the decision to pursue this goal. Although the typical duration of recovery varies widely among stroke patients, many stroke survivors achieve a relative plateau in their recovery within three to six months (6). Although the majority of recovery takes place in that time period, some degree of continued gradual improvement is common, and there is no absolute time limit on functional gains after stroke. Despite the best rehabilitation efforts, many patients remain with significant disability. Initially, it is the treating physician's responsibility to direct and coordinate care to minimize stroke severity, prevent recurrent stroke, and initiate rehabilitation while the patient is in the hospital so that ultimately a decision can be made about the feasibility of a RTW. Physicians are often tempted to provide the patient with a premature recommendation regarding RTW. It may be better to keep

the option of RTW open (when realistic) and give the recovery process more time, leaving options open as community reintegration begins. Ultimately, it is the patient's choice to return to work or not; but a doctor can often make the best estimate regarding a stroke survivor's physical abilities and how they might fit into the workplace. Patients and doctors should both stay open-minded about the possibility of returning to work. The process of stroke rehabilitation includes mastering many daily activities that are a prerequisite for RTW. It is generally accepted that early intervention gives the patient the best chance for RTW (11). Early intervention primes the stroke patient to get into the mindset of returning to work, both mentally and physically. Individuals who sustain a stroke are often in the prime of their careers and are accustomed to performing at a high level in the workplace. After a stroke, patients may question what kinds of contributions they can make in the workplace. Early intervention is important in encouraging patients to meet their full potential. If the physician can introduce a vocational rehabilitation specialist or counselor to the patient before he or she is discharged, the idea of returning to work can be planted for further nurturing as recovery takes place. Some hospitals have VRCs on staff, and these specialists should be utilized when available. The possibilities that they present to stroke patients should encourage patients in their hopes for the future. However, a survey study by Culler et al. suggested that some stroke survivors felt that they were compelled to return to work earlier in the recovery process than they felt ready. They felt that this undue pressure caused them anxiety and was a deterrent that prolonged the process of returning to work. In spite of this one report, most doctors and specialists agree that early intervention still produces the best results in terms of the patient successfully returning to work; the most successful RTW patients are those who begin evaluating their vocational situations before leaving the hospital.

These early evaluations should include a number of parameters, including the key issue of whether the patient *wants* to return to work. In either case, the reasons for such a decision should be thoroughly assessed. Many patients have "Freudian" (which are, in this case, good) reasons for wanting to resume employment: their jobs give them joy and purpose in their lives. They like to be busy, and working helps them feel productive and important. In addition, the social element that the workplace provides can be therapeutic for a recovering stroke patient from a psychosocial perspective. Socializing with coworkers not only provides them with a community, but also can help these survivors overcome solitude and dysphoria. These nonfinancial psychosocial considerations are valid, and perhaps even the most cogent reasons to return to work. Financial considerations are paramount for some patients, of course, and certainly a valid justification for RTW. Sometimes, in the face of formidable hospital bills and/or family reliance on the patient, a stroke survivor will feel that resuming employment is not a choice but a necessity to regain income and retain health care benefits. Although many factors outside of the control of the health care team are involved, ideally work should be a tool that stroke patients can incorporate into their ongoing rehabilitation rather than an unavoidable need. Patients and their families should understand their options (including formal designation as disabled in order to qualify for Social Security Disability Insurance payments) and may benefit from engaging a lawyer. From a rehabilitation provider's perspective, ideally patients would be free to make their own decisions without feeling undue pressure or any shame in either choice. Patient must not be made to feel guilty, especially if they decide not to return to work because they feel they are not ready or because they see stroke as an opportunity to retire.

Twenty percent of the societal costs of stroke are estimated to be the result of loss of employment. Each individual's decision or ability to return to work is unique and specific to that person and situation. These decisions should be approached on a patient-by-patient basis. However, guideline advice and models exist to help predict whether or not a patient is likely to return to work. In a comprehensive study done by Satoru Saeki, a set of criteria were assessed in stroke patients looking to return to work. Saeki's study focused on workplace accommodations for and functional abilities of stroke survivors. The project was designed to streamline the process of managing the poststroke existence and, in so doing, outlined four guidelines for returning to work, listed in the following box.

Saeki et al.'s General Criteria for Return to Work (12)

1. Good performance at activities of daily living (ADL), which include eating, climbing stairs, shopping, driving, housework, dressing oneself, etc.
2. Walking a distance of 300 meters or more without needing a break
3. 15 seconds of mental activity with high performance and sustained concentration
4. Emotional acceptance of the disability

Of these four, Saeki suggested that the first three will not be sufficient to propel a patient back to a work environment without the fourth. Indeed, returning to work is as dependent on a patient's mental state as his or her physical status. Even patients with more minor impairments will not perform well after RTW if they do not feel ready or are unable to cope with their disability.

Anticipatory Rehabilitation: Processes That Enhance Vocational Success

The immediate and acute management of patients after stroke includes rapid diagnosis, imaging, and, in selected cases, thrombolysis, followed by treatment to prevent recurrence. Rehabilitation begins with the assessment of functional deficits and development of a plan for remediation and compensation. In reporting a diagnosis and a preliminary prognosis, outcomes and RTW should be included when appropriate, keeping in mind the uncertainty of the ultimate outcome of

RTW plans at this early phase of care. Expressing hope keeps the patient, family, and coworkers engaged in expecting and supporting functional improvement. As patients are admitted to the hospital, their sense of personhood and station in life is often compromised. A patient's sense of self-identity can be preserved by including a picture of the family at the bedside and the vocation of the patient in the introductory and social history portion. For example, the patient is a 64-year-old trial lawyer with a new right middle cerebral artery ischemic stroke. A prior professional picture of the patient showing him or her in his office standing in front of his legal books can help to bolster professional self-worth. If there are communication, perceptual, and/or mental status deficits, a patient's life role can be expressed in photographs.

Addressing the patient's occupation is very reinforcing because work, for many, is a core element of their identity. Reviewing the tasks performed by the patient in his or her job during each day provides background on the patient's premorbid capabilities. Such detailed knowledge enhances the design of the rehabilitation program in physical therapy, occupational therapy, and speech–language therapy. Photographs or videos of the worksite provide specific evidence of the challenges of accessibility. Use of these at the bedside helps patients picture themselves back at home and at work soon. With the cooperation of family and willing coworkers, a video can be made that illustrates the worksite and includes encouraging testimonials from coworkers about support they would offer the patient upon his or her return.

As rehabilitation is initiated, clothing that the patient might wear in the work setting may be an option for the patient to wear each day in rehabilitation. As basic mobility is achieved, the tasks of transfer and wheelchair propulsion and gait can be designed to approximate activities at home and work. Initially, visitation with the patient should be limited to immediate family and close friends. Preliminary misjudgments about the patient's capabilities for RTW should be avoided. The vocational counselor should be consulted early to make preliminary contact with the employer; if unavailable, then a family member or friend may make this contact to keep the employer informed. As patient improvement ensues, planned visits from coworkers can be arranged as the patient's improving function can be showcased. Later in the process, assessments such as work capacity examinations can be utilized to assess perception, strength, and endurance. As is feasible depending on employment type, work samples can be brought to the therapist to assess more subtle aspects of cognition and problem solving. When community reintegration has been partially achieved, visits to worksites that approximate the preferred work setting allow assessment of the patient's performance without impromptu and premature pre-interviewing from those at the target worksite. In the latter stages of placement, mock-up worksite environments can be designed for practice in therapy. Successful accommodations can be designed for the actual worksite based on these therapy simulations. Finally, the patients can be transitioned back into the worksite with increasing hours and frequency as endurance increases.

Following is a case study of a patient with a stroke. Readers are encouraged to assess whether a physician should recommend that this patient return to work.

Case Study 1

A 70-year-old male physician sustains a right internal capsular ischemic stroke. After three months, he has regained most of his abilities with the exception of hemiplegia in his left arm and hand and slightly slurred speech. Before he had his stroke, he was working as a general internist at a local teaching hospital. His mental capabilities appear mildly affected; for example, he now takes 15 instead of 10 minutes to complete a crossword puzzle, and he has mild difficulty remembering list items. He is articulate, has intact language abilities, and retains strong verbal abilities. When asked about his job, he reports that his favorite part was teaching medical students and residents. He states that work as a physician, and teaching in particular, gives him a strong sense of purpose in life; he does not wish to consider retiring at this time despite adequate financial resources to do so.

Vocational Rehabilitation Process: Early Consultation, Evaluation, and Planning

While this patient is in the hospital, an inpatient rehabilitation assessment should start and a plan should be designed. (13,14). Then, once released from the acute hospital, he should continue care at an inpatient rehabilitation facility, where he should be assigned a vocational rehab counselor if available. There, the vocational counselor will recommend assessment and therapy with the interdisciplinary team. Because he has no use of his left hand, the likelihood of him being able to carry out the entire range of clinical procedures previously performed is low. If he returns to clinical practice, he may need to hire a physician's assistant or equivalent to conduct procedures ranging from injection administration to suturing wounds. The rehabilitation center should administer a neuropsychological assessment. It is hoped that this will confirm his apparently well-preserved cognitive abilities, and determine if any more subtle deficits might be present. If his performance on this assessment is impaired, a follow-up assessment when he is more fully recovered may be appropriate.

Given this physician's pre-existing interest in teaching, it may be helpful to encourage him to focus his subsequent career on teaching. This may reduce his need for workplace accommodations or assistants. A part-time status might allow him to retain the status and self-worth he derives from work without the same productivity expectations from his employers. This patient has a fairly high likelihood of returning to work because of the type of job he held prior to the stroke, because of his relatively strong mental capacities, and because his physical disability is limited to one arm. His age is a factor that may influence this decision; he may choose retirement if he is personally dissatisfied with his work abilities after completing rehabilitation.

The Particular Job Focus: Previous or New

When patients decide that they wish to return to work, the first step in this process is determining whether they can resume their prior jobs. Often, patients have a long work history and a devoted staff of coworkers at their jobs. A vocational counselor can be a valuable intermediary between patients and their employers, keeping the employers informed of the patients' progress and RTW plans and preventing undue pressure on the patients to return to work before being fully rehabilitated. Many, and perhaps most, stroke survivors have some residual impairments that may affect job performance and that should be addressed in developing a RTW plan. These residual physical, cognitive, and psychological factors may require specific rehabilitation efforts as well as specific workplace accommodations such as modified duties or adaptive equipment. Some patients will express a desire to wait until they are "fully recovered" before they return to their jobs, fearing social pressure and judgment by their workplace peers and employers (15). However, in many cases the likelihood of regaining all function is low. In fact, the actual work setting can be psychologically and physically therapeutic in itself. As Brendan Conroy observed in a prior edition of this text, "it is helpful for the survivor to return to work *in order* to feel normal" (15).

If capable, one is more likely to be successful at the job previously held than at a new one entirely. Of course, returning to the same job depends on a plethora of factors, first and foremost of which is whether the patient possesses the physical and mental *capacity* to do so. Because many stroke survivors emerge from rehabilitation with some residual impairment, the decision to resume the same job requires careful assessment and planning, in a process that often includes trial completion of work duties. In the case of mild impairments where few accommodations are needed, the stroke survivors will often return to work part-time at first, working daily for several hours per day, perhaps three days per week. This allows patients to gauge their abilities and endurance in a real-work environment, and fine-tune any accommodations that have been established. From the employer's perspective, having an employee return on a part-time basis initially allows the supervisor to assess the quality of that person's work and determine realistic productivity goals. In cases where an employee has special or unique skills, a graded RTW provides the employer with at least partial access to the employee's skills.

A common scenario for successful RTW involves a patient returning to work at the same company as before, but in a new capacity. This approach leverages existing relationships between the employee and employer, but addresses the changes in abilities that may have resulted from the stroke and may make return to prior duties impractical. Focusing on the stroke survivor's specific interests and preferences for job tasks can help assure that there is good congruence between the assigned duties after stroke and the person's abilities.

Statistically, it is more likely that a stroke survivor who was employed prior to the stroke will return to his or her prior employer than work in an entirely new job. In a study by Culler et al. on ten stroke patients, eight returned to their prestroke employer. Three out of eight returned to the same position, one had a temporarily modified work schedule, and two had permanent modifications. Of the remaining two, one returned to work in an entirely different position as an assistant to her former boss, and one did not RTW at all (7) (see Figure 51.3).

Another larger study utilizing a retrospective cohort design followed 183 individuals below the age of 65 who were actively employed prior to their strokes, and assessed RTW after a stroke (16). This study focused on the association between stroke patient characteristics and RTW. Factors positively associated with successful RTW after first stroke included normal muscle strength and absence of apraxia. Employment in a white-collar occupation also

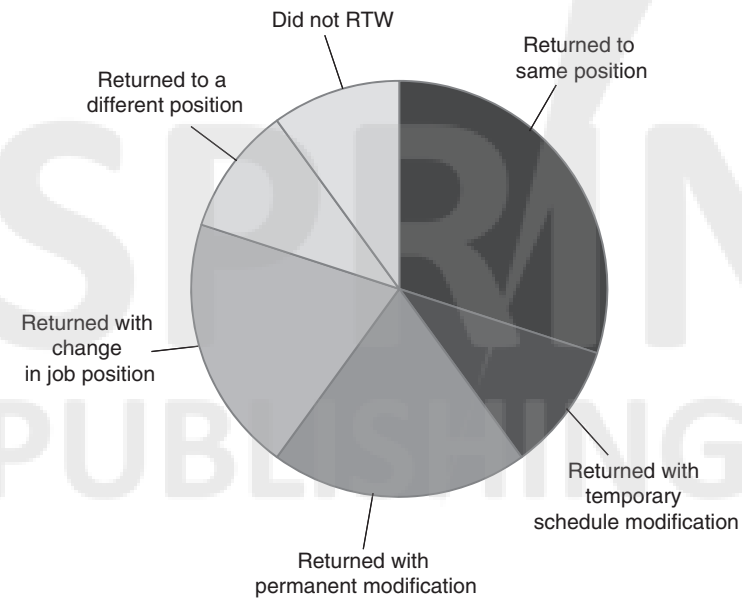

FIGURE 51.3 Return to work breakdown for 10 stroke victims.

Source: From Ref. (7). Culler KH, Wang YC, Byers K, Trierweiler R. Barriers and facilitators of return to work for individuals with strokes: perspectives of the stroke survivor, vocational specialist, and employer. *Top Stroke Rehabil*. 2011;18(4):325–340.

positively predicted RTW. The availability of governmental resources such as a social security system also impacted likelihood of RTW (16).

In the study by Culler et al., none of the stroke survivors found a job with an entirely new employer or company. The reasons for this are several, and include the existing trust between employer and employee and sense of mutual responsibility to each other. Finding a new job is often very difficult for stroke survivors, particular if they are visibly disabled. Despite the legal protections afforded by the Americans with Disabilities Act, subtle discrimination against disabled individuals in the employment market is widespread. New positions also typically entail a steeper learner curve than a familiar position (or even a new position within the same company), and are thus more demanding for the employee. Despite the fact that stroke survivors may have an easier time with their prestroke employers, a number of factors can limit returning to work even in this circumstance. For a person with disabilities, the workplace must be accessible; equally importantly, the employee with a stroke must be willing to use these accommodations (7).

Many employees also cite the employer's attitude as being essential to their own ability to RTW. Clearly, a strong support system is essential in creating a successful environment for RTW. But other factors come into play as well: how long the patient has been absent from work can influence the likelihood of returning to work. If there is an extended delay before attempting to RTW, the stroke survivor's position may have already been filled or work permanently redistributed. Another consideration is the employee's work performance prior to the stroke. Many employees do not consider whether the employer was satisfied with their performance prior to the stroke, and find lack of employer motivation for RTW an unexpected barrier. VRCs often cite this as an oversight on the part of the patient (7).

Culler et al. categorize the changes that a poststroke employee undergoes into two categories: internal and external. Internal changes involve a change in the person's attitude and self-perception. A common example (and perhaps the most important one) is learning to *accept* one's disability and work with it, in spite of the impairments that remain. External changes involve a change in job tasks and accommodations, such as switching from full time to part time or taking a bus to work instead of walking. Both internal and external changes are typical for stroke survivors, and awareness and acceptance of these changes are important factors in successful RTW.

Case Study 2

A 60-year-old left-handed woman with hypertension recently sustained a left hemisphere embolic stroke. Her problems include mild nonfluent (expressive) aphasia with anomia (word finding difficulty), moderate right-arm weakness, mild lower-extremity weakness, and some difficulty walking. She worked as a receptionist at a talent agency prior to her stroke and would like to return. Over a three-month period, she has recovered fairly good motor control and strength of her right arm and leg, but still has difficulty using her right hand for fine motor tasks. She is adept at using a computer keyboard one-handed with her left hand and has no difficulty writing with her left hand. She walks with a straight cane in the left hand and an ankle–foot orthosis (AFO) brace on the right lower extremity. Her children are grown and her husband is deceased. She lives alone in an apartment building. Her hobbies include swim aerobics at the gym and a women's book club.

Recommendation

This patient is still within standard working age, and because working seems to be an important factor in her life, she should pursue RTW. However, because of her nonfluent aphasia, a job as a receptionist is probably not the best option for her. With the help of her vocational counselor, she should contact her prestroke employer and inquire about disability accommodations, but should also look into transferring her position, perhaps to another department. Or, she could work assisting another receptionist, and might focus on memo writing, agenda organization, stocking and purchasing, and so on, as opposed to answering the phones. In the modern digital age, many companies focus on e-mail rather than voice-based correspondence, and she might play a role in customer service for nonvoice methods (e.g., an online customer service chat system).

Vocational Rehabilitation Services (VRS): Vocational Counselor and the Interdisciplinary Team

The vocational rehabilitation process enhances capabilities that enable employment in the patient's preferred job. Anyone with a disability who is seeking employment can benefit from VR services; in the case of stroke specifically, it is recommended that VR counseling begin early, during inpatient rehabilitation if feasible (Figure 51.4). VRS is paramount to a stroke survivor, especially in the current economic climate. As mentioned earlier, even many able-bodied individuals struggle to obtain employment in today's economy. Prospective employees with disabilities, particularly disabilities that impede cognitive function, are at an even greater disadvantage. VRS strive to close that gap and enable many disabled persons to RTW successfully.

VRS are offered not only by a rehabilitation institution, but also by a group of professionals trained and experienced in vocational rehabilitation. VRCs are often the most active in guiding assessment and seeking specific treatment for clients. Almost all VRCs must undergo accreditation and become licensed counselors in the field of vocational rehabilitation, which requires a master's degree (11). These professionals understand all aspects of the rehabilitation process and can collaborate with the interdisciplinary team to seek specific assessments, develop specific motor skills, and provide ergonomic modification to the worksite. Therefore, while the counselors play a leading role, the patient must keep in

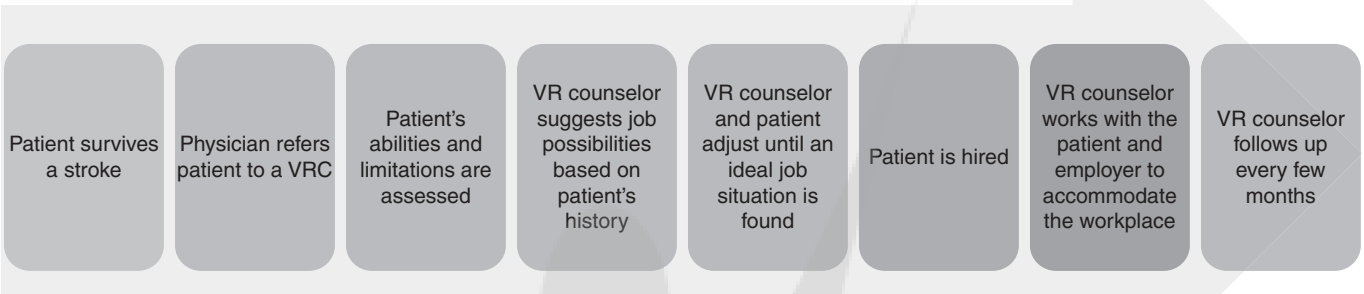

FIGURE 51.4 Schematic timeline of vocational rehabilitation after stroke.

mind the adage "it takes a village." Similarly, it takes a team of individuals to help a stroke survivor RTW. Other members of the team may include physical, occupational and speech therapists; a psychologist; physicians; family members; and technological service providers, as well as the employers themselves.

The core goal of a VRC is to assess and rehabilitate a stroke client to meet work requirement needs.

Vocational Counselor: Contributions to Vocational Rehabilitation (11)

Collect educational, vocational, medical, and psychological information to best understand the person's recent vocational skills, and current condition after stroke.

Provide and coordinate appropriate analyses (e.g., physical demands, reasonable accommodations, work capacity evaluation) so the person can make an informed choice about his or her career options.

Help design a plan for independent living and career pursuits.

Identify skills, knowledge, and further training necessary to pursue a career consistent with the person's interest and abilities.

Develop an individualized plan for achieving employment that lists the steps needed to reach the person's job goal.

Provide labor market information and other resources to obtain job leads.

Follow the person's progress at work to help in maintaining the job.

The preceding text box lists the major interventions provided by the vocational counselor to the interdisciplinary rehabilitation process for a patient with stroke.

ACHIEVEMENTS IN SELF-CARE, PSYCHOLOGICAL ADAPTATIONS, COMMUNITY MOBILITY, AND SELF CARE

The preceding section described the general duties of a VRC, but vocational counselors individualize their services to meet each client's needs. A study by Culler et al. discussed the experience of vocational rehabilitation from the perspective of the stroke survivor, the VRC, and the employer. Though all three agreed on most of the commonly experienced barriers to a successful RTW, the vocational specialists pointed out some unique impediments to the process. These included a lack of awareness of the extent of the patient's disability, and the need for continued medical care; however, the most important barrier was a lack of motivation to RTW (7). A lack of motivation on the part of the stroke survivor can result in his or her failure to contact the VRC or other professionals. A connection between counselor and patient cannot form properly if there is unwillingness on either part.

In addition to requiring communication between parties, a good relationship is dependent on frequent communication between every member of the stroke patient's interdisciplinary team. An important factor, according to a survey of 21 vocational specialists, was the patient's motivation surrounding return to work. For example, if a patient is unwilling to fill out the necessary paperwork, he will have difficulty returning to work. In fact, it was apparent to these specialists that emotional factors often have a larger impact than physical ones (7).

The journey between having a stroke and returning to work is a process that involves a number of individuals and a significant amount of time. Several months may elapse before employment is regained, and even more follow-up time is required, often on the scale of years (7). Every state in the United States has a vocational rehabilitation program. A list of them can be found at https://askjan.org/cgi-win/TypeQuery.exe?902. Although the quality and capacity of these services vary, these are key resources for anyone with a disability who is seeking to obtain aid in returning to work.

Case Study 3

A 33-year-old disabled male construction contractor with a history of atrial fibrillation had a left frontal lobe ischemic stroke. His problem is not physical weakness, but rather what seems to his family to be a shift in his personality. He has very unpredictable mood changes and is often irritable and unwilling to cooperate. Before the stroke, he was congenial, helpful, and even-tempered. He previously worked as a contractor leading teams to frame houses for a home building company. What would be the process for such an individual with a VRC?

Recommendation

The biggest vocational focus for such a patient is his own interests and affinities. Perhaps certain aspects of his prior job remain appealing to him: for example, planning and organizing the materials needed to frame rooms and support floors. The VRC should work with the patient to determine what these affinities are. His behavioral issues require further evaluation and treatment. It is unclear if he might have poststroke depression, or perhaps some component of pseudobulbar affect. Treatment of his behavioral issues should be undertaken before attempting RTW.

The VRC can also work on social skills training and effective communication skills with the patient. Only when the patient is ready to RTW should he do so; this should be determined in consultation among the VRC, the patient, and the psychologist or psychiatrist. In addition to determining the right duties and timing of RTW, consideration should be given to any necessary job accommodations. The patient should be educated on how to explain his condition to fellow workers to minimize conflict in the workplace. Frequent breaks might help such a patient with his mood swings, and the personnel at the company should be aware of his condition so that other workers can make an effort to both recognize and accommodate his behavioral difficulties.

EMPLOYER ACCOMMODATIONS

There are various steps that an employer can take to accommodate a stroke client upon RTW. The accommodations themselves are generally split into two categories: physical and interpersonal. Obviously, stroke clients with physical disabilities might find it difficult both to get to work and, once there, to meet the physical demands of that work. Because of this, there is a set of "reasonable accommodations" that an employer is expected to make for the employee. For each job, there is a set of essential job duties that any employee is expected to meet, regardless of disability. For example, a copyeditor at a publishing house must have good grammar; a receptionist at a medical office must be able to greet and interact with patients. However, beyond those essential functions, employers are legally prohibited from discriminating based on the Americans with Disabilities Act.

Once a person of with a disability is hired, he or she must work with the employer to determine which accommodations are necessary and reasonable. The patient's activity limitations should be communicated to the employer as restrictions outlined by the rehabilitation physician. Restrictions might include weight lifting limits, no use of ladders or stairs, and the like. Under Title I of the Americans with Disabilities Act, employees must provide accommodations to persons with disabilities under their hire unless doing so causes unnecessary hardship (17). The U.S. Equal Employment Opportunity Commission provides a list of some common accommodations (18):

- Making existing facilities accessible
- Job restructuring
- Part-time or modified work schedules
- Acquiring or modifying equipment
- Changing tests, training materials, or policies
- Providing qualified readers or interpreters
- Reassignment to a vacant position

For a stroke patient, these accommodations are essential in creating a productive and comfortable work environment. However, many employers are unfamiliar with this process, and may have concerns about the feasibility and cost of these accommodations, as well as their legal liability regarding accommodations. An ongoing dialogue between employer and employee is necessary for these accommodations to take place. Specific modifications can often be requested in writing and explained by an occupational therapist. If a stroke survivor needs a change in the work environment, he or she must ask for it. However, if unable to do so, the stroke patient may have a family member or even (and especially) the VRC or rehabilitation physician ask the employer on the patient's behalf.

Interviewing for a new job can be especially challenging for someone with a visible disability. A potential employee is not required to disclose a disability during an interview, by phone, or otherwise. An employee may decide to tell a potential employer about the disability, but, so long as it does not impede the employee's ability to perform essential job functions, he or she is not obligated to do so. In Culler et al.'s 2011 article, an employer stated "[T]hroughout the hiring process, we just really don't look at any disability as a reason to hire or not hire that individual. We always try to get the best candidate based on the skills and experience." Regrettably, this attitude remains far from universal.

Assistive Technologies

Assistive technology is any piece of equipment, computerized or not, that improves the functional capabilities of someone with a disability (11). These items can be home-made or store-bought, and span a very wide range of disabilities and severities.

Visual Deficits

Visual deficits are common comorbidities of stroke. Often, stroke patients may also be challenged by macular degeneration, glaucoma, or retinopathy. Visual deficits themselves are varied: refractive visual field loss, ocular motility disorders, and visual perceptual disorders. Many of these are easy to accommodate. Beyond eyeglasses, there are many computerized technologies that make it easier for a visually impaired employee to work with computers. Screen enlargers and magnifiers are built into most computer operating systems; if these are not sufficient, there are external magnifying devices are easily mountable onto a computer screen itself. This is useful for low-vision stroke survivors.

For patients who become blind after stroke, there are still more visual aids, such as screen readers, which read the text on a computer screen out loud to a user. Newer devices, such as the iPhone, may have built-in screen readers and visual magnifier tools. Siri, Apple's speech recognition system, can assist with placing phone calls, performing web searches, and other functions for the visually impaired. Windows is a leader in screen-enlargement technology, and continues to accommodate its users. Thunder, a company that works with Microsoft for Windows devices, even has an application that reads out the names of approaching bus stops while one is riding the bus.

Fine Motor Deficits

Many stroke survivors experience loss of motor control or coordination. Assistive technology exists for these patients as well. Something as slight as a tremor can seriously affect someone's work productivity. However, many keyboards come equipped with sensitivity compensations. For example, a person with a tremor might lightly hit a key many times without meaning to. A keyboard can compensate for this by being less sensitive to touch. Phones and tablets now guess at which word is being typed, which can help compensate for spelling errors. Computers can increase their response time to give someone the chance to catch up with what they are typing. A keyguard can reduce accidental key strokes by sitting over the keyboard itself, and other jackets that color-code the keys can make it easier for someone with both visual and motor deficits to type effectively.

Some patients have trouble with wrist movement; a trackball or joystick can help them work around the difficulty of having to use a conventional mouse. With a trackball, only a finger is required to move the cursor. Patients with distal but not proximal motion might opt for a joystick, which gives somewhat greater control but still reduces reliance on use of the wrist. Touchpads are still more useful, reducing much hand movement entirely. The recent popularity of touch-sensitive tablets such as the iPad makes them very good mobile computer options.

Gross Motor Deficits

Some patients are left with major impairments in motor abilities after stroke. For someone with a brainstem stroke, there may be impaired motor abilities in all four limbs. In spite of these challenges, a motivated individual may be capable of returning to work. A "sip and puff" control system allows someone to move the cursor with only head movements, and to click the mouse using sip-and-puff motions. A head-tracker, which attaches to the computer being used, can track a reflective dot on the user's forehead and determine movement of a cursor. In this case, clicking commands can be achieved through voice, or sip and puff. More specific is an eye-tracker, which uses a similar technology but tracks eye movement. This is particularly useful for patients without any upper body movement.

If a patient has use of the lower extremities, a foot mouse can be very useful. In this case, one pedal is used to move the cursor, and another to click, somewhat like driving a car. Of course, for patients with preserved language and speech abilities, hands-free speech recognition technology is becoming better and better, as it becomes a mainstream way of communicating and working.

Hearing Impairment

Although hearing loss is infrequently a direct consequence of stroke, it can sometimes coincide in older stroke patients with age-related hearing loss. Hearing aids may be useful for some patients. For those who use computers in their work, headphones may be useful. Deaf patients can use visual cues on the screen in lieu of sounds in many cases.

Social Media

Recently, with the explosion of social media (including in the workplace), stroke survivor support groups are very easy to find and join. On the "Stroke Survivor" Facebook group, many of the 898 members post their stories of experiencing a stroke and returning to work. Others thank them for their contributions. That group is one of dozens on Facebook just like it, with this number growing steadily. Some are regional, like the Stroke Survivors of Ottawa Association; and some are age-based, as is the Young Stroke Survivors Action Group. The Stroke Association even has a Twitter account, where other members hashtag phrases like "#stroke" and "#strokesurvivor" in their tweets.

Having a community can be an essential means of overcoming a recent stroke, and of finding a way to RTW, and it has never been easier to become a part of one than now. The face of rehabilitation is changing with the new world

of communication. Stroke survivors no longer have to feel so alone—in fact, a whole social network is right at their fingertips.

CONCLUSION

William Arthur Ward (1921–1997), acclaimed writer and inspirational philosopher, once remarked: *"A true friend knows your weaknesses but shows you your strengths, feels your fears but fortifies your faith; sees your anxiety but frees your spirit; recognizes your disabilities but emphasizes your possibilities."*

Inspired by this doctrine, physiatrists working closely with the rehabilitation team are uniquely suited to helping stroke survivors in their quest for vocational recovery. This chapter has attempted to provide a broad overview of this essential process, based on the collective experience of the authors. The process of applying fundamental rehabilitation principles toward this noble goal is truly its own reward.

Stroke From the Survivor's Perspective

Deborah Mack

When I had my stroke, I was working as a freelance writer and writing fiction. I'd recently signed a contract for a three-book publishing deal under which my first novel would be released the following summer. Fortunately, I received treatment quickly, and my recovery seemed miraculous. I remember walking around the CCU, feeling blessed. But then I looked at all the bed-ridden patients around me and felt horrible. After I had my stroke, I suffered a period where I couldn't sleep at all, along with a great deal of emotional lability, which I was told was normal for stroke victims. So, when I'd go to the hospital for rehab for the minor deficits at that time, I'd actually cry if I heard an announcement of a Code Blue or need for CPR. The only physical problems I had right after the stroke were slight weaknesses in my left hand and left leg. My mouth was also slightly affected, although not enough to make my speech slurred. Although my mouth would go lopsided when I smiled during the first few days after my stroke, I recovered enough within a week without rehabilitation so that no one who wasn't a trained observer could tell I suffered any deficit at all.

I underwent a few weeks of outpatient physical, occupational, and speech therapy to compensate for the minor physical deficits the stroke had caused. I remember tiring easily, which I was also told was normal. So, I made a point of taking breaks when I needed to. There were times I'd get so tired, I had to lie down.

However, after a couple of months of rehab, I seemed to be fine. I was released from further care with a clean bill of health, after having an outpatient surgical procedure to close the ASD in my heart. This hole between the atria had allowed a blood clot to reach my brain, thus causing the stroke. Once I'd had the procedure and finished rehab, I figured that was that.

Mind you, I wasn't exactly wet behind the ears when this happened. I was a practicing attorney for nine years. And I knew from experience that horrible things happen when people make the wrong choices. I also knew that life wasn't fair, from growing up poor. My family didn't live in a nice middle-class neighborhood with a white picket fence around the house. And my father was a writer, who wasn't always there for us. But he always encouraged me to be a writer. So, that was my therapy. I found solace in my work.

Because my first novel was due to come out soon, I'd arranged to speak at a local women's business club. While I was in the hospital, my husband had to cancel that speaking engagement. However, I also had a monthly deadline coming up to submit an article. After I was released from the hospital, I seemed to have fully recovered. So I got in touch with my editor and asked for an extension because I'd had a stroke. She asked me if I'd rather have someone else write it instead, but I refused. I told her I could do it if I could just get a little more time to turn it in.

I could have easily accepted her offer, but to be honest, I was afraid of being replaced. When you're a freelancer, you need to be dependable. I didn't want my editor to think my health had been compromised. As I said, I thought I was fine. Needless to say, that didn't turn out to be the case. I had the rug pulled out from under me five or six months later when I developed symptoms of dystonia in my left hand and foot (the side affected by the stroke). My first response was to seek treatment from the neurologist who'd evaluated me after I left the hospital. She diagnosed my condition, and she referred me to a movement disorder specialist and a group of physical therapists. I continued to work as if nothing had changed. In fact, I poured myself into my work because I was getting so little relief from medical treatments. And it's hard to simply relax and enjoy life when your body is constantly moving against your will.

Although my movement disorder physician was a most empathetic person and I felt lucky to have her as a doctor, my physical therapists seemed relatively clueless about my condition and state of mind. One even took this weird tone with me when I asked, "Will this *ever* get better?" Her response was, "You've had nerve damage." And she said it so matter-of-factly that I felt like an idiot for asking. Then, I wanted to slap her silly because no one should talk to a suffering person like that, least of all a person who's treating suffering people.

To make matters worse, my first novel went out-of-print nine months after it was published when the small press that released it went under. Talk about having the rug pulled out from under you.

At first, my treatment consisted of Botox injections, some medications, and physical therapy until the physical therapists basically threw up their hands and said they

couldn't do any more for me—as if they'd done anything for me in the first place. The Botox injections were a less-than-ideal treatment for my problem. The toxin weakened the muscles in my hands and arms, so my fingers ended up even less controllable. After the shots, instead of fully clenching, some of my fingers hung limp and useless from my hand, while other parts of my hand kept clenching. My grip was a joke. Dystonia is weird that way. After any given treatment, I might get some relief in one part of my hand while other parts remain clenched. This made typing a tedious chore.

Many well-meaning people suggest I use speech recognition software. This advice is actually contrary to my best interests in the long run. Because my dystonia was caused by a stroke, it makes more sense for me to keep typing. In this way, I hope to retrain my brain, like other stroke patients. This concept has been supported not only by my doctors, but also by a book I read called *Train Your Mind, Change Your Brain* by Sharon Begley. This book led me to seek alternative solutions to Western medicine.

One of the most frustrating aspects of trying to get good information about my condition has been the lack of communication between researchers. I'm assuming this failure to share knowledge is probably because of the competitive nature of research done to win prizes, grants, or other professional or financial compensation.

For me, the most interesting part of Sharon Begley's book was learning that the Dalai Lama held an annual neuroscience conference. Along with discussing how stroke patients can retrain their brains due to brain plasticity, the book explored the potential for Eastern medicine, meditation, and Buddhist techniques to aid in stroke recovery. Although dystonia wasn't mentioned in the book, I wondered if anyone at the Dalai Lama's Institute had even heard of my condition.

I looked up the Dalai Lama's Institute online and sent them an email asking if they knew about dystonia. To my surprise, they responded. However, they knew nothing about dystonia. This disheartened me and not only because dystonia is the third most common movement disorder. It just seemed to stand to reason that the institute would be seeking solutions for a neurological problem that Western medicine was incapable of treating adequately.

I even went so far as to try to contact Sharon Begley, but my email to her didn't go through. So often when I read news about brain research that didn't solve what I thought was a genuine problem, I'd wonder why they did it when people with dystonia were desperately seeking solutions. After a while, I had to stop asking that question. I could go mad, continuing to wonder why the medical and research community didn't have its act together.

I'd try to talk to people about my situation, and they'd come up with scenarios of their own. My question was always, "Why me?" One person explained to me that she had a difficult child, who seemed like he would never amount to anything. This was her and her husband's cross to bear for all the years they raised him. Eventually, he grew up and turned out fine. The ending of the story was the part where it all fell apart for me. I wanted to say, "Where's my happy ending? Don't I deserve a break from the torture?"

Naturally, people suggested finding support groups. My first attempt at finding such support was by reaching out to the dystonia community through the Dystonia Medical Research Foundation, because their name came up in a Google search right at the top. I got to know various people in my area through this organization and others online through Twitter. The problem with this approach was that dystonia manifests itself in myriad ways. Every type is different, so it was hard to find anyone with whom I could truly find totally common ground. In fact, if anything, getting involved with the dystonia community made me all the more aware of how fortunate I was compared to some. I still needed to find support, and this seemed inadequate.

The one time I spoke to a psychologist about my condition, he said, "Well, it won't kill you, right?" Right, doc, it'll only make you wish you were dead. Every damn day. For the rest of your life. And I was young. And it wasn't fair.

As a result, I had to simply go on with the capabilities I still possessed and a whole lot of unanswered questions. This meant that the best I could do was try things and hope that they made a difference. I tried all sorts of alternative therapies, ranging from acupuncture to acupressure to neurofeedback to nutritional supplements. I also tried a variety of pharmaceuticals. Everything I tried involved time and/or money. Each time I tried something, I'd hope for even the slightest improvement, only to have my hopes dashed.

There were days when I would get so frustrated, I'd simply howl at the top of my lungs. I'd curse god even though I didn't believe in a deity. I wasn't about to start believing in one that would do this to me. But then I'd feel bad because I knew that there were others who had it worse than I did. In fact, I was lucky I could do what I could. I was still able to write. I could walk. I could still think clearly. These were things I realized I should appreciate from a larger perspective. I realized that I was nobody special. I knew rationally that god wouldn't care more about my problems than anyone else's. This led me to question why a just god would create so many problems for all of us to begin with.

As a result, any suggestion that I look for support from god or religion seemed ridiculous. Even seeking support from other people seemed hopeless. When I tried to explain how I felt to others, they always told me to hang in there and not to lose hope. Often they suffered from chronic illnesses of their own, and they suggested possible solutions with the best of intentions, not knowing that their situation was completely different from mine.

Ultimately, coping with my condition involved a combination of finding joy in my life, family, and work and reaching out to others for support, although it took time for me to achieve a better work–life balance and to realize the source of that support.

Two years after my stroke, I started a blog called Random and Sundry Things. Blogging was considered the modern way for writers, consultants, and other businesses to market online. In starting my blog, I was trying to keep on working as

usual, using a blog to establish an online presence. Although everyone said you needed a niche for your blog, I refused to follow the rules and decided that I was too much of an "unrepentant generalist" to focus on any one subject. And because I had dystonia, I used the blog to raise awareness of the disorder and share resources and information because I could blog about anything there.

Although I started the blog as a place where I could post my thoughts about virtually any subject of interest that I might wish to write about, it became much more than that as time went by. I began expressing my opinion more openly about many subjects, including the failure to find a cure for medical conditions like dystonia.

The blog posts could vary in length and tone from satirical to a simple statement or video or photo. At one point, I was even included on a list of women political bloggers, much to my surprise. Blogging seemed to be a great way of connecting with others and sharing views while getting a benefit in return. To me, it was like a combined form of publishing, marketing, and networking. However, it also turned out to have therapeutic value for me, one I wouldn't realize until many years later.

What happened as a result was that I became increasingly immersed in blogging and when I saw a promising niche, I'd start a new blog to establish my credentials on the subject.

In fact, I decided, at some point, to start a second blog called Writing for Hire. The blog focused on the business aspects of being an independent writer, regardless of the type of writing one did.

This is where the online world put me at an advantage. No one could see my disability, so I could conduct business online as if nothing were wrong. I realize now that creating a wall between my business and personal life was taking a toll on me. However, it took years of working through pain and frustration to reach the point where I knew I had to learn to cope at a much deeper level.

After writing several book reviews on Random and Sundry Things, I started a book review blog called The Book Grrl. I hadn't planned to write reviews for fear of holding back and giving a less than honest opinion. However, I also knew that publishers did a bad job of promoting their mid-list authors and that good word-of-mouth helped sell books. After reviewing a few books on my first blog, I saw an opportunity to establish good will and expertise in the fiction and reviewing arena with a book review blog. This had the added benefit of making me a more discerning reader. I became better at evaluating the essence of each story and how it worked.

In addition, when you read and review lots of books, you develop an appreciation for good writing and a better sense of what works and what doesn't. This gave me insight into what agents must go through in choosing to sign clients. This made me all the more aware of the uphill battle I faced in trying to find agency representation for my novels. I continued to freelance, write novels, submit queries, and get really encouraging rejection letters on top of everything else.

I was blogging every day on all three blogs, along with doing my work and writing fiction. I was also going out to networking events to meet people at writer's conferences, local mixers, and other venues. In this way, I kept busy and didn't allow my dystonia to distract me from the goal of making a living as a writer. My main fear was that I'd be perceived as an object of pity or that if I defined myself in terms of my disability, people would see me as incapable and looking for a handout or a break. I only wanted to be judged on my own merits, like anyone else. Meanwhile, my first blog, Random and Sundry Things, continued to be the one where I could write about anything, including my own occasional news, frustrations, or hopes related to dystonia.

Then, I happened to see the film *Ikiru*, which may have changed my life. Kurasowa's *Ikiru* is about a bureaucrat who sees no point to his existence. He hates his job, one in which he tries and fails to accomplish goals he thinks are important. He's lonely and has no one to turn to until he meets a young woman, who works in a toy factory. It's in the simple task of creating toys for children that she finds her life's meaning. He sees the goodness in her because her nature is essentially so giving.

Then he finds out he has cancer. At this point, he decides he must do something to make his mark and bring joy to the world. He decides he's going to build a public park, no matter what it takes or how much red tape he has to wade through. By the end of the film, the man is dead, but the park is built. The final scene shows him or perhaps his spirit, in his park, on the swing. The film was so beautiful and inspirational that I decided I had to do something, too.

I decided to organize a fundraiser for the Dystonia Medical Research Foundation. This seemed logical because I had ties to the group already and I knew another local dystonia sufferer who held an annual fundraiser. I did this while freelancing and writing fiction, so I was immersing myself in work and philanthropic efforts full-time. I look back on this and realize that doing this was part of my coping process. I had to do something with myself. I couldn't just sit around useless. I was always a busy, productive person before I had dystonia, and I wanted to continue being one.

The year 2009 ended up being one for the books. The fundraiser took place in May 2009. While I was organizing the fundraiser, I took a screenwriting course and finished a screenplay I had started years before. In June 2009, I re-released my first novel by self-publishing it as an ebook, then as a print book one month later. In September, my husband and I took our first trip overseas. We went to Italy, the country of his ancestors, and a place I'd always wanted to see. Thinking back on it, I realize it was a year of making great things happen because I could. However, at the time, I was simply keeping busy and trying to get things done that I thought were important.

Meanwhile, I kept seeking solutions from different alternative medical providers, but nothing they did seemed to really work. With each attempt, I'd have to ask myself, am I wasting time and money I could be spending more productively? No one had the answers, of course. So, I had to

decide for myself. This was like trying to walk through a maze blindfolded. I had no idea what I was doing or guidelines for how to make the right decisions. And no one could give me any real guidance. This, of course, was terribly frustrating.

What made matters even worse was that my disability went unnoticed. I felt that no one could understand the degree to which I was suffering. But I couldn't go around complaining all the time. That would annoy people. As a result, I kept my frustration bottled up, but allowed it to release through my writing, blogging, and other activities.

Meanwhile, I continued to look for answers and otherwise cope through engaging in my work as if I didn't have a disability. In fact, I tended to downplay it around others for fear of seeming weak or incompetent to do my job. I simply refused to be defined by my limitations. Yet, with no indication that anyone could truly understand what I was going through, I felt cheated. I began to resent people who actually suffered more than me, simply because people noticed their suffering and acknowledged it.

In my heart, I knew this was wrong. I didn't want to be in a wheelchair, nor did I want to suffer more. I also bore no ill will toward people who had suffered. If anything, I felt so bad for them, it began to take a toll on my mental health over time.

My sheer determination to make a living as a writer through freelancing led me to consider a variety of niche subject areas. Over the years, I'd joined a variety of groups and considered specializing in various topics. However, each of these groups involved going to meetings and interacting socially on a regular basis, which was becoming increasingly difficult for me, both physically and mentally.

Nonetheless, because I had both interest and expertise in environmental issues, as a former land use attorney and EPA lawyer, this seemed like a great subject in which to specialize. So, I started a fourth blog called Green Reality Check. Therefore, along with trying to find clients through networking on and offline, I was now posting to four blogs. I was also scanning headlines for news items and blog posts that could provide material for any of the blogs. This kept me well-informed of developments on a wide array of topics, including politics, publishing, bookselling, writing, sustainability, environmentalism, nature conservation, films, book reviews, travel, health news, and dystonia.

Between the onslaught of information I was picking through, the physical demands of all the work and the overall stress of everything, I was already feeling a bit overwhelmed. But I refused to give up. I wanted to make a living as a writer, and I wanted to write fiction and find a publisher and/or an agent. I also planned to write a series, per the terms of my old publishing contract. But I couldn't have imagined making a living as a fiction writer at that point.

One of the most frustrating hurdles I faced when my novel went out of print was that many agents didn't seem interested in representing my out-of-print novel, despite the fact that the book had been well received before the small press went under and there was the potential to create a whole series of books based on the protagonist, which was what mystery readers tend to like.

Despite this, I revised a previous novel to make it the sequel and wrote the third novel in the series. Then, at the suggestion of various agents, I wrote two stand-alone novels. I was at a loss for where to go next, so I just kept writing, submitting queries and getting rejections. The process reminded me of the old maxim: "Insanity is doing the same thing over and over and expecting a different result."

I learned over time that I had to conserve my strength and focus on the positive things in life. I had to stay focused on getting the job done and not be distracted by wasted gestures and activities. I believe that over time this failure to acknowledge my own frustration and rage at my situation ultimately hurt me. I was so focused on proving to myself that I still had what it took to succeed that I needed a way to ridicule myself for lack of other outlets.

Hell, there were nights I'd pray (even though I didn't believe in god and cursed the nonexistent god's name on more than one occasion), "Please, let me die in my sleep tonight." But I didn't, nor did I kill myself because I felt I had a mission. And killing myself would be a waste of my potential. My life would've amounted to nothing. And my husband and family would suffer.

But I couldn't talk about it for fear of sounding ungrateful. Dystonia sufferers all differ, so I could truly empathize with them, but it was hard to explain my particular predicament. None of my writer friends truly understood my pain. On top of which, I felt guilty, because I knew others suffered much more than I did.

When I decided to self-publish my out-of-print novel, I hit upon an idea for a blog to market myself as an author. I called the blog, My Life on the Mid-List, in homage to Kathy Griffin. I thought it was because Kathy Griffin was doing the kinds of things authors did all the time to promote themselves—events and so on. She made a joke of her own life and it worked out for her. I thought that idea had possibilities, though I wasn't sure how well it would work for a writer.

However, I'd reached the point where my own life seemed so ridiculous, the only thing I could think to do was laugh at my calamities. And so I began my fifth blog. Significantly, the very first thing I posted after the initial post was called "There's No Crying in Publishing." Essentially, it was a humorous diatribe that said, "You think you have problems? Try being me." I look at that now and realize I was a very angry person, who had to laugh at her own life or go mad. However, at the time, I was so consumed with presenting myself as being strong and capable despite my disability, I failed to address the now obvious emotional issues I was burying beneath the humor.

All the while I'd been freelancing, I was writing fiction and sending queries to agents and reputable small publishers. I started my fifth blog in June 2009, along with self-publishing my out-of-print first novel, in a bid to establish a readership while I was seeking an agent or new publisher. The book had received a handful of great reviews from various publications. It also got some rave online reviews from readers.

My blog became my forum for sending up the bizarre nature of the publishing world. Self-publishing my work as ebooks wasn't part of a big plan on my part. I stumbled across the information by reading blogs about the subject while writing posts for Writing for Hire. As a writer seeking a readership, it only made sense to me to take advantage of new technology to create, market, and sell my books.

It didn't take long for me to figure out that, if I priced my ebooks low, I could make more money from volume sales. So I took this approach in the hope that selling my ebooks cheaply would generate more sales, which hopefully would lead to more and better word of mouth about the books. When I started to see significant financial results, I threw myself even harder toward succeeding as a fiction writer. Based on my writers group's suggestion, I revised the third novel in the series and made it the sequel. I also wrote occasional short stories, some of which were published in anthologies.

Eventually, my husband could see I was wearing myself out, and he suggested that I focus solely on fiction writing. I also grew tired of waiting for the publishing world to accept me. So I decided to take the leap to self-publishing all my novels.

This felt like a huge gamble. Up until then, I would never have thought to self-publish all my work, let alone start trying to earn a living from fiction writing, before I'd had time to build a more substantial readership. However, once I saw how well self-publishing ebooks could pay, if you played your cards right, I figured all the effort I was putting toward freelancing could be better spent establishing my credentials as an author.

So, I approached fiction writing and marketing the same way I did when I was freelancing. I looked for ways to sell my work, on- and offline. In the process, I discovered that many approaches authors took to marketing their work were time-consuming and required both physical stamina and social skills, both of which I was pushing to the limit. My secret disorder made it all the harder to keep going to events that didn't pay off financially or doing things the old-fashioned way, such as driving all over creation to book signings, book festivals, and other traditional selling venues.

Along with that, although I didn't realize it, blogging was therapeutic for me. The Internet and social media provided a way to market my work more easily than in the past. This way I could continue to do my work while being relieved of the stress created by social interaction. The only problem with this approach was that the more dependent I became on it, the less I stepped away from my computer. The effect was to isolate me, which wasn't healthy.

I began to rely increasingly on technology, the Internet, blogging, and Twitter to sell my work. Because writing takes time and more effort when you have a condition like dystonia, the less physical strain and time I put into marketing, the better off I was. Or so it seemed. Online marketing required far less time and was much more cost-efficient than the usual ways of getting the work out there.

Although I gained financially, having hit the ebook market early enough to avoid the huge competition new authors face now, I lost touch with people. At least, my face-to-face dealings with them were minimized so much, I began to feel like a hermit. However, I got to know people online, which seemed like enough for a while.

Furthermore, my ebook sales were far greater than I could have ever imagined possible, not only in the United States, but also in the United Kingdom. Many authors asked how I was doing this, and I had no idea. I just assumed my author blog and perhaps my interactions on Twitter with people in England and Ireland were helping. And I had gotten to know one reader in particular in England through blogging as well as an author who had been kind enough to leave a comment on my blog suggesting the names of two agents in the United Kingdom I could try to approach if I wanted to.

It soon got to the point where the only times I stepped away from the computer were on weekends, at writers conferences, and for the odd special occasion. I literally had to pencil in relaxation time. I forced myself to do other things, because I feared becoming a complete shut-in. I yearned for the time when relaxation and fun came so simply. Yet going out to parties and other social events requires that you always be on. I had to bite my tongue many times to keep from shouting my frustration to one hapless person or other who couldn't see the ordeal all the fun was for me.

Clearly, I was becoming consumed by my work and Internet interactions to the point where I was losing touch with people right in my own backyard. It's hard not to seek release through losing yourself in creative work and the freedom of speech the Internet grants you when you're suffering and you have no idea if it will ever stop.

For nearly seven years, I conducted business this way. I kept writing, blogging, and suffering silently. I think I found meaning and purpose in doing things for people online. Engaging in random acts of kindness on the Internet seemed to help me work through my own sorrows. It was also smart marketing and networking, in my opinion. And I could do it from home without worrying about how happy I looked, whether I was responding appropriately on the fly, how the exertion would affect me physically, and myriad other things I'd always taken for granted before I developed a movement disorder.

To complicate matters, I started to see and feel changes in my body because of my movement disorder. My balance was affected. I'd developed a bunion-like growth on my hand. This worried me on top of everything else.

Eventually, my work wore me down so much, I had to face my demons. The turning point may have come while I was attending a regional dystonia conference. I was fast reaching the end of my rope when I heard a speaker talking about acupuncture.

I'd done acupuncture before, so I wasn't terribly hopeful when I sat in on the session. However, the presenter got me thinking about it again. His position was that you needed to see a practitioner that knew dystonia and was right for you. Acupuncture takes a highly subjective approach to treatment and cure. Not only is it more holistic than Western

medicine, but it also emphasizes individualized care, based upon factors specific to each patient.

In other words, the only way to find out if acupuncture could help me was to find the right practitioner and give it a real shot. This had to be with the understanding that each patient requires a different approach. Each acupuncturist takes a different approach to the same set of symptoms. I think it's this lack of standardized care that makes acupuncture so suspect or seemingly unworthy of being taken seriously by Western medicine and traditional physicians.

However, I'd arrived at the point where I had to take responsibility and change the way I was treating and coping with my health problems. Simply writing, blogging, and marketing weren't cutting it anymore.

So, between my husband's and my efforts, we were able to find an acupuncture clinic that treated stroke and movement disorders right at the hospital where I was going for traditional medical care. After a time, I noticed acupuncture seemed to provide small amounts of relief. Although it didn't fix the problem, I could feel a difference in my capabilities. These benefits took time to register on my radar. In addition, when my acupuncturist tested my grip after I underwent several months of treatment, even I could tell there were small improvements that I hadn't noticed and wouldn't have if he hadn't bothered to check for them.

On top of this, acupuncture helped my overall relaxation and improved my mood to an extent. I'm assuming that the theory would be that by balancing my body's *chi*, acupuncture was treating my problems overall at both a physical and emotional level.

I began to notice that after a session, I'd have thoughts that seemed almost revelatory. I started blogging about my postacupuncture thoughts because they seemed important, and I wanted to share information, as usual.

These were thoughts I posted on my first blog because I could write about anything there. So, in effect, that blog became like an online shrink, a place where I could vent about my problems and breakthroughs. However, I didn't limit myself to talking about dystonia. I continued to fear being shunned or categorized, based upon my health problems. Further, I'd reached a point in my writing career where I had achieved enough success that I was being taken seriously by my peers in the business. So I worried about making too much of my condition on one blog while marketing myself as an author on another. Given the still unhappy state of my physical and mental health, I'd begun discussing my problems more openly on my author blog. Always I would turn my problems into a joke, because the whole purpose of the blog was to laugh at my own misfortunes. This approach worked until it didn't.

I eventually became so worn down by exertion and emotional baggage that I became depressed. When it reached the point where I couldn't bear to move or do anything, I realized I needed more help than acupuncture alone could provide. However, I think acupuncture helped me understand that my moods were my responsibility. Thus, by blogging and getting acupuncture, I was realizing things about myself and sharing those thoughts online. In this way, my Random and Sundry Things blog became a virtual sounding board in which I did a slow turnaround in my mood and coping with my condition. However, this took time.

By the end of 2011, I'd reached an epic low outlook when I decided to start taking antidepressants. I'd tried them before and, for some reason, chose not to keep taking them. However, when I realized that I'd become so depressed that I could barely muster the strength to get up in the morning, I knew I had to do something. So, I took another crack at managing my moods through pharmaceuticals.

A few things happened, all at once, that turned me around. The first thing I noticed was that I was willing to try new approaches to my work. In fact, I seemed to find new resolve. But the drugs weren't the only thing that changed my outlook. The acupuncture was bringing out long-buried thoughts and feelings that I needed to work through, as well as providing some relief from my physical symptoms.

By that time, I'd enjoyed more financial success as a fiction writer than I'd ever have thought possible as a new author with two novels and a handful of short stories. I was on the cusp of publishing my third novel in an increasingly competitive fiction writing market. And I could already read the writing on the wall. The boom days of self-publishing ebooks were over. My huge success the previous year, along with making the *New York Times* ebook bestseller list, were temporary states of being for an author who couldn't or wouldn't crank out books as fast as possible or, in essence, sell out to Amazon, a company that was poised to monopolize the publishing business.

The publishing world had changed in both good ways and bad. Now, everyone was jumping aboard the self-publishing bandwagon. This made it much harder for any one author to stand out, especially one without much name recognition unless you were willing to self-publish exclusively for limited periods with Amazon, which I chose not to do. Frankly, I believed the long-term effect of Amazon's limited exclusivity program would be to devalue our work to the point where fiction writers would be back to where they were when they were accepting terrible deals to land a publisher.

The pressure was on for me to adjust to changing times, even as I struggled with my own physical and emotional problems. This made my decision not to publish exclusively with Amazon all the tougher because I had so much to lose financially. However, I refused to compromise the value of my books or my personal values while making those adjustments.

By the time I started taking antidepressants, I was looking for new outlets: something to rejuvenate my passion for my work. I'd already focused more on improving my blogging and was seeing results in terms of attracting new followers and other bloggers who liked what they saw or left comments. At that point, I realized that blogging was like publishing, but different. Bloggers could gravitate toward one another, based on their shared interests, passions or other commonalities. They could, in essence, be like an online support group.

In January 2012, I registered for an indie film seminar that covered all the details of planning, financing, and creating films as an independent producer. Even though I'd never thought about producing films, the seminar seemed like a good way to step away from my computer, meet new people, and learn the ropes of the film business. I also had not only a feature film script but hopes that someday my novels might be turned into movies.

In short, I fell back upon what I knew about personal networking. In my opinion, there's no substitute for going places and actually meeting people. I'd found this to be true before I got dystonia when I attended more writer's conferences and events.

So I attended the seminar and learned about film production. I even realized that I could be a film producer if I chose to be because it entailed using the same skills I used when organizing the fundraiser. This realization was such a positive affirmation in itself that I blogged about it and even attributed my dystonia as the spark that set things in motion.

My thinking was that if not for getting dystonia, I wouldn't have organized the fundraiser; thus I never would have realized my own ability to be a producer. However, this epiphany was just one of many related to my dystonia.

Shortly after I took the seminar, I read a self-help book on happiness. I'll admit I wasn't expecting it to be much more than a lot of pop psychology. However, there was a reference in the book to Viktor Frankl's theory about the gap between stimulus and response. Basically, the theory was that we could all choose to be happy despite our circumstances. I thought, "Can it really be that simple?" Then, I realized that these were the thoughts of a Jewish man who'd lost his family and been tortured by Nazis in a concentration camp. I knew then that I could choose happiness too.

Even so, it helped immeasurably when my doctor had a talk with me about my feelings. He said that I sounded guilty. I realized that I was letting guilt ruin my happiness. In fact, instead of choosing to be happy, I had been allowing guilt and anger to make me unhappy.

I also realized that no one could really judge another person's pain. I decided that from then on, I wouldn't compare myself to anyone or engage in senseless arguments because neither were worth it. Humor, on the other hand, made the world bearable. As long as I could laugh at life on my blogs, I felt better about everything. This actually attracted new followers, which helped even more. At that point, I realized that coping with a bad condition was up to me. I realized that I could adapt and thrive, despite everything, if I wanted to. I might never have reached this point if it hadn't been for friends in my day-to-day life as well as those I made online. Whereas traditional medicine hasn't provided all the solutions for my problem, blogging and social media have actually helped.

Given what I'd learned about film production, it was only a matter of time before I realized that the same skills applied to producing books. And because I was actually a book producer, because I published my books under my own publishing imprint, all I had to do was use Internet resources to distribute them.

At the film seminar, I learned about crowdsourcing. This gave me an idea that I thought could result in a win for me, for readers, bookstores, and authors. And I thought it was the perfect solution for self-published authors—one that could allow me to earn a living as a writer despite my disability.

Part of the reason I thought this could work is that I had previously sold and donated books on the Internet to places as far away as England and Australia because I'd gotten to know people living in those countries through blogging and social media.

This knowledge in itself was a powerful affirmation of what anyone could do on the Internet. However, I also realized that I needed to get out more and spend quality time in the real world more often. So, in the summer of 2012, I decided we should take another overseas trip. This time, my husband and I went to Ireland and the United Kingdom. I left my laptop behind and made plans to meet people I'd gotten to know only online.

As with the trip to Italy, it was an unforgettable experience. However, meeting people I'd only gotten to know because of Twitter or blogging made it all the more special. This included not only an author in Ireland but also a reader in England, who I'd gotten to know through blogging and a shared love of Bond movies and *Doctor Who*. Not many authors get to both find and actually meet one of their own readers, in such an unusual way.

On top of all that, the salutary effects of traveling and experiencing other cultures cannot be understated. I came back from that vacation feeling reinvigorated and more confident that I could accomplish my goals despite whatever setbacks I might experience trying to reach them.

That year, I also submitted the screenplay I'd finished in 2009 to a contest and made the quarterfinals cut. As a result, I attended the Austin Film Festival as well as the mystery convention Bouchercon in Cleveland, OH. Both events took place in October 2012. Much as I love to travel, this tested my endurance some. But I think coping with dystonia or any poststroke chronic condition is a matter of choosing to focus on the positive and testing the boundaries of one's abilities. Both experiences were well worth the effort, and I couldn't be happier for having chosen to take the challenge of going to both events.

And so I continue to write novels and short stories and, with any luck, will write more screenplays. I have high hopes that someday one of my books might even be adapted into a film. I try to take my life one day at a time, one step at a time.

If I were asked to provide a wish list to the medical community about what they might want to do for stroke survivors with movement disorders, I'd include the following:

1. Talk to your patients and encourage them to talk to you about their feelings.
2. Encourage your patients to engage in life activities and not to shut the world out. Suggest therapy, where it seems appropriate. The online world can provide support in many cases, as I've discovered.

3. Keep doing research on better methods to treat movement disorders like dystonia and, ideally, find a cure.
4. Coordinate your research and treatment with acupuncture and other nontraditional methods.
5. Find ways to raise awareness of poststroke movement disorders so that the general public is more aware of them.

Learning to cope with poststroke dystonia has been and continues to be a process. The details of each person's coping process will differ, but the secret lies in one's attitude. Be grateful for what you can do and keep doing it. Whatever happens, choose to be happy.

I'm not perfect at doing this, but I'd like to think of myself as a work in progress. As long as I can keep my spirits up and keep my work, play, and life balanced, I figure I'll be okay.

In my wildest dreams, I would love to meet with the Dalai Lama and tell him about dystonia so the subject could be covered at one of his neurological conferences. I also wish that Western and Eastern medicine would combine forces to find more effective ways to deal with dystonia and, ideally, find a cure for it.
